# Preface

---

During the 27 years since the publication of the first edition of this textbook, many changes have occurred in the field of public water supply that impact directly the theory and practice of water treatment, the subject of this book. The following are some important changes:

1. Improved techniques and new instrumental methods for the measurement of constituents in water, providing lower detection limits and the ability to survey a broader array of constituents.
2. The emergence of *new* chemical constituents in water whose significance is not understood well and for which standards are not available. Many of these constituents have been identified using the new techniques cited above, while others are continuing to find their way into water as a result of the synthesis and development of new compounds. Such constituents may include disinfection by-products, pharmaceuticals, household chemicals, and personal care products.
3. Greater understanding of treatment process fundamentals including reaction mechanisms and kinetics, through continued research. This new understanding has led to improved designs and operational strategies for many drinking water treatment processes.
4. The development and implementation of new technologies for water treatment, including membrane technologies (e.g., membrane filtration and reverse osmosis), ultraviolet light (UV) disinfection, and advanced oxidation.
5. The development and implementation of new rules to deal with the control of pathogenic microorganisms, while at the same time minimizing the formation of disinfection by-products.

6. The ever-increasing importance of the management of residuals from water treatment plants, including such issues as concentrate management from reverse-osmosis processes.

The second edition of this textbook, published in 2005, was a complete rewrite of the first edition and addressed many of these changes. This third edition continues the process of revising the book to address these changes, as well as reorganizing some topics to enhance the usefulness of this book as both a textbook and a reference for practicing professionals. Major revisions incorporated into this edition are presented below.

1. A new chapter on advanced oxidation (Chap. 18) has been added.
2. A table of important nomenclature has been added to the beginning of each chapter to provide a resource for students and practitioners learning the vocabulary of water treatment.
3. The theory and practice of mixing has been moved from the coagulation/flocculation chapter to the reactor analysis chapter to unify the discussion of hydraulics and mixing.
4. A new section on enhanced coagulation has been added to the coagulation chapter.
5. The adsorption chapter has been expanded to provide additional detail on competitive adsorption, kinetics, and modeling of both fixed-bed and flow-through adsorption systems.
6. Material has been updated on advanced treatment technologies such as membrane filtration, reverse osmosis, and side-stream reactors for ozone addition.
7. The discussion of applications for RO has been updated to include brackish groundwater, wastewater, and other impaired water sources, as well as expanded discussion of concentrate management and energy recovery devices.
8. A new section on pharmaceuticals and personal care products has been added to Chap 20.
9. New section headings have been added in several chapters to clarify topics and make it easier to find content.
10. Topics and material has been reorganized in some chapters to clarify material.
11. The final chapter in this book has been updated with new case studies that demonstrate the synthesis of full-scale treatment trains. This chapter has been included to allow students an opportunity to learn how water treatment processes are assembled to create a water treatment plant, to achieve multiple water quality objectives, starting with different raw water qualities.

## Important Features of This Book

---

This book is written to serve several purposes: (1) an undergraduate textbook appropriate for elective classes in water treatment, (2) a graduate-level textbook appropriate for teaching water treatment, groundwater remediation, and physical chemical treatment, and (3) a reference book for engineers who are designing or operating water treatment plants.

To convey ideas and concepts more clearly, the book contains the following important elements: (1) 170 example problems worked out in detail with units, (2) 399 homework problems, designed to develop students understanding of the subject matter, (3) 232 tables that contain physical properties of chemicals, design data, and thermodynamic properties of chemicals, to name a few, and (4) 467 illustrations and photographs. Metric SI and U.S. customary units are given throughout the book. Instructors will find the example problems, illustrations, and photographs useful in introducing students to fundamental concepts and practical design issues. In addition, an instructor's solutions manual is available from the publisher.

## The Use of This Book

---

Because this book covers a broad spectrum of material dealing with the subject of water treatment, the topics presented can be used in a variety of undergraduate and graduate courses. Topics covered in a specific course will depend on course objectives and the credit hours. Suggested courses and course outlines are provided below.

The following outline would be appropriate for a one-semester introductory course on water treatment.

Topic	Chapter	Sections
Introduction to Water Quality	1	All
Physical and Chemical Quality of Water	2	All
Microbiological Quality of Water	3	All
Introduction to Water Treatment	4	All
Chemical Oxidation	8	8-1, 8-2, 8-3
Coagulation and Flocculation	9	9-1, 9-2, 9-4, 9-5, 9-7
Gravity Separation	10	All
Granular Filtration	11	All
Membrane Filtration	12	All
Disinfection	13	All, except 13-4 and 13-5
Synthesis of Treatment Trains: Case Studies from Bench to Full Scale	23	All

The following outline would be appropriate for a two-semester course on water treatment.

<b>First Semester</b>		
<b>Topic</b>	<b>Chapter</b>	<b>Sections</b>
Introduction to Water Quality	1	All
Physical and Chemical Quality of Water	2	All
Microbiological Quality of Water	3	All
Introduction to Water Treatment	4	All
Principles of Chemical Reactions	5	All
Principles of Reactor Analysis and Mixing	6	All
Coagulation and Flocculation	9	All
Gravity Separation	10	All
Granular Filtration	11	All
Membrane Filtration	12	All
Disinfection	13	All
Synthesis of Treatment Trains: Case Studies from Bench to Full Scale	23	All
<b>Second Semester</b>		
Principles to Mass Transfer	7	All
Aeration and Stripping	14	All
Adsorption	15	All
Ion Exchange	16	All
Reverse Osmosis	17	All
Chemical Oxidation and Reduction	8	All
Advanced Oxidation	18	All
Disinfection/Oxidation Byproducts	19	All
Removal of Selected Constituents	20	All
Residuals Management	21	All
Internal Corrosion of Water Conduits	22	All

The following outline would be appropriate for a one-semester course on physical chemical treatment.

<b>Topic</b>	<b>Chapter</b>	<b>Sections</b>
Principles of Chemical Reactions	5	All
Principles of Reactor Analysis and Mixing	6	All
Chemical Oxidation and Reduction	8	All
Disinfection/Oxidation Byproducts	19	All
Coagulation and Flocculation	9	All
Gravity Separation	10	All
Granular Filtration	11	All
Membrane Filtration	12	All

*(continued)*

Topic	Chapter	Sections
Principles of Mass Transfer	7	All
Aeration and Stripping	14	All
Adsorption	15	All
Ion Exchange	16	All
Reverse Osmosis	17	All

The following topics would be appropriate for the physical-chemical portion of a one-semester course on ground water remediation.

Topic	Chapter	Sections
Principles of Chemical Reactions	5	All
Principles of Reactor Analysis and Mixing	6	All
Principles of Mass Transfer	7	All
Aeration and Stripping	14	All
Adsorption	15	All
Ion Exchange	16	All
Chemical Oxidation and Reduction	8	8-1, 8-2, 8-3, 8-4, 8-5, 8-6
Advanced Oxidation	18	All
Disinfection/Oxidation Byproducts	19	All

The following topics would be appropriate for a portion of a one-semester course on water quality.

Topic	Chapter	Sections
Introduction to Water Quality	1	All
Physical and Chemical Quality of Water	2	All
Microbiological Quality of Water	3	All
Introduction to Water Treatment	4	All
Disinfection	13	All
Internal Corrosion of Water Conduits	22	All

# Acknowledgments

---

Many people assisted with the preparation of the third edition of this book. First, Mr. James H. Borchardt, PE, Vice President at MWH, served as a liaison to MWH, coordinated technical input from MWH staff regarding current design practices, assisted with providing photographs of treatment facilities designed by MWH, and took the lead role in writing Chap. 23.

Most of the figures in the book were edited or redrawn from the second edition by Dr. Harold Leverenz of the University of California at Davis. Figures for several chapters were prepared by Mr. James Howe of Rice University. Mr. Carson O. Lee of the Danish Technical Institute and Mr. Daniel Birdsell of the University of New Mexico reviewed and checked many of the chapters, including the figure, table, and equation numbers, the math in example problems, and the references at the end of the chapters. Dr. Daisuke Minakata of Georgia Tech contributed to writing and revising Chap. 18, and Dr. Zhonming Lu of Georgia Tech contributed to organizing and revising Chap. 15. Joshua Goldman of the University of New Mexico reviewed Chap. 16. Ms. Lana Mitchell of the University of New Mexico assisted with the preparation of the solutions manual for the homework problems.

A number of MWH employees provided technical input, prepared case studies, gathered technical information on MWH projects, prepared graphics and photos, and provided administrative support. These include: Ms. Donna M. Arcaro; Dr. Jamal Awad, PE, BCEE; Mr. Charles O. Bromley, PE, BCEE; Dr. Arturo A. Burbano, PE, BCEE; Mr. Ronald M. Cass, PE; Mr. Harry E. Dunham, PE; Mr. Frieder H. Ehrlich, C Eng, MAICHEM; Mr. Andrew S. Findlay, PE; Mr. Mark R. Graham, PE; Mr. Jude D. Grounds, PE; Ms. Stefani O. Harrison, PE; Dr. Joseph G. Jacangelo, REHS; Ms. Karla J. Kinser, PE; Mr. Peter H. Kreft, PE; Mr. Stewart E. Lehman, PE; Mr. Richard Lin, PE; Mr. William H. Moser, PE; Mr. Michael A. Oneby, PE; Mr. Michael L. Price, PE; Mr. Nigel S. Read, C Eng; Mr. Matthieu F. Roussillon, PE;

Ms. Stephanie J. Sansom, PE; Mr. Gerardus J. Schers, PE; Ms. Jackie M. Silber; Mr. William A. Taplin, PE; and Dr. Timothy A. Wolfe, PE, BCEE.

We gratefully acknowledge the support and help of the Wiley staff, particularly Mr. James Harper, Mr. Robert Argentieri, Mr. Bob Hilbert, and Mr. Daniel Magers.

Finally, the authors acknowledge the steadfast support of Mr. Murli Tolaney, Chairman Emeritus, MWH Global, Inc. Without his personal commitment to this project, this third edition of the MWH textbook could not have been completed. We all owe him a debt of gratitude.

# Foreword

---

Since the printing of the first edition of *Water Treatment Principles and Design* in 1984, and even since the second edition in 2005, much has changed in the field of water treatment. There are new technologies and new applications of existing technologies being developed at an ever-increasing rate. These changes are driven by many different pressures, including water scarcity, regulatory requirements, public awareness, research, and our creative desire to find better, more cost-effective solutions to providing safe water.

Change is cause for optimism, as there is still so much to be done. According to the recent United Nations Report *Sick Water* (UNEP and UN-HABITAT, 2010), over half of the world's hospital beds are occupied with people suffering from illnesses linked to contaminated water and more people die as a result of polluted water than are killed by all forms of violence including wars. Perhaps our combined technologies and dedication can help change this reality.

The purpose of this third edition is to update our understanding of the technologies used in the treatment of water, with the hope that this will be more usable to students and practitioners alike. We are extremely fortunate to have assembled such an esteemed group of authors and to have received such extensive support from so many sources. We are extremely happy and proud of the result.

I would like to personally thank the principal authors Dr. Kerry J. Howe of the University of New Mexico and a former Principal Engineer at MWH, Dr. George Tchobanoglous of the University of California at Davis, Dr. John C. Crittenden of the Georgia Institute of Technology, Dr. R. Rhodes Trussell of Trussell Technologies, Inc. and a former Senior Vice President and Board Member of MWH, Dr. David W. Hand of the Michigan Technological University, and Mr. James H. Borchardt, Vice President of MWH.

A special thanks goes to the entire senior management team of MWH, particularly Mr. Robert B. Uhler, CEO and Chairman, and Mr. Alan J. Krause, President, for supporting these efforts with commitment and enthusiasm. For the many officers, colleagues, and clients who have shared their dedication and inspiration for safe water, you are forever in my thoughts.

Finally, I would challenge those who read this book to consider their role in changing our world, one glass of water at a time.

Murli Tolaney  
Chairman Emeritus  
MWH Global, Inc.

# 1 Introduction

## **1-1 History of the Development of Water Treatment**

### **1-2 Health and Environmental Concerns**

Nineteenth Century

Twentieth Century

Looking to the Future

### **1-3 Constituents of Emerging Concern**

Number of Possible Contaminants

Pharmaceuticals and Personal Care Products

Nanoparticles

Other Constituents of Emerging Concern

### **1-4 Evolution of Water Treatment Technology**

Traditional Technologies

Introduction of Additional Treatment Technologies

Developments Requiring New Approaches and Technologies

Revolution Brought about by Use of Membrane Filtration

### **1-5 Selection of Water Treatment Processes**

## **References**

---

Securing and maintaining an adequate supply of water has been one of the essential factors in the development of human settlements. The earliest developments were primarily concerned with the quantity of water available. Increasing population, however, has exerted more pressure on limited high-quality surface sources, and the contamination of water with municipal, agricultural, and industrial wastes has led to a deterioration of water quality in many other sources. At the same time, water quality regulations have become more rigorous, analytical capabilities for detecting contaminants have become more sensitive, and the general public has become both more knowledgeable and more discriminating about water

quality. Thus, the quality of a water source cannot be overlooked in water supply development. In fact, virtually all sources of water require some form of treatment before potable use.

Water treatment can be defined as the processing of water to achieve a water quality that meets specified goals or standards set by the end user or a community through its regulatory agencies. Goals and standards can include the requirements of regulatory agencies, additional requirements set by a local community, and requirements associated with specific industrial processes. The evolution of water treatment practice has a rich history of empirical and scientific developments and challenges met and overcome.

The primary focus of this book is the application of water treatment for the production of potable, or drinking, water on a municipal level. Water treatment, however, encompasses a much wider range of problems and ultimate uses, including home treatment units, community treatment plants, and facilities for industrial water treatment with a wide variety of water quality requirements that depend on the specific industry. Water treatment processes are also applicable to remediation of contaminated groundwater and other water sources and wastewater treatment when the treated wastewater is to be recycled for new uses. The issues and processes covered in this book are relevant to all of these applications.

This book thoroughly covers a full range of topics associated with water treatment, starting in Chaps. 2 and 3 with an in-depth exploration of the physical, chemical, and microbiological aspects that affect water quality. Chapter 4 presents an overview of factors that must be considered when selecting a treatment strategy. Chapters 5 through 8 explain background concepts necessary for understanding the principles of water treatment, including fundamentals of chemical reactions, chemical reactors, mass transfer, and oxidation/reduction reactions. Chapters 9 through 18 are the heart of the book, presenting in-depth material on each of the principal unit processes used in municipal water treatment. Chapters 19 through 22 present supplementary material that is essential to an overall treatment system, including issues related to disinfection by-products, treatment strategies for specific contaminants, processing of treatment residuals, and corrosion in water distribution systems. The final chapter, Chap. 23, synthesizes all the previous material through a series of case studies.

The purpose of this introductory chapter is to provide some perspective on the (1) historical development of water treatment, (2) health concerns, (3) constituents of emerging concern, (4) evolution of water treatment technology, and (5) selection of water treatment processes. The material presented in this chapter is meant to serve as an introduction to the chapters that follow in which these and other topics are examined in greater detail.

## 1-1 History of the Development of Water Treatment

---

Some of the major events and developments that contributed to our understanding of the importance of water quality and the need to provide some means of improving the quality of natural waters are presented in Table 1-1. As reported in Table 1-1, one of the earliest water treatment techniques (boiling of water) was primarily conducted in containers in the households using the water. From the sixteenth century onward, however, it became increasingly clear that some form of treatment of large quantities of water was essential to maintaining the water supply in large human settlements.

## 1-2 Health and Environmental Concerns

---

The health concerns from drinking water have evolved over time. While references to filtration as a way to clarify water go back thousands of years, the relationship between water quality and health was not well understood or appreciated. Treatment in those days had as much to do with the aesthetic qualities of water (clarity, taste, etc.) as it did on preventing disease. The relationship between water quality and health became clear in the nineteenth century, and for the first 100 years of the profession of water treatment engineering, treatment was focused on preventing waterborne disease outbreaks. Since 1970, however, treatment objectives have become much more complex as public health concerns shifted from acute illnesses to the chronic health effects of trace quantities of anthropogenic (man-made) contaminants.

In the middle of the nineteenth century it was a common belief that diseases such as cholera and typhoid fever were primarily transmitted by breathing miasma, vapors emanating from a decaying victim and drifting through the night. This view began to change in the last half of that century. In 1854, Dr. John Snow demonstrated that an important cholera epidemic in London was the result of water contamination (Snow, 1855). Ten years later, Dr. Louis Pasteur articulated the germ theory of disease. Over the next several decades, a number of doctors, scientists, and engineers began to make sense of the empirical observations from previous disease outbreaks. By the late 1880s, it was clear that some important epidemic diseases were often waterborne, including cholera, typhoid fever, and amoebic dysentery (Olsztynski, 1988). As the nineteenth century ended, methods such as the coliform test were being developed to assess the presence of sewage contamination in a water supply (Smith, 1893), and the conventional water treatment process (coagulation/flocculation/sedimentation/filtration) was being developed as a robust way of removing contamination from municipal water supplies (Fuller, 1898).

### **Nineteenth Century**

**Table 1-1**

Historical events and developments that have been precursors to development of modern water supply and treatment systems

Period	Event
4000 B.C.	Ancient Sanskrit and Greek writings recommend water treatment methods. In the Sanskrit Ousruta Sanghita it is noted that “impure water should be purified by being boiled over a fire, or being heated in the sun, or by dipping a heated iron into it, or it may be purified by filtration through sand and coarse gravel and then allowed to cool.”
3000 to 1500 B.C.	Minoan civilization in Crete develops technologies so advanced they can only be compared to modern urban water systems developed in Europe and North America in the second half of the nineteenth century. Technology is exported to Mediterranean region.
1500 B.C.	Egyptians reportedly use the chemical alum to cause suspended particles to settle out of water. Pictures of clarifying devices were depicted on the wall of the tomb of Amenophis II at Thebes and later in the tomb of Ramses II.
Fifth century B.C.	Hippocrates, the father of medicine, notes that rainwater should be boiled and strained. He invents the “Hippocrates sleeve,” a cloth bag to strain rainwater.
Third century B.C.	Public water supply systems are developed at the end of the third century B.C. in Rome, Greece, Carthage, and Egypt.
340 B.C. to 225 A.D.	Roman engineers create a water supply system that delivers water [490 megaliters per day (130 million gallons per day)] to Rome through aqueducts.
1676	Anton van Leeuwenhoek first observes microorganisms under the microscope.
1703	French scientist La Hire presents a plan to French Academy of Science proposing that every household have a sand filter and rainwater cistern.
1746	French scientist Joseph Amy is granted the first patent for a filter design. By 1750 filters composed of sponge, charcoal, and wool could be purchased for home use.
1804	The first municipal water treatment plant is installed in Paisley, Scotland. The filtered water is distributed by a horse and cart.
1807	Glasgow, Scotland, is one of the first cities to pipe treated water to consumers.
1829	Installation of slow sand filters in London, England.
1835	Dr. Robley Dunlingsen, in his book <i>Public Health</i> , recommends adding a small quantity of chlorine to make contaminated water potable.
1846	Ignaz Semmelweiss (in Vienna) recommends that chlorine be used to disinfect the hands of physicians between each visit to a patient. Patient mortality drops from 18 to 1 percent as a result of this action.
1854	John Snow shows that a terrible epidemic of Asiatic cholera can be traced to water at the Broad Street Well, which has been contaminated by the cesspool of a cholera victim recently returned from India. Snow, who does not know about bacteria, suspects an agent that replicates itself in the sick individuals in great numbers and exits through the gastrointestinal tract, and is transported by the water supply to new victims.
1854	Dr. Falipo Pacini, in Italy, identifies the organism that causes Asiatic cholera, but his discovery goes largely unnoticed.

**Table 1-1** (Continued)

Period	Event
1856	Thomas Hawksley, civil engineer, advocates continuously pressurized water systems as a strategy to prevent external contamination.
1864	Louis Pasteur articulates the germ theory of disease.
1874	Slow sand filters are installed in Poughkeepsie and Hudson, New York.
1880	Karl Eberth isolates the organism ( <i>Salmonella typhosa</i> ) that causes typhoid fever.
1881	Robert Koch demonstrates in the laboratory that chlorine will inactivate bacteria.
1883	Carl Zeiss markets the first commercial research microscope.
1884	Professor Escherich isolates organisms from the stools of a cholera patient that he initially thought were the cause of cholera. Later it is found that similar organisms are also present in the intestinal tracts of every healthy individual as well. Organism eventually named for him ( <i>Escherichia coli</i> ).
1884	Robert Koch proves that Asiatic cholera is due to a bacterium, <i>Vibrio cholerea</i> , which he calls the comma bacillus because of its comma-like shape.
1892	A cholera epidemic strikes Hamburg, Germany, while its neighboring city, Altona, which treats its water using slow sand filtration, escapes the epidemic. Since that time, the value of granular media filtration has been widely recognized.
1892	The New York State Board of Health uses the fermentation tube method developed by Theobald Smith for the detection of <i>E. coli</i> to demonstrate the connection between sewage contamination of the Mohawk River and the spread of typhoid fever.
1893	First sand filter built in America for the express purpose of reducing the death rate of the population supplied is constructed at Lawrence, Massachusetts. To this end, the filter proves to be a great success.
1897	G. W. Fuller studies rapid sand filtration [5 cubic meters per square meter per day (2 gallons per square foot per day)] and finds that bacterial removals are much better when filtration is preceded by good coagulation and sedimentation.
1902	The first drinking water supply is chlorinated in Middelkerke, Belgium. Process is actually the "Ferrochlor" process wherein calcium hypochlorite and ferric chloride are mixed, resulting in both coagulation and disinfection.
1903	The iron and lime process of treating water (softening) is applied to the Mississippi River water supplied to St Louis, Missouri.
1906	First use of ozone as a disinfectant in Nice, France. First use of ozone in the United States occurs some four decades later.
1908	George Johnson, a member of Fuller's consulting firm, helps install continuous chlorination in Jersey City, New Jersey.
1911	Johnson publishes "Hypochlorite Treatment of Public Water Supplies" in which he demonstrates that filtration alone is not enough for contaminated supplies. Adding chlorination to the process of water treatment greatly reduces the risk of bacterial contamination.

## Twentieth Century

The twentieth century began with the development of continuous chlorination as a means for bacteriological control, and in the first four decades the focus was on the implementation of conventional water treatment and chlorine disinfection of surface water supplies. By 1940, the vast majority of water supplies in developed countries had “complete treatment” and were considered microbiologically safe. In fact, during the 1940s and 1950s, having a microbiologically safe water supply became one of the principal signposts of an advanced civilization. The success of filtration and disinfection practices led to the virtual elimination of the most deadly waterborne diseases in developed countries, particularly typhoid fever and cholera.

### FROM BACTERIA TO VIRUSES

The indicator systems and the treatment technologies for water treatment focused on bacteria as a cause of waterborne illness. However, scientists demonstrated that there were some infectious agents much smaller than bacteria (viruses) that could also cause disease. Beginning in the early 1940s and continuing into the 1960s, it became clear that viruses were also responsible for some of the diseases of the fecal–oral route, and traditional bacterial tests could not be relied upon to establish their presence or absence.

### ANTHROPOGENIC CHEMICALS AND COMPOUNDS

Concern also began to build about the potential harm that anthropogenic chemicals in water supplies might have on public health. In the 1960s, the U.S. PHS developed some relatively simple tests using carbon adsorption and extraction in an attempt to assess the total mass of anthropogenic compounds in water. Then in the mid-1970s, with the development of the gas chromatograph/mass spectrometer, it became possible to detect these compounds at much lower levels. The concern about the potential

harm of man-made organic compounds in water coupled with improving analytical capabilities has led to a vast array of regulations designed to address these risks. New issues with anthropogenic chemicals will continue to emerge as new chemicals are synthesized, analytical techniques improve, and increasing population density impacts the quality of water sources.

#### **DISINFECTION BY-PRODUCTS**

A class of anthropogenic chemicals of particular interest in water treatment is chemical by-products of the disinfection process itself (disinfection by-products, or DBPs). DBPs are formed when disinfectants react with species naturally present in the water, most notably natural organic matter and some inorganic species such as bromide. The formation of DBPs increases as the dose of disinfectants or contact time with the water increases. Reducing disinfectant use to minimize DBP formation, however, has direct implications for increasing the risk of illness from microbial contamination. Thus, a trade-off has emerged between using disinfection to control microbiological risks and preventing the formation of undesirable man-made chemicals caused by disinfectants. Managing this trade-off has been one of the biggest challenges of the water treatment industry over the last 30 years.

#### **MODERN WATERBORNE DISEASE OUTBREAKS**

While severe waterborne disease has been virtually eliminated in developed countries, new sources of microbiological contamination of drinking water have surfaced in recent decades. Specifically, pathogenic protozoa have been identified that are zoonotic in origin, meaning that they can pass from animal to human. These protozoan organisms are capable of forming resistant, encysted forms in the environment, which exhibit a high level of resistance to treatment. The resistance of these organisms has further complicated the interrelationship between the requirements of disinfection and the need to control DBPs. In fact, it has become clear that processes that provide better physical removal of pathogens are required in addition to more efficient processes for disinfection.

The significance of these new sources of microbiological contamination has become evident in recent waterborne disease outbreaks, such as the outbreaks in Milwaukee, Wisconsin, in 1993 and Walkerton, Ontario, in 2000. In Milwaukee, severe storms caused contamination of the water supply and inadequate treatment allowed *Cryptosporidium* to enter the water distribution system, leading to over 400,000 cases of gastrointestinal illness and over 50 deaths (Fox and Lytle, 1996). The Walkerton incident was caused by contamination of a well in the local water system by a nearby farm. During the outbreak, estimates are that more than 2300 persons became ill due to *E. coli* O157:H7 and *Campylobacter* species (Clark et al., 2003). Of the 1346 cases that were reported, 1304 (97 percent) were considered to be directly due to the drinking water. Sixty-five

persons were hospitalized, 27 developed hemolytic uremic syndrome, and 6 people died.

Another challenge associated with microbial contamination is that the portion of the world's population that is immunocompromised is increasing over time, due to increased life spans and improved medical care. The immunocompromised portion of the population is more susceptible to health risks, including those associated with drinking water.

### **Looking to the Future**

As the twenty-first century begins, the challenges of water treatment have become more complex. Issues include the identification of new pathogens such as *Helicobacter pylori* and the noroviruses, new disinfection by-products such as *N*-nitrosodimethylamine (NDMA), and a myriad of chemicals, including personal care products, detergent by-products, and other consumer products. As analytical techniques improve, it is likely that these issues will grow, and the water quality engineer will face ever-increasing challenges.

## 1-3 Constituents of Emerging Concern

---

Contaminants and pathogens of emerging concern are by their very nature unregulated constituents that may pose a serious threat to human health. Consequently, they pose a serious obstacle to delivering the quality and quantity of water that the public demands. Furthermore, emerging contaminants threaten the development of more environmentally responsible water resources that do not rely on large water projects involving reservoirs and dams in more pristine environments. Creating acceptable water from water resources that are of lower quality because of contaminants of emerging concern is more expensive, and there is resistance to increased spending for public water supply projects (NRC, 1999).

### **Number of Possible Contaminants**

The sheer number of possible contaminants is staggering. The CAS (Chemical Abstracts Service, a division of the American Chemical Society) Registry lists more than 55 million unique organic and inorganic chemicals (CAS, 2010a). In the United States, about 70,000 chemicals are used commercially and about 3300 are considered by the U.S. Environmental Protection Agency (EPA) to be high-volume production chemicals [i.e., are produced at a level greater than or equal to 454,000 kg/yr (1,000,000 lb/yr)]. The CAS also maintains CHEMLIST, a database of chemical substances that are the target of regulatory activity someplace in the world; this list currently contains more than 248,000 substances (CAS, 2010b).

### **Pharmaceuticals and Personal Care Products**

Increasing interconnectedness between surface waters used for discharge of treated wastewater and as a source for potable water systems has created concern about whether trace contaminants can pass through the wastewater treatment system and enter the water supply. Many recent investigations

have found evidence of low concentrations of pharmaceuticals and personal care products (PPCPs) and endocrine disrupting compounds (EDCs) in the source water for many communities throughout the United States and other developed nations.

Pharmaceuticals can enter the wastewater system by being excreted with human waste after medication is ingested or because of the common practice of flushing unused medication down the toilet. Pharmaceuticals include antibiotics, analgesics [painkillers such as aspirin, ibuprofen (Advil), acetaminophen (Tylenol)], lipid regulators (e.g., atorvastatin, the active ingredient in Lipitor), mood regulators (e.g., fluoxetine, the active ingredient in Prozac), antiepileptics (e.g., carbamazepine, the active ingredient in many epilepsy and bipolar disorder medications), and hundreds of other medications. Personal care products, which include cosmetics and fragrances, acne medications, insect repellants, lotions, detergents, and other products, can be washed from the skin and hair during washing or showering. Endocrine disrupting chemicals are chemicals that have the capability to interfere with the function of human hormones. EDCs include actual hormones, such as estrogens excreted by females after use of birth-control pills, or other compounds that mimic the function of hormones, such as bisphenol A. Studies have shown that some of these compounds are effectively removed by modern wastewater treatment processes, but others are not. Although the compounds are present at very low concentrations when they are detected, the public is concerned about the potential presence of these compounds in drinking water.

The manufacture of nanoparticles is a new and rapidly growing field. Nanoparticles are very small particles ranging from 1 to 100 nanometers (nm) used for applications such as the delivery of pharmaceuticals across the blood–brain barrier. Because nanomaterials are relatively new and the current market is small, a knowledge base of the potential health risks and environmental impacts of nanomaterials is lacking. As the manufacture of nanomaterials increases, along with the potential for discharge to the environment, more research to establish health risks and environmental impacts may be appropriate.

In addition to the constituents listed above, other constituents of emerging concern include (1) fuel oxygenates (e.g., methyl *tert*-butyl ether, MTBE), (2) *N*-nitrosodimethylamine (NDMA), (3) perchlorate, (4) chromate, and (5) veterinary medications that originate from concentrated animal-feeding operations.

## Nanoparticles

## Other Constituents of Emerging Concern

## 1-4 Evolution of Water Treatment Technology

---

To understand how the treatment methods discussed in this book developed, it is appropriate to consider their evolution. Most of the methods in use at the beginning of the twentieth century evolved out of physical

observations (e.g., if turbid water is allowed to stand, a clarified liquid will develop as the particles settle) and the relatively recent (less than 120 years) recognition of the relationship between microorganisms in contaminated water and disease. A list of plausible methods for treating water at the beginning of the twentieth century was presented in a book by Hazen (1909) and is summarized in Table 1-2. It is interesting to note that all of the treatment methods reported in Table 1-2 are still in use today. The most important modern technological development in the field of water treatment not reflected in Table 1-2 is the use of membrane technology.

**Table 1-2**

Summary of methods used for water treatment early in the twentieth century

Treatment Method	Agent/Objectives
I. Mechanical separation	<input type="checkbox"/> By gravity—sedimentation <input type="checkbox"/> By screening—screens, scrubbers, filters <input type="checkbox"/> By adhesion—scrubbers, filters
II. Coagulation	<input type="checkbox"/> By chemical treatment resulting in drawing matters together into groups, thereby making them more susceptible to removal by mechanical separation but without any significant chemical change in the water
III. Chemical purification	<input type="checkbox"/> Softening—by use of lime <input type="checkbox"/> Iron removal <input type="checkbox"/> Neutralization of objectionable acids
IV. Poisoning processes (now known as disinfection processes)	<input type="checkbox"/> Ozone <input type="checkbox"/> Sulfate of copper <input type="checkbox"/> The object of these processes is to poison and kill objectionable organisms without at the same time adding substances objectionable or poisonous to the users of the water
V. Biological processes	<input type="checkbox"/> Oxidation of organic matter by its use as food for organisms that thereby effect its destruction <input type="checkbox"/> Death of objectionable organisms, resulting from the production of unfavorable conditions, such as absence of food (removed by the purification processes) and killing by antagonistic organisms
VI. Aeration	<input type="checkbox"/> Evaporation of gases held in solution that are the cause of objectionable tastes and odors <input type="checkbox"/> Evaporation of carbonic acid, a food supply for some kinds of growths <input type="checkbox"/> Supplying oxygen necessary for certain chemical purifications and especially necessary to support growth of water-purifying organisms
VII. Boiling	<input type="checkbox"/> Best household method of protection from disease-carrying waters

Source: Adapted from Hazen (1909).

For the 100 years following the work of Fuller's team in Louisville in the late 1880s (see Table 1-1), the focus in the development of water treatment technology was on the further refinement of the technologies previously developed, namely coagulation, sedimentation, filtration, and disinfection with chlorine (see Fig. 1-1). There were numerous developments during that period, among them improvements in the coagulants available, improved understanding of the role of the flocculation process and the optimization of its design, improvements in the design of sedimentation basins, improvements in the design of filter media and in the filter rates that can be safely achieved, and improvements in the control of chlorination and chlorine residuals. These technologies have also been widely deployed, to the point where the vast majority of surface water supplies have treatment of this kind.

A variety of new treatment technologies were introduced at various times during the twentieth century in response to more complex treatment goals. Ion exchange and reverse osmosis are processes that are able to remove a wide variety of inorganic species. A typical use for ion exchange is the removal of hardness ions (calcium and magnesium). Although ion exchange is typically expensive to implement at the municipal scale, the first large U.S. ion exchange facility was a 75.7 megaliter per day (75.7 ML/d) [20 million gallons per day (20 mgd)] softening plant constructed by the Metropolitan Water District of Southern California in 1946. The first commercial reverse osmosis plant provided potable water to Coalinga, California, in 1965 and had a capacity of 0.019 ML/d (0.005 mgd).

Aeration is accomplished by forcing intimate contact between air and water, most simply done by spraying water into the air, allowing the water to splash down a series of steps or platforms, or bubbling air into a tank of water. Early in the history of water treatment, aeration was employed to control tastes and odors associated with anaerobic conditions. The number and type of aeration systems have grown as more source waters have been contaminated with volatile organic chemicals.

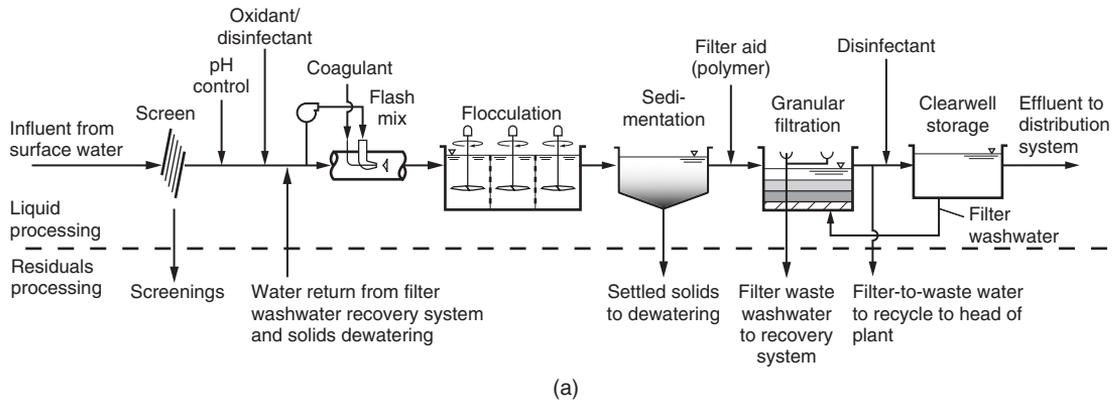

Organic chemicals can be effectively removed by adsorption onto activated carbon. Adsorption using granular activated carbon was introduced in Hamm, Germany, in 1929 and Bay City, Michigan, in 1930. Powdered activated carbon was used as an adsorbent in New Milford, New Jersey, in 1930. During this time and the next few decades, the use of activated carbon as an adsorbent was primarily related to taste and odor control. In the mid-1970s, however, the increasing concern about contamination of source waters by industrial wastes, agricultural chemicals, and municipal discharges promoted the interest in adsorption for control of anthropogenic contaminants.

During the last three decades of the twentieth century, three developments took place requiring new approaches to treatment. Two of these changes were rooted in new discoveries concerning water quality, and one was the development of a new technology that portends to cause dramatic change

## **Traditional Technologies**

## **Introduction of Additional Treatment Technologies**

## **Developments Requiring New Approaches and Technologies**

**Figure 1-1**

in the effectiveness of water treatment. The first discovery concerning water quality was that the oxidants used for disinfecting water, particularly chlorine, react with the natural organic matter in the water supply to form chemical by-products, some of which are suspected carcinogens. The second discovery was that certain pathogenic microorganisms, namely *Giardia* and *Cryptosporidium*, can be of zoonotic origin and, therefore, can occur in a water supply that is completely free of wastewater contamination. The final and perhaps most significant change was the development of membrane filtration technologies suitable for the treatment of water on the scale required for domestic supply. Membrane technologies have the potential to completely reject pathogens by size exclusion, a possibility that could substantially improve the safety of drinking water. Further development and refinement of membrane technologies will be required before they reach their full potential.

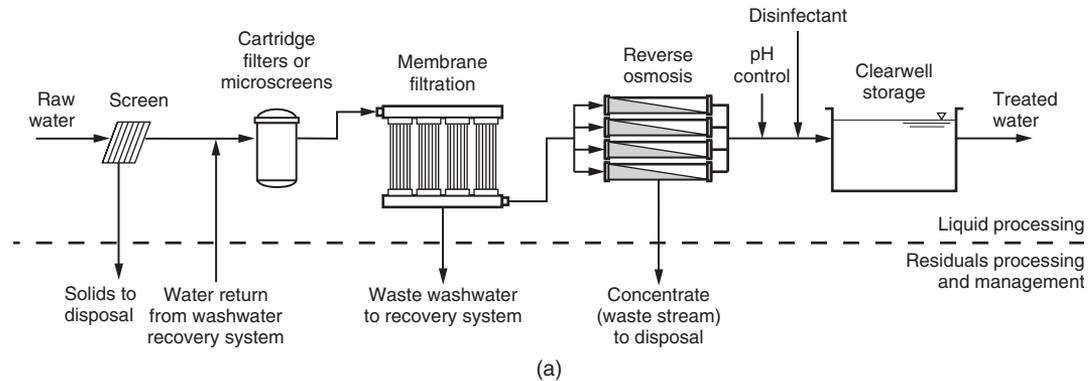

The first membranes were developed near the middle of the twentieth century but initially were only used in limited applications. In the late 1950s membranes began to be used in laboratory applications, most notably as an improvement in the coliform test. By the mid-1960s membrane filtration was widely used for beverages, as a replacement for heat pasteurization as a method of purification and microbiological stabilization. In virtually all of these applications the membranes were treated as disposable items. The idea of treating large volumes of drinking water in this manner seemed untenable. In the mid-1980s, researchers in both Australia and France began to pursue the idea of membrane filtration fibers that could be backwashed after each use, so that the membrane need not be disposed of but could be used on a continuous basis for a prolonged period of time. In the last decade of the twentieth century these products were commercialized, and by the turn of the twenty-first century there were numerous manufacturers of commercial membrane filtration systems and municipal water plants as large as 300 ML/d (80 mgd) were under construction (see Fig. 1-2). Membranes are arguably the most important development in the treatment of drinking water since the year 1900 because they offer the potential for complete and continuous rejection of microbiological contaminants on the basis of size exclusion.

**Revolution  
Brought about by  
Use of Membrane  
Filtration**

## 1-5 Selection of Water Treatment Processes

---

To produce water that is safe to drink and aesthetically pleasing, treatment processes must be selected that, when grouped together, can be used to remove specific constituents. The most critical determinants in the selection of water treatment processes are the quality of the water source and the intended use of the treated water. The two principal water sources are groundwater and surface water. Depending on the hydrogeology of a basin, the levels of human activity in the vicinity of the source, and other

(b)

(c)

**Figure 1-2**

factors, a wide range of water qualities can be encountered. Surface waters typically have higher concentrations of particulate matter than groundwater, and groundwater often has increased concentrations of dissolved minerals due to the long contact times between subsurface water with rocks and minerals. Surface water may have more opportunity for exposure to anthropogenic chemicals.

Another major distinction is based on the level of dissolved salts or total dissolved solids (TDS) present in the water source. Water containing TDS less than 1000 mg/L is considered to be freshwater, and water with TDS between 1000 and 10,000 mg/L is considered to be brackish water. Freshwater is the most easily used for drinking water purposes, and brackish water can be used under specific circumstances with adequate treatment. Finally, the most abundant water source, the ocean, contains approximately 35,000 mg/L TDS and requires demineralization prior to use. Each of the predominant types of water sources, including natural or man-made lakes and rivers, requires a different treatment strategy.

(a)

(b)

**Figure 1-3**

Views of pilot plant test installations: (a) test facilities for evaluation of a proprietary process (the MIEX process; see Chap.16) for the removal of natural organic matter before coagulation, flocculation, sedimentation, and filtration, and (b) reverse osmosis for the removal of dissolved constituents.

The steps that are typically involved in the selection and implementation of water treatment plants are

1. Characterization of the source water quality and definition of the treated water quality goals or standards
2. Predesign studies, including pilot plant testing (see Fig. 1-3), process selection, and development of design criteria
3. Detailed design of the selected alternative;
4. Construction
5. Operation and maintenance of the completed facility

These five steps may be performed as discrete steps or in combination and require input from a wide range of disciplines, including engineering, chemistry, microbiology, geology, architecture, and financial analysis. Each discipline plays an important role at various stages in the process. The predominant role, however, rests with professional engineers who carry the responsibility for the success of the water treatment process.

**Problems and Discussion Topics****References****Terminology for Physical and Chemical Quality of Water**

<b>Term</b>	<b>Definition</b>
Absorbance	Amount of light absorbed by the constituents in a solution.
Aggregate water quality indicators	Measured parameter values caused by a number of individual constituents.
Alkalinity	Measure of the ability of a water to resist changes in pH.
Colloids	Particles smaller than about 1 $\mu\text{m}$ in size; although definitions vary, they are generally distinguished because they will not settle out of solution naturally.
Color	Reduction in clarity of water caused by the absorption of visible light by dissolved substances, including organic compounds (fulvic acid, humic acid) and inorganic compounds (iron, manganese).
Conductivity	Measure of the concentration of dissolved constituents based on their ability to conduct electrical charge.
Hydrogen bonding	Attractive interaction between a hydrogen atom of one water molecule and the unshared electrons of the oxygen atom in another water molecule.
Natural organic matter (NOM)	Complex matrix of organic chemicals present in all water bodies, originating from natural sources such as biological activity, secretions from the metabolic activity, and excretions from fish or other aquatic organisms.
Particles	Constituents in water larger than molecules that exist as a separate phase (i.e., as solids). Water with particles is a suspension, not a solution. Particles include silt, clay, algae, bacteria, and other microorganisms.
pH	Parameter describing the acid–base properties of a solution.

<b>Term</b>	<b>Definition</b>
Radionuclides	Unstable atoms that are transformed through the process of radioactive decay.
Suspended solids	See: particles
Synthetic organic compounds (SOCs)	Man-made (anthropogenic) organic synthetic chemicals. Some SOC's are volatile; others tend to stay dissolved in water instead of evaporating.
Total dissolved solids (TDS)	Total amount of ions in solution, analyzed by filtering out the suspended material, evaporating the filtrate, and weighing the remaining residue.
Total organic halogen	Total mass concentration of organically bound halogen atoms (X = Cl, Br, or I) present in water.
Trace constituents	Constituents (inorganic and organic) of natural waters found in the parts-per-billion to parts-per-trillion range.
Transmittance	Measure of the amount of light, expressed as a percentage, that passes through a solution. The percent transmittance affects the performance of ultraviolet (UV) disinfection processes.
Trihalomethane (THM)	One of a family of organic compounds named as derivative of methane. THMs are generally by-products of chlorination of drinking water that contains organic material.
Trihalomethane (THM) formation potential	Maximum tendency of the organic compounds in a given water supply to form THMs upon disinfection.
Turbidity	Reduction in clarity of water caused by the scattering of visible light by particles.

Naturally occurring water is a solution containing not only water molecules but also chemical matter such as inorganic ions, dissolved gases, and dissolved organics; solid matter such as colloids, silts, and suspended solids; and biological matter such as bacteria and viruses. The structure of water, while inherently simple, has unique physicochemical properties. These properties have practical significance for water supply, water quality, and water treatment engineers. The purpose of this chapter is to present background information on the physical and chemical properties of water, the units used to express the results of physical and chemical analyses, and the constituents found in water and the methods used to quantify them. Topics considered in this chapter include (1) the fundamental and engineering properties of water, (2) units of expression for chemical concentrations, (3) the physical aggregate characteristics of water, (4) the

inorganic chemical constituents found in water, (5) the organic chemical constituents found in water, (6) taste and odor, (7) the gases found in water, and (8) the radionuclides found in water. All of the topics introduced in this chapter are expanded upon in the subsequent chapters as applied to the treatment of water.

## 2-1 Fundamental and Engineering Properties of Water

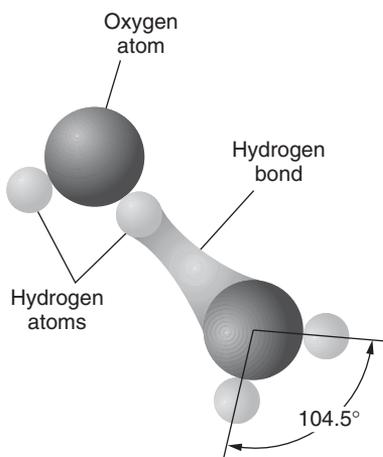

The fundamental and engineering properties of water are introduced in this section. The fundamental properties relate to the basic composition and structure of water in its various forms. The engineering properties of water are used in day-to-day engineering calculations.

### Fundamental Properties of Water

The fundamental properties of water include its composition, dimensions, polarity, hydrogen bonding, and structural forms. Because of their importance in treatment process theory and design, polarity and hydrogen bonding are considered in the following discussion. Details on the other properties may be found in books on water chemistry and on a detailed website dedicated to water science and structure (Chapin, 2010).

#### POLARITY

The asymmetric water molecule contains an unequal distribution of electrons. Oxygen, which is highly electronegative, exerts a stronger pull on the shared electrons than hydrogen; also, the oxygen contains two unshared electron pairs. The net result is a slight separation of charges or dipole, with the slightly negative charge ( $\delta^-$ ) on the oxygen end and the slightly positive charge ( $\delta^+$ ) on the hydrogen end. Attractive forces exist between one polar molecule and another such that the water molecules tend to orient themselves with the hydrogen end of one directed toward the oxygen end of another.

**Figure 2-1**  
Hydrogen bonding between water molecules.

#### HYDROGEN BONDING

The attractive interaction between a hydrogen atom of one water molecule and the unshared electrons of the oxygen atom in another water molecule is known as a hydrogen bond, represented schematically on Fig. 2-1. Estimates of hydrogen bond energy between molecules range from 10 to 40 kJ/mol, which is approximately 1 to 4 percent of the covalent O–H bond energy within a single molecule (McMurry and Fay, 2003). Hydrogen bonding causes stronger attractive forces between water molecules than the molecules of most other liquids and is responsible for many of the unique properties of water.

Compared to other species of similar molecular weight, water has higher melting and boiling points, making it a liquid rather than a gas under ambient conditions. Hydrogen bonding, as described above, can be used to explain the unique properties of water including density, high heat capacity, heat of formation, heat of fusion, surface tension, and viscosity of water. Examples of the unique properties of water include its capacity to dissolve a variety of materials, its effectiveness as a heat exchange fluid, its high density and pumping energy requirements, and its viscosity. In dissolving or suspending materials, water gains characteristics of biological, health-related, and aesthetic importance. The type, magnitude, and interactions of these materials affect the properties of water, such as its potability, corrosivity, taste, and odor. As will be demonstrated in subsequent chapters, technology now exists to remove essentially all of the dissolved and suspended components of water. The principal engineering properties encountered in environmental engineering and used throughout this book are reported in Table 2-1. The typical numerical values given in Table 2-1 are to provide a frame of reference for the values that are reported in the literature.

## Engineering Properties of Water

**Table 2-1**  
Engineering properties of water

Property	Symbol	Unit		Value <sup>a</sup>		Definition/Notes
		SI	U.S. Customary	SI	U.S. Customary	
Boiling point	bp	°C	°F	100	212	Temperature at which vapor pressure equals 1 atm; high value for water keeps it in liquid state at ambient temperature.
Conductivity	$\kappa$	$\mu\text{S}/\text{m}$	$\mu\text{S}/\text{m}$	5.5	5.5	Pure water is not a good conductor of electricity; dissolved ions increase conductivity.
Density	$\rho$	$\text{kg}/\text{m}^3$	$\text{slug}/\text{ft}^3$	998.2	1.936	
Dielectric constant	$\epsilon_r$	unitless	unitless	80.2	80.2	Measure of the ability of a solvent to maintain a separation of charges; high value for water indicates it is a very good solvent.
Dipole moment	$p$	$\text{C}\cdot\text{m}$	D (debye)	$6.186 \times 10^{-30}$	1.855	Measure of the separation of charge within a molecule; high value for water indicates it is very polar.

**Table 2-1** (Continued)

Property	Symbol	Unit		Value <sup>a</sup>		Definition/Notes
		SI	U.S. Customary	SI	U.S. Customary	
Enthalpy of formation	$\Delta H_f$	kJ/mol	btu/lb <sub>m</sub>	-286.5	-6836	Energy associated with the formation of a substance from the elements.
Enthalpy of fusion <sup>b</sup>	$\Delta H_{fus}$	kJ/mol	btu/lb <sub>m</sub>	6.017	143.6	Energy associated with the conversion of a substance between the solid and liquid states (i.e., freezing or melting).
Enthalpy of vaporization <sup>c</sup>	$\Delta H_v$	kJ/mol	btu/lb <sub>m</sub>	40.66	970.3	Energy associated with the conversion of a substance between the liquid and gaseous states (i.e., vaporizing or condensing); high value for water makes distillation very energy intensive.
Heat capacity <sup>d</sup>	$c_p$	J/mol·°C	btu/lb <sub>m</sub> ·°F	75.34	0.999	Energy associated with raising the temperature of water by one degree; high value for water makes it impractical to heat or cool water for municipal treatment purposes.
Melting point	mp	°C	°F	0	32	
Molecular weight	MW	g/mol <sup>e</sup>	g/mol <sup>e</sup>	18.016	18.016	Also known as molar mass.
Specific weight	$\gamma$	kN/m <sup>3</sup>	lb <sub>f</sub> /ft <sup>3</sup>	9.789	62.37	
Surface tension	$\sigma$	N/m	lb <sub>f</sub> /ft	0.0728	0.00499	
Vapor pressure	$p_v$	kN/m <sup>2</sup>	lb <sub>f</sub> /in <sup>2</sup>	2.339	0.34	
Viscosity, dynamic	$\mu$	N·s/m <sup>2</sup>	lb <sub>f</sub> ·s/ft <sup>2</sup>	$1.002 \times 10^{-3}$	$2.089 \times 10^{-5}$	
Viscosity, kinematic	$\nu$	m <sup>2</sup> /s	ft <sup>2</sup> /s	$1.004 \times 10^{-6}$	$1.081 \times 10^5$	

<sup>a</sup>All values for pure water at 20°C (68°F) and 1 atm pressure unless noted otherwise.

<sup>b</sup>At the melting point (0°C).

<sup>c</sup>At the boiling point (100°C).

<sup>d</sup>Often called the molar heat capacity when expressed in units of J/mol·°C and specific heat capacity or specific heat when expressed in units of J/g·°C.

<sup>e</sup>Molecular weight has units of Daltons (Da) or atomic mass units (AMU) when expressed for a single molecule (i.e., one mole of carbon-12 atoms has a mass of 12 g and a single carbon-12 atom has a mass of 12 Da or 12 AMU).

## 2-2 Units of Expression for Chemical Concentrations

---

Water quality characteristics are often classified as physical, chemical (organic and inorganic), or biological and then further classified as health related or aesthetic. To characterize water effectively, appropriate sampling and analytical procedures must be established. The purpose of this section is to review briefly the units used for expressing the physical and chemical characteristics of water. The basic relationships presented in this section will be illustrated and expanded upon in subsequent chapters. Additional details on the subject of sampling, sample handling, and analyses may be found in Standard Methods (2005).

Commonly used units for the amount or concentration of constituents in water are as follows:

1. *Mole:*

$6.02214 \times 10^{23}$  elementary entities (molecules, atoms, etc.)  
of a substance

1.0 mole of compound = molecular weight of compound, g (2-1)

2. *Mole fraction:* The ratio of the amount (in moles) of a given solute to the total amount (in moles) of all components in solution is expressed as

$$x_B = \frac{n_B}{n_A + n_B + n_C + \cdots + n_N} \quad (2-2)$$

where  $x_B$  = mole fraction of solute B

$n_A$  = moles of solute A

$n_B$  = moles of solute B

$n_C$  = moles of solute C

⋮

$n_N$  = moles of solvent N

The application of Eq. 2-2 is illustrated in Example 2-1.

3. *Molarity (M):*

$$M, \text{ mol/L} = \frac{\text{mass of solute, g}}{(\text{molecular weight of solute, g/mol})(\text{volume of solution, L})} \quad (2-3)$$

4. *Molality (m):*

$$m, \text{ mol/kg} = \frac{\text{mass of solute, g}}{(\text{molecular weight of solute, g/mol})(\text{mass of solution, kg})} \quad (2-4)$$

### Example 2-1 Determination of molarity and mole fractions

Determine the molarity and the mole fraction of a 1-L solution containing 20 g sodium chloride (NaCl) at 20°C. From the periodic table and reference books, it can be found that the molar mass of NaCl is 58.45 g/mol and the density of a 20 g/L NaCl solution is 1.0125 kg/L.

#### Solution

1. The molarity of the NaCl solution is computed using Eq. 2-3

$$[\text{NaCl}] = \frac{20 \text{ g}}{(58.45 \text{ g/mol})(1.0 \text{ L})} = 0.342 \text{ mol/L} = 0.342 \text{ M}$$

2. The mole fraction of the NaCl solution is computed using Eq. 2-2
  - a. The amount of NaCl (in moles) is

$$n_{\text{NaCl}} = \frac{20 \text{ g}}{58.45 \text{ g/mol}} = 0.342 \text{ mol}$$

- b. From the given solution density, the total mass of the solution is 1012.5 g, so the mass of the water in the solution is 1012.5 g – 20 g = 992.5 g and the amount of water (in moles) is

$$n_{\text{H}_2\text{O}} = \frac{992.5 \text{ g}}{18.02 \text{ g/mol}} = 55.08 \text{ mol}$$

- c. The mole fraction of NaCl in the solution is

$$x_{\text{NaCl}} = \frac{n_{\text{NaCl}}}{n_{\text{NaCl}} + n_{\text{H}_2\text{O}}} = \frac{0.342 \text{ mol}}{0.342 \text{ mol} + 55.07 \text{ mol}} = 6.17 \times 10^{-3}$$

#### Comment

The molar concentration of pure water is calculated by dividing the density of water by the MW of water; i.e., 1000 g/L divided by 18 g/mol equals 55.56 mol/L. Because the amount of water is so much larger than the combined values of the other constituents found in most waters, the mole fraction of constituent A is often approximated as  $x_A \approx (n_A/55.56)$ . If this approximation had been applied in this example, the mole fraction of NaCl in the solution would have been computed as  $6.16 \times 10^{-3}$ .

5. *Mass concentration:*

$$\text{Concentration, g/m}^3 = \frac{\text{mass of solute, g}}{\text{volume of solution, m}^3} \quad (2-5)$$

Note that  $1.0 \text{ g/m}^3 = 1.0 \text{ mg/L}$ .

6. *Normality (N)*:

$$N, \text{ eq/L} = \frac{\text{mass of solute, g}}{(\text{equivalent weight of solute, g/eq})(\text{volume of solution, L})} \quad (2-6)$$

where

$$\text{Equivalent weight of solute, g/eq} = \frac{\text{molecular weight of solute, g/mol}}{Z, \text{ eq/mol}} \quad (2-7)$$

For most compounds,  $Z$  is equal to the number of replaceable hydrogen atoms or their equivalent; for oxidation–reduction reactions,  $Z$  is equal to the change in valence. Also note that  $1.0 \text{ eq/m}^3 = 1.0 \text{ meq/L}$ .

7. *Parts per million (ppm)*:

$$\text{ppm} = \frac{\text{mass of solute, g}}{10^6 \text{ g of solution}} \quad (2-8)$$

Also,

$$\text{ppm} = \frac{\text{concentration of solute, g/m}^3}{\text{specific gravity of solution (density of solution divided by density of water)}} \quad (2-9)$$

8. *Other units*:

$\text{ppm}_m = \text{parts per million by mass (for water } \text{ppm}_m = \text{g/m}^3 = \text{mg/L)}$

$\text{ppm}_v = \text{parts per million by volume}$

$\text{ppb} = \text{parts per billion}$

$\text{ppt} = \text{parts per trillion}$

Also,  $1 \text{ g (gram)} = 1 \times 10^3 \text{ mg (milligram)} = 1 \times 10^6 \mu\text{g (microgram)}$   
 $= 1 \times 10^9 \text{ ng (nanogram)} = 1 \times 10^{12} \text{ pg (picogram)}$ .

## 2-3 Physical Aggregate Characteristics of Water

---

Most first impressions of water quality are based on physical rather than chemical or biological characteristics. Water is expected to be clear, colorless, and odorless (Tchobanoglous and Schroeder, 1985). Most natural waters will contain some material in suspension typically comprised of inorganic soil components and a variety of organic materials derived from nature. Natural waters are also colored by exposure to decaying organic material. Water from slow-moving streams or eutrophic water bodies will often contain colors and odors. These physical parameters are known as *aggregate characteristics* because the measured value is caused by a number of individual constituents. Parameters commonly used to quantify the aggregate physical characteristics include (1) absorption/transmittance, (2) turbidity, (3) number and type of particles, (4) color, and (5) temperature. Taste and odor, sometimes identified as physical characteristics, are considered in Sec. 2-6.

## Absorbance and Transmittance

The absorbance of a solution is a measure of the amount of light that is absorbed by the constituents in a solution at a specified wavelength. According to the Beer–Lambert law, the amount of light absorbed by water is proportional to the concentration of light-absorbing molecules and the path length the light takes in passing through water, regardless of the intensity of the incident light. Because even pure water will absorb incident light, a sample blank (usually distilled water) is used as a reference. Absorbance is given by the relationship

$$\log\left(\frac{I}{I_0}\right) = -\varepsilon(\lambda)Cx = -k_A(\lambda)x = -A(\lambda) \quad (2-10)$$

where

$I$  = intensity of light after passing through a solution of known depth containing constituents of interest at wavelength  $\lambda$ ,  $\text{mW}/\text{cm}^2$

$I_0$  = intensity of incident light after passing through a blank solution (i.e., distilled water) of known depth (typically 1.0 cm) at wavelength  $\lambda$ ,  $\text{mW}/\text{cm}^2$

$\lambda$  = wavelength, nm

$\varepsilon(\lambda)$  = molar absorptivity of light-absorbing solute at a wavelength  $\lambda$ ,  $\text{L}/\text{mol} \cdot \text{cm}$

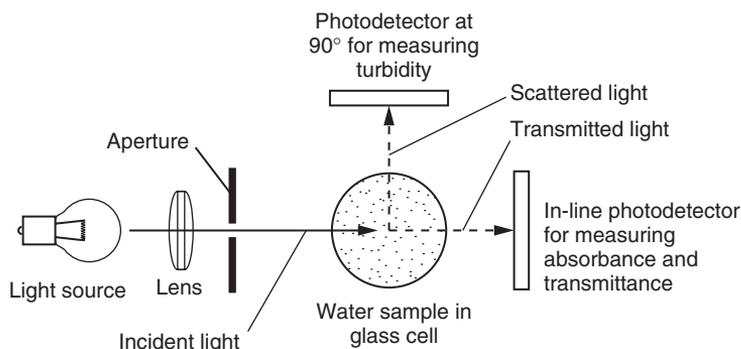

$C$  = concentration of light-absorbing solute,  $\text{mol}/\text{L}$

$x$  = length of light path, cm

$k_A(\lambda) = \varepsilon(\lambda)C$  = absorptivity at wavelength  $\lambda$ ,  $\text{cm}^{-1}$

$A(\lambda) = \varepsilon(\lambda)Cx$  = absorbance at wavelength  $\lambda$ , dimensionless

If the left-hand side of Eq. 2-10 is expressed as a natural logarithm, then the right-hand side of the equation must be multiplied by 2.303 because the absorbance coefficient (also known as the extinction coefficient) is determined in base 10. Absorbance is measured using a spectrophotometer, as illustrated on Fig. 2-2. Typically, a fixed sample path length of 1.0 cm is used. The absorbance  $A(\lambda)$  is unitless but is often reported in units of reciprocal centimeters, which corresponds to absorptivity  $k_A(\lambda)$ . If the

**Figure 2-2**

Schematic of a spectrophotometer used to measure absorbance and turbidity.

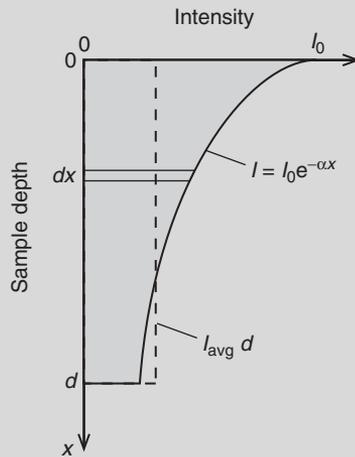

length of the light path is 1 cm, absorptivity is equal to the absorbance. The absorbance of water is typically measured at a wavelength of 254 nm. Typical absorbance values for various waters at  $\lambda = 254$  are given in Table 13-10. The application of Eq. 2-10 is illustrated in the following example.

### Example 2-2 Determine average UV intensity

If the intensity of the UV radiation measured at the water surface in a Petri dish is  $15 \text{ mW/cm}^2$ , determine the average UV intensity to which a sample will be exposed if the depth of water in the Petri dish is 12 mm (1.2 cm). Assume the absorptivity  $k_A(\lambda) = 0.1/\text{cm}$ .

#### Solution

1. Develop the equation to determine the average intensity.
  - a. The definition sketch for this problem is given below.

where  $\alpha = 2.303k_A(\lambda)$

- b. Develop the required equation:

$$\begin{aligned}
 I_{\text{avg}} &= \int_0^d I_0 e^{-\alpha x} dx = -\frac{I_0}{\alpha} e^{-\alpha x} \Big|_0^d \\
 &= -\frac{I_0}{\alpha} e^{-\alpha d} + \frac{I_0}{\alpha} = \frac{I_0}{\alpha} (1 - e^{-\alpha d}) \\
 I_{\text{avg}} &= \frac{I_0}{\alpha d} (1 - e^{-\alpha d})
 \end{aligned}$$

2. Compute the average intensity for a depth of 12 mm (1.2 cm):
  - a. Assume  $k_A(\lambda) = 0.1/\text{cm}$
  - b.  $\alpha = 2.303 k_A(\lambda) = 2.303 (0.1/\text{cm}) = 0.2303/\text{cm}$
  - c. Solve for  $I_{\text{avg}}$

$$I_{\text{avg}} = \frac{I_0}{\alpha d} (1 - e^{-\alpha d}) = \frac{15 \text{ mW/cm}^2}{(0.2303/\text{cm})(1.2 \text{ cm})} \left[ 1 - e^{-(0.2303)(1.2)} \right]$$

$$= 13.1 \text{ mW/cm}^2$$

The transmittance of a solution is defined as

$$\text{Transmittance, } T, \% = \left( \frac{I}{I_0} \right) \times 100 \quad (2-11)$$

Thus, the transmittance at a given wavelength can also be derived from absorbance measurements using the relationship

$$T = 10^{-A(\lambda)} \quad (2-12)$$

The term *percent transmittance*, commonly used in the literature, is given as

$$T, \% = 10^{-A(\lambda)} \times 100 \quad (2-13)$$

The extreme values of  $A$  and  $T$  are as follows (Delahay, 1957):

For a perfectly transparent solution  $A(\lambda) = 0$ ,  $T = 1$ .

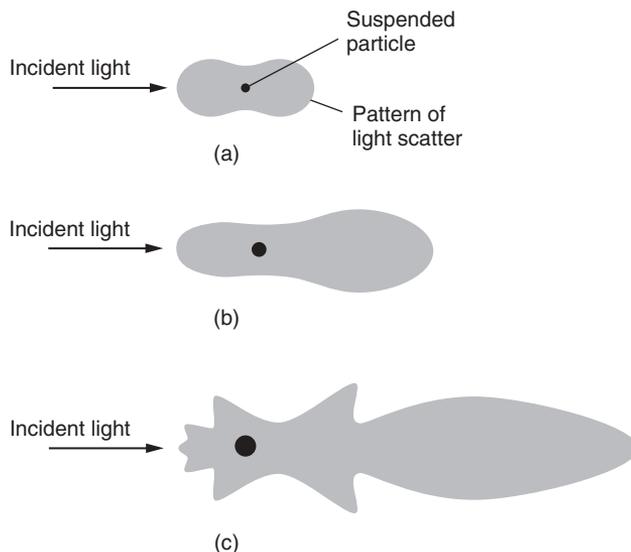

For a perfectly opaque solution  $A(\lambda) \rightarrow \infty$ ,  $T = 0$ .

The principal water characteristics that affect the percent transmittance include selected inorganic compounds (e.g., copper and iron), organic compounds (e.g., organic dyes, humic substances, and aromatic compounds such as benzene and toluene), and small colloidal particles ( $\leq 0.45 \mu\text{m}$ ). If samples contain particles larger than  $0.45 \mu\text{m}$ , the sample should be filtered before transmittance measurements are made. Of the inorganic compounds that affect transmittance, iron is considered to be the most important with respect to UV light absorbance because dissolved iron can absorb UV light directly. Organic compounds containing double bonds and aromatic functional groups can also absorb UV light. Absorbance values for a variety of compounds are given in the on-line resources for this text at the URL listed in App. E. The reduction in transmittance observed in surface waters during storm events is often ascribed to the presence of humic substances and particles from runoff, wave action, and stormwater flows (Tchobanoglous et al., 2003).

**Turbidity**

Turbidity in water is caused by the presence of suspended particles that reduce the clarity of the water. Turbidity is defined as “an expression of the optical property that causes light to be scattered and absorbed rather than transmitted with no change in direction or flux level through the sample” (Standard Methods, 2005). Turbidity measurements require a light source (incandescent or light-emitting diode) and a sensor to measure the scattered light. As shown on Fig. 2-2, the scattered light sensor is located at  $90^\circ$  to the light source. The measured turbidity increases as the intensity of the scattered light increases. Turbidity is expressed in nephelometric turbidity units (NTU).

It is important to note that the scattering of light caused by suspended particles will vary with the size, shape, refractive index, and composition of the particles. Also, as the number of particles increases beyond a given level, multiple scattering occurs, and the absorption of incident light is increased, causing the measured turbidity to decrease (Hach, 2008). The spatial distribution and intensity of the scattered light, as illustrated on Fig. 2-3, will depend on the size of the particle relative to the wavelength of the light source. For particles less than one-tenth of the wavelength of the incident light, the scattering of light is fairly symmetrical. As the particle size increases relative to the wavelength of the incident light, the light reflected from different parts of the particle creates interference patterns that are additive in the forward direction (Hach, 2008). Also, the intensity of the scattered light will vary with the wavelength of the incident light. For example, blue light will be scattered more than red light. Based on these considerations, turbidity measurements tend to be more sensitive to

**Figure 2-3**  
Light-scattering patterns for different particle sizes that occur when measuring turbidity. (Adapted from Hach, 2008.)

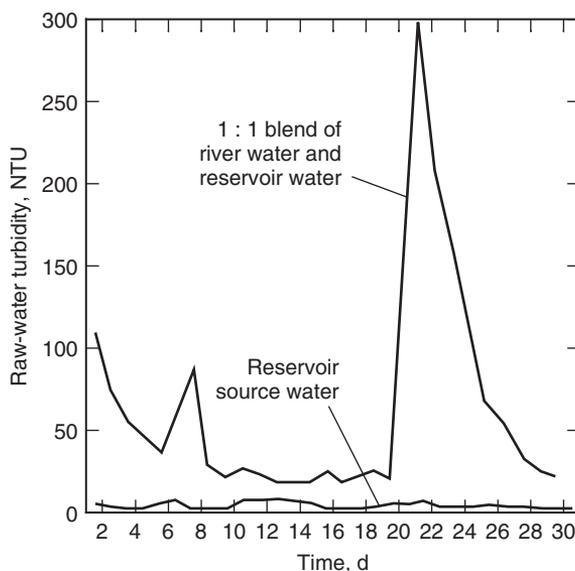

particles in the size range of the incident-light wavelength (0.3 to 0.7  $\mu\text{m}$  for visible light). A further complication with turbidity measurements is that some particles such as carbon black will essentially absorb most of the light and only scatter a minimal amount of the incident light.

Depending on the water source, turbidity can be the most variable of the water quality parameters of concern in drinking water supplies. Turbidity measurements are useful for comparing different water sources or treatment facilities and are used for process control and regulatory compliance. Increases in turbidity measurements are often used as an indicator for increased concentrations of water constituents, such as bacteria, *Giardia* cysts, and *Cryptosporidium* oocysts.

In lakes or reservoirs, turbidity is frequently stable over time and ranges from about 1 to 20 NTU, excluding storm events. Turbidity in rivers is more variable due to storm events, runoff, and changes in flow rate in the river. Turbidity in rivers can range from under 10 to over 4000 NTU. Streams and rivers where the turbidity can change by several hundred NTU in a matter of hours (see Fig. 2-4) are often described as “flashing” because of the rapid change in the turbidity. In such rivers, careful turbidity monitoring is critical for successful process control. The regulatory standard for turbidity in finished water is 0.3 NTU, and many water treatment facilities have a treatment goal of <0.1 NTU, which is near the detection limit for turbidity meters.

## Particles

Particles are defined as finely divided solids larger than molecules but generally not distinguishable individually by the unaided eye, although

**Figure 2-4**

Observed variation in raw-water turbidity values.  
(Adapted from James M. Montgomery, 1981.)

clumps of particles are often encountered. It should be noted that with 20–20 vision it is possible to resolve a particle size of about  $37\ \mu\text{m}$  at a distance of 0.3 m. Particles in water are important for a variety of reasons, including their impact on treatment processes and the potential health impacts of pathogen-associated particles. Particles in water may be classified according to their source, size, chemical structure, electrical charge characteristics, and water–solid interface characteristics. The source, size, shape, number and distribution, and quantification of particles is considered in the following discussion. The electrical properties of particles and particle interactions are considered in Chap. 9. The impact of particles in water on key water treatment processes, that is, coagulation, sedimentation, granular filtration, membrane filtration, and disinfection, is considered in Chaps. 9, 10, 11, 12, and 13, respectively.

#### **SOURCE OF PARTICLES IN WATER**

The sources of particles in water are summarized in Table 2-2, along with the sources of chemical constituents and gases. As reported in Table 2-2, the principal natural sources of particles in water are soil-weathering processes and biological activity. Clays and silts are produced by weathering. Algae, bacteria, and other higher microorganisms are the predominant types of particles produced biologically. Some particles have both natural and anthropogenic sources, a notable example being asbestos fibers. Industrial and agricultural activities tend to augment these natural sources by increasing areas of runoff through cultural eutrophication, the increase in the rate of natural eutrophication as a result of human activity, or direct pollution with industrial residues. Particles may be transported into water through direct erosion from terrestrial environments, be suspended due to turbulence and mixing in water, or form in the water column during biological activity or chemical precipitation or through atmospheric deposition.

#### **SIZE CLASSIFICATION OF PARTICLES**

The size of particles in water considered in this text is typically in the range of 0.001 to  $100\ \mu\text{m}$ . Suspended particles are generally larger than  $1.0\ \mu\text{m}$ . The size of colloidal particles will vary from about 0.001 to  $1\ \mu\text{m}$  depending on the method of quantification. It should be noted that some researchers have classified the size range for colloidal particles as varying from 0.0001 or less to  $1\ \mu\text{m}$ . In practice, the distinction between colloidal and suspended particles is blurred because the suspended particles that can be removed by gravity settling will depend on the design of the sedimentation facilities. Some standard analytical procedures operationally define dissolved material as that which will pass through a  $0.45\ \mu\text{m}$  filter. In practice, however, colloids as small as  $0.001\ \mu\text{m}$  can behave as particles and affect water quality and treatment processes as particles rather than dissolved substances. A suspension comprised of particles of one size is

**Table 2-2**  
Summary of important particulate, chemical, and biological constituents found in water according to their source

Source	Particulate constituents		Ionic and Dissolved Constituents		Gases and Neutral Species
	Colloidal	Suspended	Positive ions	Negative ions	
Contact of water with minerals, rocks, and soil (e.g., weathering)	Clay Silica (SiO <sub>2</sub> ) Ferric oxide (Fe <sub>2</sub> O <sub>3</sub> ) Aluminum oxide (Al <sub>2</sub> O <sub>3</sub> ) Magnesium dioxide (MnO <sub>2</sub> )	Clay, silt, sand, and other inorganic soils	Calcium (Ca <sup>2+</sup> ) Iron (Fe <sup>2+</sup> ) Magnesium (Mg <sup>2+</sup> ) Manganese (Mn <sup>2+</sup> ) Potassium (K <sup>+</sup> ) Sodium (Na <sup>+</sup> ) Zinc (Zn <sup>2+</sup> )	Bicarbonate (HCO <sup>-</sup> ) Borate (H <sub>2</sub> BO <sub>3</sub> <sup>-</sup> ) Carbonate (CO <sub>3</sub> <sup>2-</sup> ) Chloride (Cl <sup>-</sup> ) Fluoride (F <sup>-</sup> ) Hydroxide (OH <sup>-</sup> ) Nitrate (NO <sub>3</sub> <sup>-</sup> ) Phosphate (PO <sub>4</sub> <sup>3-</sup> ) Sulfate (SO <sub>4</sub> <sup>2-</sup> )	Carbon dioxide (CO <sub>2</sub> ) Silicate (H <sub>4</sub> SiO <sub>4</sub> )
Rain in contact with atmosphere			Hydrogen (H <sup>+</sup> )	Bicarbonate (HCO <sup>-</sup> ) Chloride (Cl <sup>-</sup> ) Sulfate (SO <sub>4</sub> <sup>2-</sup> )	Carbon dioxide (CO <sub>2</sub> ) Nitrogen (N <sub>2</sub> ) Oxygen (O <sub>2</sub> ) Sulfur dioxide (SO <sub>2</sub> )
Decomposition of organic matter in environment	Various organic polymers	Cell fragments	Ammonium (NH <sub>4</sub> <sup>+</sup> ) Hydrogen (H <sup>+</sup> ) Sodium (Na <sup>+</sup> )	Bicarbonate (HCO <sup>-</sup> ) Chloride (Cl <sup>-</sup> ) Hydroxide (OH <sup>-</sup> ) Nitrate (NO <sub>3</sub> <sup>-</sup> ) Nitrite (NO <sub>2</sub> <sup>-</sup> ) Sulfide (HS <sup>-</sup> ) Sulfate (SO <sub>4</sub> <sup>2-</sup> )	Ammonia (NH <sub>3</sub> ) Carbon dioxide (CO <sub>2</sub> ) Hydrogen sulfide (H <sub>2</sub> S) Hydrogen (H <sub>2</sub> ) Methane (CH <sub>4</sub> ) Nitrogen (N <sub>2</sub> ) Oxygen (O <sub>2</sub> ) Silicate (H <sub>4</sub> SiO <sub>4</sub> )

Living organisms	Bacteria, algae, viruses, etc.	Algae, diatoms, minute animals, fish, etc.	—	—	Ammonia (NH <sub>3</sub> ) Carbon dioxide (CO <sub>2</sub> ) Hydrogen sulfide (H <sub>2</sub> S) Hydrogen (H <sub>2</sub> ) Methane (CH <sub>4</sub> ) Nitrogen (N <sub>2</sub> ) Oxygen (O <sub>2</sub> )
Municipal, industrial, and agricultural sources and other human activity	Inorganic and organic solids, constituents causing color, chlorinated organic compounds, bacteria, worms, viruses, etc.	Clay, silt, grit, and other inorganic solids; organic compounds; oil; corrosion products; etc.	Inorganic ions, including a variety of anthropogenic compounds and heavy metals	Inorganic ions, including a variety of anthropogenic compounds, organic molecules, color, etc.	Chlorine (Cl <sub>2</sub> ) Sulfur dioxide (SO <sub>2</sub> )

Source: Adapted, in part, from Tchobanoglous and Schroeder (1985).

called monodispersed and a suspension with a variety of particle sizes is called heterodispersed (typical of natural waters).

Many water treatment processes are designed to remove particles based on sedimentation and size exclusion. The type and size of various waterborne particles and processes used for measurement and removal are presented on Fig. 2-5. As shown on Fig. 2-5, conventional treatment processes such as sedimentation and depth filtration alone are not sufficient for the removal of all water constituents; however, with the addition of coagulation and flocculation, the effective range of these treatment processes is greatly extended.

#### **PARTICLE SHAPE**

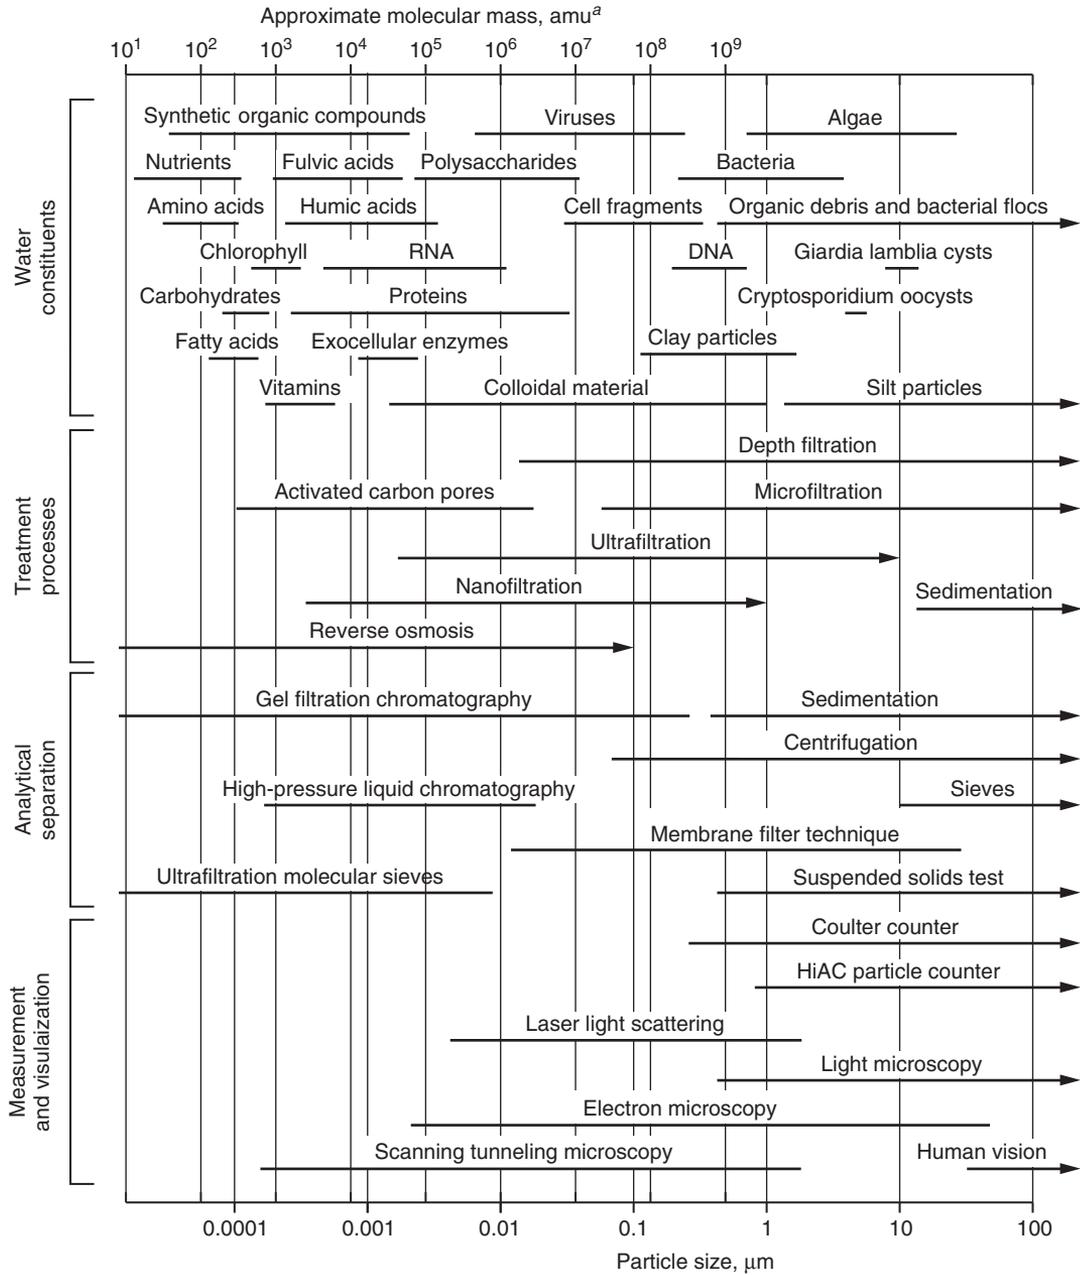

Particle shapes found in water can be described as spherical, semispherical, ellipsoids of various shapes (e.g., prolate and oblate), rods of various length and diameter, disk and disklike, strings of various lengths, and random coils. Inorganic particles are typically defined by the dimensions of their long, intermediate, and short axes and the ratio of the intermediate-to-long and the short-to-intermediate diameters. Because of the many different particle shapes, the nominal or equivalent particle diameter is used (Dallavalle, 1948). Large organic molecules are often found in the form of coils that may be compressed, uncoiled, or almost linear. The shape of some larger particles is often described as fractal. The particle shape will vary depending on the characteristics of the source water.

#### **PARTICLE QUANTIFICATION**

Methods used for the quantification and analysis of particulate material include gravimetric techniques, electronic particle size counting, and microscopic observation. Although regulations concerning particle concentrations are typically based on turbidity measurements, monitoring particle counts throughout a treatment process can aid in understanding and controlling the process. Also, as noted above, turbidity measurements cannot be correlated to any quantifiable particle characteristics. While particle quantification may be useful for evaluating a treatment process, except for microscopic observation, these methods cannot be used reliably for determining the source or type of particle (e.g., distinguish between a viable cyst and a colloid). In addition, due to the limitations of particle analysis methods, the use of more than one method is recommended when assessing water quality data.

##### *Gravimetric techniques*

The total mass of particles may be estimated by filtering a volume of water through a membrane of known weight and pore size. Filtration of the same water sample through a series of membranes with incrementally decreasing pore sizes is known as serial filtration. Serial filtration may be used to determine an approximate particle size distribution (Levine et al., 1985).

**Figure 2-5**

Characterization of particulate matter in natural water by type and size, appropriate treatment methods, analytical separation methods, and measurement techniques. (Adapted from Tchobanoglous et al., 2003.)

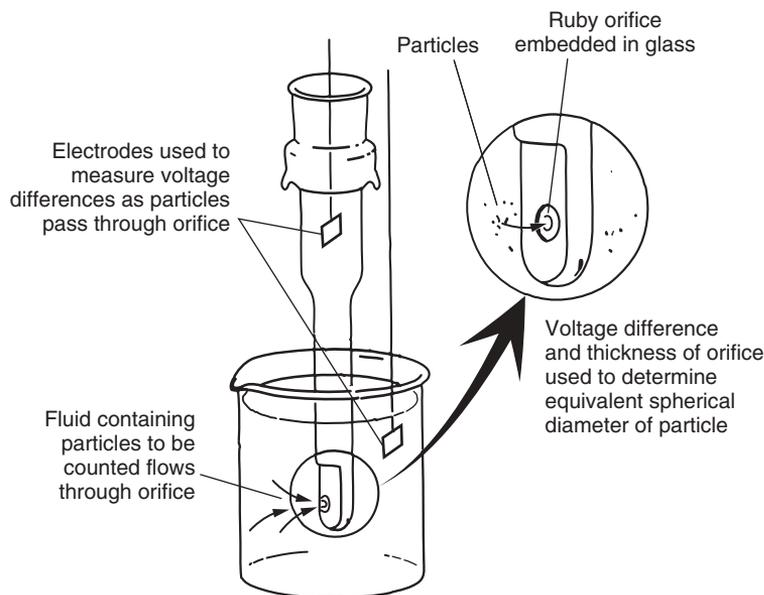

Particle size distribution may also be measured using electronic particle-counting devices, as discussed below.

#### *Electronic particle size counting*

Particle concentration measurements provide more specific information about the size and number of particles in a water sample. Electronic particle size counters estimate the particle size concentration by either (1) passing a water sample through a calibrated orifice and measuring the change in conductivity (see Fig. 2-6) or (2) passing the sample through a laser beam and measuring the change in intensity due to light scattering. The change in conductivity or light intensity is correlated to the diameter of an equivalent sphere. Particle counters have sensors available in different size ranges, such as 1.0 to 60  $\mu\text{m}$  or 2.5 to 150  $\mu\text{m}$ , depending on the manufacturer and application. Particle counts are typically measured and recorded in about 10 to 20 subranges of the sensor range. Typical particle size counters are shown on Fig. 2-7. A comparison of analytical techniques used for particle size analysis is presented in Table 2-3. Particle counts may also be used as an indicator of *Giardia* and *Cryptosporidium* cysts from water (LeChevallier and Norton, 1992, 1995).

#### *Microscopic observation*

The use of microscopic observation allows for the determination of particle size counts and, in some cases, for more rigorous identification of a particle's

**Figure 2-6**

origin than is possible with other analysis techniques. A measured volume of sample is placed in a particle-counting cell and the individual particles may be counted, often with the use of a stain to enhance the particle contrast. Optical imaging software may also be used to obtain a more quantitative assessment of particle characteristics. Images of water particles are obtained with a digital camera attached to a microscope and sent to a computer for imaging analysis. The imaging software typically allows for

the determination of minimum, mean, and maximum size, shape, surface area, aspect ratio, circumference, and centroid location.

#### PARTICLE NUMBER AND DISTRIBUTION

The number of particles in raw surface water can vary from 100 to over 10,000/mL depending on the time of year and location where the sample is taken (e.g., a river or storage reservoir). The number of particles, as will be discussed later, is of importance with respect to the method to be used for their removal. The size distribution of particles in natural waters may be defined on the basis of particle number, particle mass, particle diameter, particle surface area, or particle volume. In water treatment design and operation, particle size distributions are most often determined using a particle size counter, as discussed above. In most particle size counters, the detected particles of a given size are counted and grouped with other particles within specified size ranges (e.g., 1 to 2  $\mu\text{m}$ , 5 to 10  $\mu\text{m}$ ). When the counting is completed, the number of particles in each bin is totaled.

The particle number frequency distribution  $F(d)$  can be expressed as the number concentration of particles,  $dN$ , with respect to the incremental change in particle size,  $d(d_p)$ , represented by the bin size:

$$F(d_p) = \frac{dN}{d(d_p)} \quad (2-14)$$

where  $F(d_p)$  = function defining frequency distribution of particles  $d_1$ ,  $d_2$ ,  $d_3$

$dN$  = particle number concentration with respect to incremental change in particle diameter  $d(d_p)$

$d(d_p)$  = incremental change in particle diameter (bin size)

Because of the wide particle size ranges encountered in natural waters, it is common practice to plot the frequency function  $dF(d)$  against the logarithm of size,  $\log d_p$ :

$$2.303(d_p)F(d) = \frac{dN}{d(\log d_p)} \quad (2-15)$$

Similar relationships can be derived based on particle surface area and volume (Dallavalle, 1948; O'Melia, 1978).

It has also been observed that in natural waters the number of particles increases with decreasing particle diameter and that the frequency distribution typically follows a power law distribution of the form

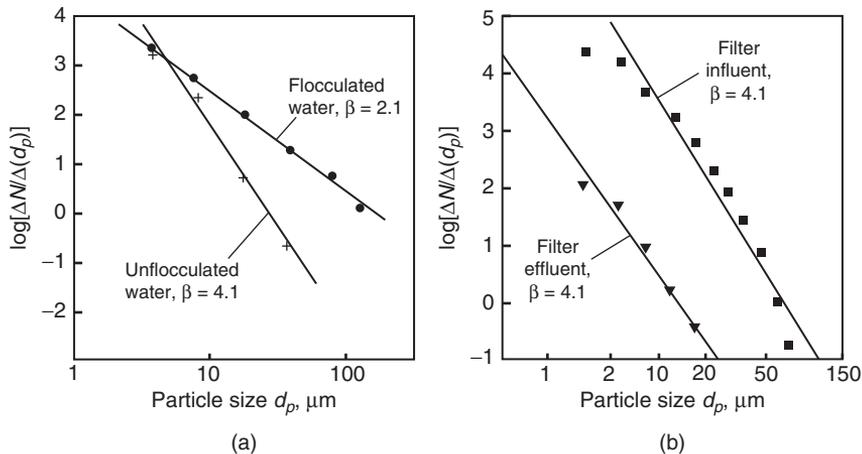

$$\frac{dN}{d(d_p)} = A (d_p)^{-\beta} \simeq \frac{\Delta N}{\Delta(d_p)} \quad (2-16)$$

where  $A$  = power law density coefficient  
 $d_p$  = particle diameter,  $\mu\text{m}$   
 $\beta$  = power law slope coefficient

Taking the log of both sides of Eq. 2-16 results in the following expression, which can be plotted to determine the unknown coefficients  $A$  and  $\beta$ :

$$\log[\Delta N/\Delta(d_p)] = \log A - \beta \log(d_p) \quad (2-17)$$

The value of  $A$  is determined when  $d_p = 1 \mu\text{m}$ . As the value of  $A$  increases, the total number of particles in each size range increases. The slope  $\beta$  is a measure of the relative number of particles in each size range. Thus, if  $\beta < 1$ , the particle size distribution is dominated by large particles; if  $\beta = 1$ , all particle sizes are represented equally; and if  $\beta > 1$ , the particle size distribution is dominated by small particles (Trussell and Tate, 1979). The value of the coefficient for most natural waters varies between 2 and 5 (O'Melia, 1978; Trussell and Tate, 1979). Typical plots of particle size data determined using a particle size counter for various waters are given on Fig. 2-8. On Fig. 2-8a, the effect of flocculation in producing large particles is evident by comparing the  $\beta$  values for the unflocculated versus the flocculated influent (4.1 versus 2.1). As shown on Fig. 2-8b, the removal of all particle sizes by filtration is very similar, because the slopes of the two plots are nearly identical. The analysis of data obtained from a particle size counter is shown in Example 2-3.

**Figure 2-8**  
 Typical examples of particle size distributions: (a) unflocculated and flocculated and (b) filter influent and effluent. (Adapted from Trussell and Tate, 1979.)

### Example 2-3 Analysis of particle size information

Determine the slope and density coefficients  $A$  and  $\beta$  in Eq. 2-17 for the following particle size data obtained from settled water during a pilot study.

Channel (Bin)	Particle size range, $\mu\text{m}$	Number of Particles, #/mL
1	1–3	1785
2	3–5	243
3	5–7	145
4	7–12	186
5	12–32	132
6	32–120	2.9
	Total	2493.9

#### Solution

- Calculate the necessary values for the first data channel.
  - Mean particle diameter:

$$d_p = \frac{1}{2} (1 \mu\text{m} + 3 \mu\text{m}) = 2 \mu\text{m}$$

- Log of the mean particle diameter:

$$\log(d_p) = \log(2 \mu\text{m}) = 0.301$$

- Particle diameter range:

$$\Delta(d_p) = 3 \mu\text{m} - 1 \mu\text{m} = 2 \mu\text{m}$$

- Number of particles:

$$\Delta N = 1785/\text{mL}$$

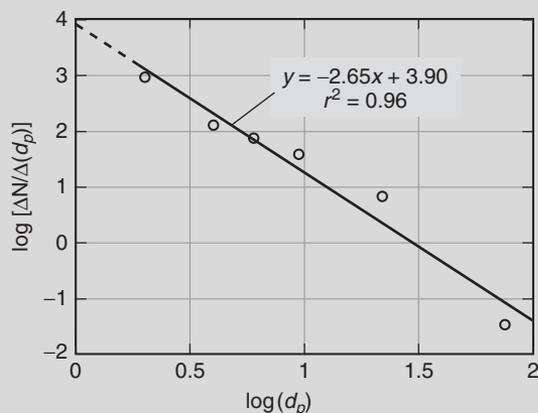

- Log of the particle size distribution function:

$$\log \left[ \frac{\Delta N}{\Delta(d_p)} \right] = \log \left( \frac{1785/\text{mL}}{2 \mu\text{m}} \right) = 2.95$$

- Calculate the necessary values for the remaining data channels. The results are tabulated below.

Channel	(A) $d_p$	(B) $\log(d_p)$	(C) $\Delta(d_p)$	(D) $\Delta N$	(E) $\log[\Delta N/\Delta(d_p)]$
1	2	0.301	2	1785	2.95
2	4	0.602	2	243	2.08
3	6	0.778	2	145	1.86
4	9	0.978	5	186	1.57
5	22	1.342	20	132	0.82
6	76	1.881	88	2.9	-1.48

3. Prepare a plot of  $\log[\Delta N/\Delta(d_p)]$  versus  $\log(d_p)$  draw a linear trendline and display the trendline equation and  $r^2$  value on the chart. The resulting chart is shown below.

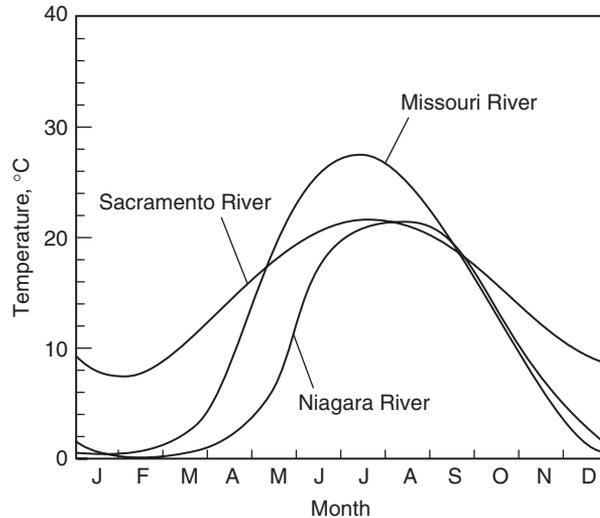

4. Determine  $A$  and  $\beta$  in Eq. 2-17 from the line of best fit in the above plot.
- When  $\log(d_p) = 0$ , the intercept value is equal to  $\log(A)$ . Thus,  $A = 7,940$ .
  - The slope of the line of best fit is equal to  $-\beta$ . Thus,  $\beta = 2.65$ .

The color of a water is an indication of the organic content, including humic and fulvic acids, the presence of natural metallic ions such as iron and manganese, and turbidity. Apparent color is measured on unfiltered samples and true color is measured in filtered samples (0.45- $\mu\text{m}$  filter). Turbidity increases the apparent color of water, while the true color is caused by dissolved species and is used to define the aesthetic quality of water. The color of potable waters is typically assessed by visually comparing a water sample to known color solutions made from serial dilutions or concentrations of a standard platinum–cobalt solution. The platinum–cobalt standard is related to the color-producing substance in the water only by hue.

The presence of color is reported in color units (c.u.) at the pH of the solution. In water treatment, one of the difficulties with the comparison method is that at low levels of color it is difficult to differentiate between low values (e.g., 2 versus 5 c.u.). If the water sample contains constituents (e.g., industrial wastes) that produce unusual colors or hues that do not match the platinum–cobalt standards, then instrumental methods must be

## Color

**Figure 2-9**

Generalized monthly variations in temperature in the Missouri River near Blair, Nebraska; in the Niagara River at Buffalo, New York; and in the Sacramento River near Sacramento, California. (Adapted from Tchobanoglous and Schroeder, 1985.)

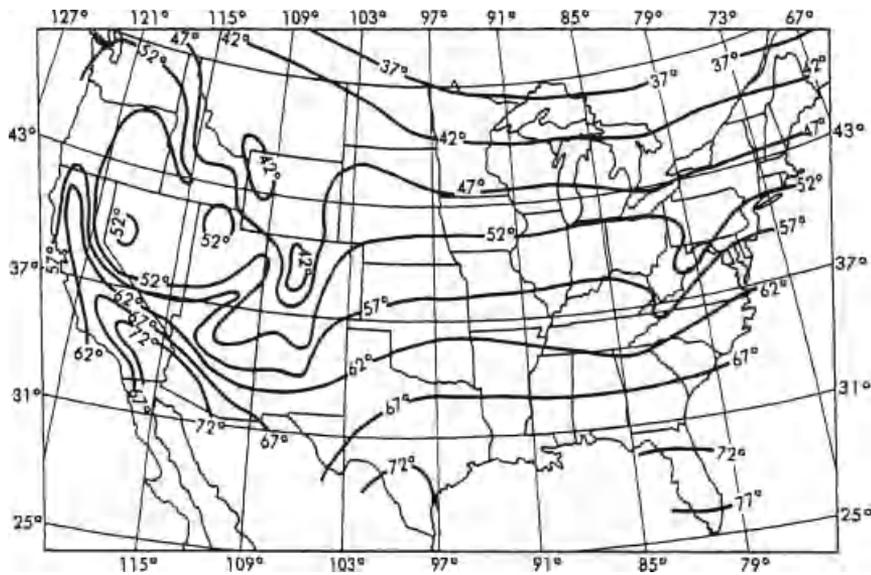

used. Instrumental methods are used to determine (1) the hue (red, green, yellow, etc.), (2) the luminance (brightness), and (3) the saturation (pale, deep, etc.) of a solution. In turn, these three parameters can be related to the *chromaticity*. It should be noted that the results obtained with the two methods are not comparable.

## Temperature

Water temperature is of importance because it affects many parameters that impact engineering designs. These parameters include density, viscosity, vapor pressure, surface tension, solubility, the saturation value of gases dissolved in water, and the rates of chemical, biochemical, and biological activity. As the heat capacity of water is much greater than that of air, water temperature changes much more slowly than air temperature. Depending on the geographic location, the mean annual temperature of river water in the United States varies from about 0.5 to 3°C in the winter to 23 to 27°C in the summer (see Fig. 2-9). In small slow-moving streams, summer temperatures may exceed 30°C. Lakes, reservoirs, ponds, and other impoundments are also subject to temperature changes. Extremely wide temperature variations can occur in shallow impoundments. Typical groundwater temperatures are as shown on Fig. 2-10. In general, groundwater temperatures are not as variable as surface water temperatures.

## 2-4 Inorganic Chemical Constituents

Water in the environment can contain a variety of colloidal and suspended solids inorganic and organic ionic and dissolved constituents and

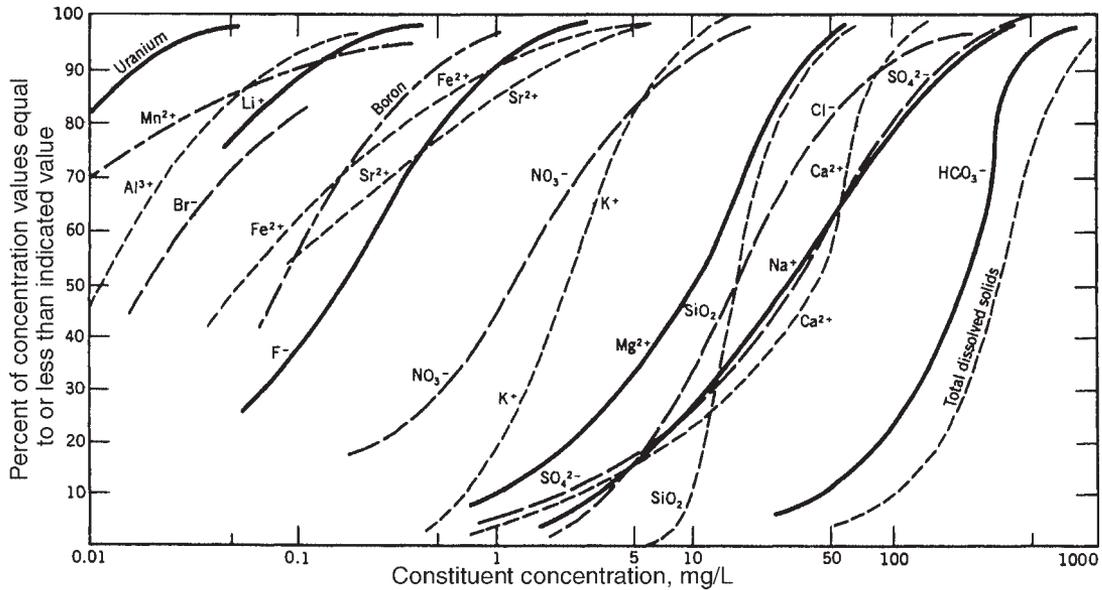

**Figure 2-10**  
Approximate temperature of groundwater from nonthermal wells at depths varying from 10 to 20 m. Note temperatures are given in degrees Fahrenheit.

compounds, and gases (see Table 2-2). The sources of particulate (both colloidal and suspended) constituents in water were discussed previously in Sec. 2-3. The focus of this section is on the ionic and dissolved inorganic constituents found in most natural waters as identified in Table 2-2. Specific topics include (1) the major inorganic chemical constituents in natural water, (2) the minor inorganic constituents found in natural waters, and (3) the principal inorganic water quality indicators. Organic constituents are considered in Sec. 2-5.

Inorganic chemical constituents commonly found in water in significant quantities (1.0 to 1000 mg/L) include calcium, magnesium, sodium, potassium, bicarbonate, chloride, sulfate, and nitrate. Inorganic constituents that are generally present in lesser amounts (0.01 to 10 mg/L) include iron, lead, copper, arsenic, and manganese. The range of concentrations found for individual inorganic constituents in a survey of natural waters is shown on Fig. 2-11. The plotted lines for each constituent represent the percent of the samples in which each constituent was found to be equal to or less than a specified concentration. For example, potassium occurred over a range of 0.4 to 15 mg/L, and samples from 80 percent of the natural waters in this survey had potassium concentrations below 5 mg/L. Additional details on the major inorganic constituents found in natural waters are presented in Table 2-4.

### Major Inorganic Constituents

**Figure 2-11**

Cumulative curves showing frequency distribution of various constituents in terrestrial water. Data are mostly from the United States from various sources. (Adapted from Davies and DeWiest, 1966.)

### Minor and Trace Inorganic Constituents

Constituents of natural waters found in the parts-per-billion to parts-per-trillion range may still be of significant health or water quality concern. Constituents of concern include a number of inorganics and numerous trace organics, as discussed in the following section. Information on the water quality significance of several inorganic trace constituents is presented in Table 2-5. As shown, the trace constituents have been grouped under four categories: (1) alkali metals, (2) alkaline metals, (3) other metallic elements depending on their properties, and (4) nonmetals.

### Inorganic Water Quality Indicators

Several chemically related quality measures are utilized to characterize the properties of a water supply including (1) the hydrogen ion concentration (pH), (2) polyvalent cation content (hardness), (3) total dissolved solids (TDS), and (4) electrical conductivity.

#### pH (HYDROGEN ION CONCENTRATION)

pH is a measurement of the acid–base properties of a solution. pH is an important parameter in water treatment as it directly influences the dosages of chemicals added to reduce hardness and coagulate particles. pH is measured as the negative logarithm of the concentration of hydrogen ions:

$$\text{pH} = -\log_{10}[\text{H}^+] \quad (2-18)$$

**Table 2-4**  
Summary of the major cations and anions in natural water<sup>a</sup>

Ion	Description
<b>Cations</b>	
Calcium (Ca <sup>2+</sup> )	Calcium is generally among the most prevalent three or four ions in groundwaters. Common mineral forms of calcium are calcite, also known as aragonite (CaCO <sub>3</sub> ), gypsum (CaSO <sub>4</sub> ·2H <sub>2</sub> O), anhydrite (CaSO <sub>4</sub> ), and fluorite (CaF <sub>2</sub> ). Calcium is generally present as the free ion, Ca <sup>2+</sup> , in natural waters and adsorbed onto soil particles. Along with magnesium and other multivalent ions Ca <sup>2+</sup> is responsible for the hardness of a water as discussed later in this section.
Iron (Fe <sup>2+</sup> , <sup>3+</sup> )	Iron is found in rocks, soils, and waters in a variety of forms and oxidation states. Common mineral sources (deposits) of iron include ferric oxides and hydroxides such as hematite (Fe <sub>2</sub> O <sub>3</sub> ) and ferric hydroxide [Fe(OH) <sub>3</sub> ], which gives rocks and soils their red and yellow color. In oxygenated surface waters (pH 5–8), typical concentrations of total iron are around 0.05–0.2 mg/L. In groundwater, the occurrence of iron at concentrations of 1.0–10 mg/L is common, and higher concentrations (up to 50 mg/L) are possible in low-bicarbonate and low-oxygen waters.
Magnesium (Mg <sup>2+</sup> )	Magnesium salts are more soluble than calcium, but they are less abundant in rocks and therefore less available for weathering reactions. Concentrations of magnesium are typically below 10–20 mg/L in surface waters and below 30–40 mg/L in groundwaters. Taken together, calcium and magnesium comprise most natural water hardness.
Manganese (Mn <sup>2+</sup> )	Manganese is abundant in rocks and soils, typically in the form of manganese oxides and hydroxides in association with other metallic cations. At low and neutral pH values, the predominant dissolved form of manganese is the divalent cation Mn <sup>2+</sup> . Concentrations on the order of 0.1–1 mg/L are common, although in low-pH waters higher concentrations can occur. Manganese often is present with iron in groundwaters and, like iron, may cause aesthetic problems such as laundry and fixture staining.
Potassium (K <sup>+</sup> )	Although a common element of the earth's crust, the concentration of potassium in natural waters is much lower than sodium. Potassium occurs in nature only in ionic or molecular form and has many properties that are similar to sodium, so it occasionally replaces sodium in industrial applications.
Sodium (Na <sup>+</sup> )	Sodium compounds comprise almost 3% of the earth's crust, and a significant amount is found in rock and soil. Sodium is transported into water from rocks through weathering and soil through ion exchange reactions. In natural waters, sodium is generally present as the free ion Na <sup>+</sup> . Several complexes and ion pairs may occur in natural waters, including sodium carbonate (NaCO <sub>3</sub> <sup>-</sup> ), sodium bicarbonate (NaHCO <sub>3</sub> ), sodium sulfate (NaSO <sub>4</sub> <sup>-</sup> ), and sodium chloride (NaCl).

(continues)

Table 2-4 (Continued)

Ion	Description
<b>Anions and neutral species</b>	
Bicarbonate (HCO <sub>3</sub> <sup>-</sup> )	The carbonate–bicarbonate system in natural water performs important functions in acid–base chemistry, buffer capacity, metal complexation, solids formation, and biological metabolism. Species comprising the carbonate system include CO <sub>2</sub> , H <sub>2</sub> CO <sub>3</sub> , HCO <sub>3</sub> <sup>-</sup> , and CO <sub>3</sub> <sup>2-</sup> . The dominant role of the carbonate system in acid–base chemistry of natural waters is well documented, although exceptions occur in waters with very high concentrations of dissolved organics or in high-sulfate groundwaters.
Chloride (Cl <sup>-</sup> )	Chloride is present in water supplies almost exclusively as the chloride ion (Cl <sup>-</sup> ), although hydrolysis products of chlorine (HOCl and OCl <sup>-</sup> ) exist temporarily where chlorine has been added as a disinfectant. In typical surface waters the concentration of chloride ion is less than 10 mg/L; however, in areas subject to seawater intrusion or hot-spring inflows or where evaporation greatly exceeds precipitation, the chloride concentrations can approach seawater levels.
Flouride (F <sup>-</sup> )	Although the amount of fluoride in crustal rocks is much greater than chloride, fluoride remains bound in minerals to a much greater degree. Fluorite (CaF <sub>2</sub> ) is a common fluoride mineral and fluorapatite [Ca <sub>5</sub> F(PO <sub>4</sub> ) <sub>3</sub> ] also commonly contains fluoride. In natural waters, fluoride is present primarily as the F <sup>-</sup> ion or as a complex with aluminum, beryllium, or ferric iron. In waters with TDS < 1000 mg/L, fluoride is typically <1 mg/L, although ground waters affected by volcanic activity are found with levels higher than 10 mg/L.
Nitrogen (N)	<p>The most common and important forms of nitrogen in water and their corresponding oxidation state in the water/soil environment are ammonia gas (NH<sub>3</sub>, –III), ammonium (NH<sub>4</sub><sup>+</sup>, –III), nitrogen gas (N<sub>2</sub>, 0), nitrite ion (NO<sub>2</sub><sup>-</sup>, + III), and nitrate ion (NO<sub>3</sub><sup>-</sup>, + V). The oxidation state of nitrogen in most organic compounds is –III. The oxidation states of nitrogen range from –3 to +5 and are summarized below (Sawyer et al., 2003):</p> $\overset{-III}{\text{NH}_3} - \overset{0}{\text{N}_2} - \overset{I}{\text{N}_2\text{O}} - \overset{II}{\text{NO}} - \overset{III}{\text{N}_2\text{O}_3} - \overset{IV}{\text{NO}_2} - \overset{V}{\text{N}_2\text{O}_5}$ <p>Other forms of nitrogen in water include organic compounds such as urea (NH<sub>2</sub>CONH<sub>2</sub>), amino acids and their breakdown products, ammonia (NH<sub>3</sub>), ammonium ion (NH<sub>4</sub><sup>+</sup>), hydroxylamine (NH<sub>2</sub>OH), nitrogen gas (N<sub>2</sub>), and nitrite (NO<sub>2</sub><sup>-</sup>). Ammonia, ammonium ion, and protein by-products are all reduced species, N<sub>2</sub> gas is in the zero oxidation state, nitrite is at +3, and nitrate is at +5. Transformation from one state to another is closely tied to biological activity, the influx of domestic wastes, and the local use of nitrogen fertilizers.</p>
Silica (SiO <sub>2</sub> )	Silica is present in almost all rocks, soils, and natural waters. In water, silica is hydrated as H <sub>4</sub> SiO <sub>4</sub> or Si(OH) <sub>4</sub> , although water analyses commonly represent dissolved silica as SiO <sub>2</sub> . The concentration of silica most commonly found in natural waters is between 1 and 30 mg/L. The solubility of silica is complex, but temperature is a critical factor. Sodium silicates have been used as coagulants in water treatment and as corrosion inhibitors on iron pipes.

**Table 2-4** (Continued)

Ion	Description
<b>Anions and neutral species</b>	
Sulfur (S)	Sulfur occurs in natural waters as sulfate (e.g., $\text{SO}_4^{2-}$ ) and sulfides (e.g., $\text{H}_2\text{S}$ , $\text{HS}^-$ , $\text{Na}_2\text{S}_2\text{O}_3$ ). The primary sources of sulfates are evaporite rocks, which are formed by water evaporation and mineral precipitation, such as gypsum ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ) and anhydrite ( $\text{CaSO}_4$ ), sedimentary rock such as pyrite ( $\text{FeS}_2$ ), rainfall, and bacterial metabolism. The concentration of sulfate in oxidized waters typically range from 5 to 30 mg/L.

<sup>a</sup>Cations and anions are arranged alphabetically

**Table 2-5**

Minor and trace elements found in natural waters<sup>a</sup>

Constituent	Concentration in Natural Waters, $\mu\text{g/L}$	Significance in Water Supplies
		<i>Alkali Metals</i>
Cesium	0.05–0.02 <sup>b</sup>	
Lithium	0.001–0.3	Potentially toxic to plants, but not at concentrations likely to be encountered in irrigation waters
Rubidium	0.0015	
		<i>Alkaline Earth Metals</i>
Barium	0.043 (median public water)	Ingestion of soluble barium salts can be fatal. Normal water concentrations have no effect.
Beryllium	0.001–1	Highly toxic, but occurs at very low concentration.
Strontium	0.6 (median river water), 0.11 (median public water)	Concentration in natural water is less than solubility.
		<i>Other Metallic Elements</i>
Cadmium	ND–10	Toxic. Presence may indicate industrial contamination.
Chromium	5.8 (median river water), 0.43 (median public water)	Industrial pollutant.
Cobalt	ND–1.0	Essential in nutrition in small quantities.
Copper	10	Utilized in water treatment and metal fabrication; used to inhibit algae growth in reservoirs; essential for nutrition of flora and fauna.
Gold	ND–trace	—
Lead	1–10	Older plumbing systems contain lead, which may dissolve at low pH.

(continues)

**Table 2-5** (Continued)

Constituent	Concentration in Natural Waters, $\mu\text{g/L}$	Significance in Water Supplies
Mercury	ND–<10	Highly toxic. Presence indicates pollution from mining, industry, or metallurgical works.
Molybdenum	0.35 (median river water); 1.4 (median public water)	Accumulated by vegetation. Forage crops may become toxic.
Nickel	10	—
Silver	0.1–0.3	Has been used as disinfectant.
Titanium	8.6 (median river water); <1.5 (median public waters)	—
Vanadium	<70	May concentrate in vegetation.
Zinc	10	Widely found in industry wastes; found in wastes dissolved from galvanized pipes, cooling-water treatment, etc.
Arsenic	0–1000	Used in industry in some herbicides and pesticides; lethal in animals above 44 mg/kg. Long-term ingestion of 0.21 mg/L reported to be poisonous.
Bromine	20	May react with disinfectants and form brominated species, which are suspected carcinogens.
Iodine	0.2–2	Essential nutrient in higher animals; has been used to seed clouds.
Selenium	0.2	Taken up by vegetation.

<sup>a</sup>Values presented are approximate and represent one or more author's best estimate. ND = nondetected. Public water refers to drinking water.

<sup>b</sup>Values observed in six analyses of rivers in Japan.

Sources: NAS (1977), Livingstone (1963), Turekian (1971), and Hem (1971).

The hydrogen ion concentration in water is connected closely with the extent to which water molecules dissociate. Water will dissociate into hydrogen and hydroxide ions as follows:

Applying the law of mass action (see discussion in Chap. 5) to Eq. 2-19 yields

$$\frac{[\text{H}^+][\text{OH}^-]}{[\text{H}_2\text{O}]} = K \quad (2-20)$$

where the brackets indicate concentration of the constituents in moles per liter. Because the concentration of water in a dilute aqueous system is essentially constant, this concentration can be incorporated into the

equilibrium constant  $K$  to give

$$[\text{H}^+][\text{OH}^-] = K_w \quad (2-21)$$

where  $K_w$  is known as the ionization constant or ion product of water and is approximately equal to  $1 \times 10^{-14}$  at a temperature of  $25^\circ\text{C}$ . Equation 2-21 can be used to calculate the hydroxide ion concentration when the hydrogen ion concentration is known, and vice versa.

With pOH, which is defined as the negative logarithm of the hydroxyl ion concentration, for water at  $25^\circ\text{C}$ , the following relation is used:

$$\text{pH} + \text{pOH} = 14 \quad (2-22)$$

The pH of aqueous systems typically is measured with a pH-sensing electrode. Various pH papers and indicator solutions that change color at definite pH values are also used. When using pH paper or indicator solution, pH is determined by comparing the color of the paper or solution to a series of color standards.

#### HARDNESS

Multivalent cations, particularly magnesium and calcium, are often present at significant concentrations in natural waters. These ions are easily precipitated and in particular react with soap to form a difficult-to-remove scum. Hardness is an important parameter to industry as an indicator of potential (interfering) precipitation, such as with carbonates in cooling towers or boilers, with soaps and dyes in cleaning and textile industries, and with emulsifiers in photographic development. For most practical purposes, hardness of water can be represented as the sum of the calcium and magnesium concentrations, given in milliequivalents per liter:

$$\text{Hardness, eq/L} = 2[\text{Ca}^{2+}] + 2[\text{Mg}^{2+}] \quad (2-23)$$

In Eq. 2-23, the concentrations of Ca and Mg are given in mol/L, and the coefficient 2 reflects the divalent nature of both ions, i.e., both have 2 equivalents per mole. Two general types of hardness are of interest: carbonate hardness, associated with  $\text{HCO}_3^-$  and  $\text{CO}_3^{2-}$ , and noncarbonate hardness, associated with other anions, particularly  $\text{Cl}^-$  and  $\text{SO}_4^{2-}$ . The balance between carbonate and noncarbonate hardness is important in water softening (hardness removal) and in scale formation. Because  $\text{HCO}_3^-$  dissociates at high temperatures, the result of heating hard water is scale formation due to  $\text{CaCO}_3$  precipitation:

Scale formation plugs pipes, decreases heat transfer coefficients, and changes the frictional resistance to flow in pipes. Hardness is also of concern to consumers due to the occurrence of scaling on fixtures and water-related appliances. With respect to hardness, waters are typically

classified as follows:

Soft	0 to <50 mg/L as CaCO <sub>3</sub>
Moderately hard	50 to <100 mg/L as CaCO <sub>3</sub>
Hard	100 to <150 mg/L as CaCO <sub>3</sub>
Very hard	>150 mg/L as CaCO <sub>3</sub>

Another range of values that may be encountered in the literature for the same classifications are 0 to <60, 60 to <120, 120 to <180, and >180 as CaCO<sub>3</sub>.

#### ALKALINITY

Alkalinity is a measure of the ability of a water to resist changes in pH. Alkalinity in water is due to the presence of weak acid systems that consume hydrogen ions produced by other reactions or produce hydrogen ions when they are needed by other reactions, allowing chemical or biological activities to take place within a water without changing the pH. The primary source of alkalinity is the carbonate system, although phosphates, silicates, borates, carboxylates, and other weak acid systems can also contribute. Alkalinity is determined by titrating with acid, and the results are expressed in concentrations of meq/L or as concentration of calcium carbonate (mg/L as CaCO<sub>3</sub>). When the individual species are expressed as molar concentrations, alkalinity is calculated as

$$\text{Alkalinity, eq/L} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{OH}^-] - [\text{H}^+] \quad (2-25)$$

where the coefficient on carbonate (CO<sub>3</sub><sup>2-</sup>) is necessary because carbonate is divalent (2 eq/mol) and the other species are monovalent (1 eq/mol). When the individual species are expressed in concentrations of meq/L, alkalinity is calculated as

$$\text{Alkalinity, meq/L} = (\text{HCO}_3^-) + (\text{CO}_3^{2-}) + (\text{OH}^-) - (\text{H}^+) \quad (2-26)$$

In practice, alkalinity is expressed in terms of mass concentration as calcium carbonate. To convert from meq/L to mg/L as CaCO<sub>3</sub>, it is helpful to remember that

$$\begin{aligned} \text{Millequivalent mass of CaCO}_3 &= \frac{100 \text{ mg/mmol}}{2 \text{ meq/mmol}} \\ &= 50 \text{ mg/meq} \end{aligned}$$

Thus 3 meq/L of alkalinity would be expressed as 150 mg/L as CaCO<sub>3</sub>:

$$\begin{aligned} \text{Alkalinity as CaCO}_3 &= (3.0 \text{ meq/L})(50 \text{ mg/meg CaCO}_3) \\ &= 150 \text{ mg/L as CaCO}_3 \end{aligned}$$

**TOTAL DISSOLVED SOLIDS**

Total dissolved solids (TDS) is a measure of the total ions in solution, analyzed by filtering out the suspended material, evaporating the filtrate, and weighing the remaining residue. Local TDS concentrations in arid regions or in waters subjected to pollution runoff can be high. For example, Colorado River water, after reaching southern California, has a TDS content in the range of 700 to 800 mg/L. The TDS of seawater is about 35,000 mg/L.

**CONDUCTIVITY**

A parameter related to TDS is electrical conductivity (EC) or specific conductance. Electrical conductivity is actually a measure [in microsiemens per centimeter ( $\mu\text{S}/\text{cm}$ ) or micromhos per centimeter ( $\mu\text{M}/\text{cm}$ )] of the ionic activity of a solution in terms of its capacity to transmit current. In dilute solutions, the two measures are reasonably comparable; that is,  $\text{TDS} = 0.5 \times \text{EC}$ . However, as the solution becomes more concentrated ( $\text{TDS} > 1000 \text{ mg/L}$ ,  $\text{EC} > 2000 \mu\text{S}/\text{cm}$ ), the proximity of the solution ions to each other depresses their activity and consequently their ability to transmit current, although the physical amount of dissolved solids is not affected. At high TDS values, the ratio of TDS to EC increases and the relationship tends toward  $\text{TDS} = 0.9 \text{ (slope of line)} \times \text{EC}$ . Thus, the slope for any one sample can fall between 0.5 and 0.9, but for several samples having the same TDS the slope will also vary; therefore, each water sample should be characterized separately.

## 2-5 Organic Chemical Constituents

---

A variety of organic compounds that can affect water quality are found in drinking water supplies. Several types of organic chemicals cause disagreeable tastes and odors in drinking water, and other types are known to be toxic. Many organic contaminants are known to be carcinogenic or are classified as cancer-suspect agents. Organic compounds in water are derived from natural and anthropogenic sources. Anthropogenic contaminants are generally present at extremely low concentrations and might not pose an immediate health hazard. However, a number of long-term research studies have been focused on the question "at what level do trace organic contaminants exert an impact on human health?" Based on the results to date it seems likely that the answers to this question will continue to be pursued.

Topics discussed in this section are (1) a brief review of organic compounds and their properties, (2) the potential sources of organic compounds and their introduction to drinking water and drinking water supplies, (3) the characteristics of the natural organic matter found in water, (4) organic compounds originating from human activity, (5) organic compounds formed during disinfection, (6) organic compounds added during

treatment, (7) surrogate measures for organic water quality indicators, and (8) the analysis of trace organics.

### Definition and Classification

The term *organics* refers to the general class of chemicals composed of carbon (C) and one or more of the following elements: hydrogen (H), nitrogen (N), and oxygen (O). The term organic dates to early studies of chemistry when substances were categorized as inorganic when they were obtained from mineral sources and as organic when they were derived from living organisms. Today, many organic compounds are derived from sources other than biological activity. A wide variety of materials are synthesized by the chemicals industry. The molecular structure of these synthesized compounds may also contain atoms of sulfur (S), phosphorus (P), and/or one or more of the halogens, that is, fluorine (F), chlorine (Cl), bromine (Br), and iodine (I), as well as a variety of other elements. Many naturally occurring compounds may also contain these atoms as well, but they are found to a lesser degree. There are many chemical species that are commonly considered to be inorganic in spite of having C, H, O, and N within their structure. Examples of such compounds include carbon monoxide (CO), carbon dioxide (CO<sub>2</sub>), carbonate (CO<sub>3</sub><sup>2-</sup>), bicarbonate (HCO<sub>3</sub><sup>-</sup>), and cyanide (CN<sup>-</sup>). The principal structural feature that distinguishes organic compounds from inorganic substances is the existence of strong carbon-carbon bonds.

#### CLASSIFICATION ACCORDING TO SIZE AND MOLECULAR WEIGHT

From an environmental standpoint, it is especially convenient to classify organic substances into groups according to their chemical or physical properties. Knowledge of these properties facilitates the selection of appropriate methods for the analysis and treatment of these materials in water. One important property of organic compounds is molecular weight. The molecular weight of organic compounds ranges from 16 g/mol for methane (CH<sub>4</sub>) to values approaching one million (10<sup>6</sup>) grams per mole for polymeric materials. The dimension of organic molecules varies from less than 1 nm for simple compounds such as chloroform (CHCl<sub>3</sub>) to approximately 0.1 μm for complex organic polymers. The relative size of some organic molecules as compared to microorganisms and other material commonly found in aquatic systems was illustrated previously on Fig. 2-5.

#### OTHER METHODS OF CLASSIFICATION

The polarity of an organic substance can also be used to define the degree to which one segment of a molecule is either positively or negatively charged with respect to another part of the molecular structure (McMurry and Fay, 2003). A frequently used measure of the polarity of a compound is given by the dipole moment. The dipole moment of organic substances can vary from a value of 0 D (debye) for molecules such as carbon

tetrachloride ( $\text{CCl}_4$ ), which have a highly symmetric spatial distribution of electron density about their bonding structures, to approximately 1.87 D for chloromethane ( $\text{CH}_3\text{Cl}$ ) (McMurry and Fay, 2003). The volatility of an organic substance is generally reflected by its boiling point or vapor pressure. At ambient atmospheric pressure (1 atm, 760 mm Hg), the boiling points of organic contaminants may vary from as low as  $-13.4^\circ\text{C}$  for highly volatile compounds such as vinyl chloride to temperatures in excess of  $400^\circ\text{C}$  for nonvolatile polycyclic aromatic hydrocarbons.

There are four major sources from which organics may be introduced to drinking water:

1. Natural organic material
2. Compounds originating from human activities
3. Compounds formed through chemical reactions that occur during disinfection
4. Compounds added or formed during the treatment and transmission of water

Each of these sources is considered in the following discussion.

*Natural organic matter* (NOM) is the term used to describe the complex matrix of organic chemicals originating from natural sources that are present in all water bodies. Natural organic matter originates from a water body due to biological activity, including secretions from the metabolic activity of algae, protozoa, microorganisms, and higher life-forms; decay of organic matter by bacteria; and excretions from fish or other aquatic organisms. The bodies and cellular material of aquatic plants and animals contribute to NOM. Natural organic matter can also be washed into a watercourse from land, originating from many of the same biological activities but undergoing different reactions due to the presence of soil and different organisms.

Historically, the significance of NOM in drinking water was related to its impact on aesthetic quality, as NOM imparts a yellowish tinge to water that many people find unpalatable. More recently, concern about NOM has focused on its ability to react with chlorine and form disinfection by-products, which are often carcinogenic. The presence of NOM affects many water quality parameters and processes. A summary of some important impacts of NOM is provided in Table 2-6.

In drinking water supplies, NOM is measured most commonly using total organic carbon (TOC) as a surrogate measure. Typical TOC concentrations for a variety of waters are reported on Fig. 2-12. The TOC concentrations of ground and surface waters often fall in the ranges of 0.1 to 2 and 1 to 20 mg/L, respectively. By contrast, the TOC levels of highly colored waters found in swamps can be in the range of 100 to 200 mg/L.

### Sources of Organic Compounds in Drinking Water

### Natural Organic Matter

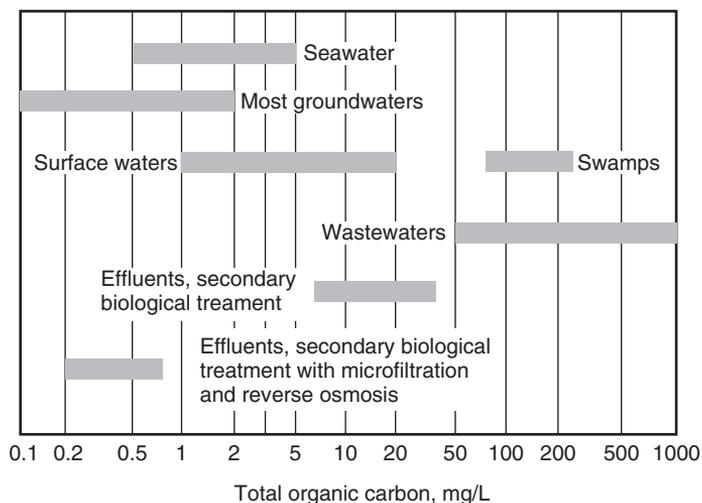

**Table 2-6**

Effect of NOM on water quality parameters and processes

Parameter	Effect of NOM
<i>Water Quality Parameters</i>	
Color	NOM can impart an unpalatable yellowish tinge to water at high concentrations.
Disinfection by-products	NOM reacts with chemical disinfectants, forming disinfection by-products. Many of these by-products have been demonstrated to be carcinogenic or have other adverse public health effects.
Metals/synthetic organics	NOM can complex with metals and hydrophobic organic chemicals (such as pesticides), making them more soluble. Once these chemicals are soluble, they can be transported more easily in the aquatic environment and are more difficult to remove during treatment.
<i>Water Treatment Processes</i>	
Disinfection	NOM reacts with and consumes disinfectants, so that the required dose to achieve effective disinfection is much higher than it would be in the absence of NOM.
Coagulation	NOM reacts with and consumes coagulants, so that the required dose to achieve effective turbidity removal is much higher than it would be in the absence of NOM.
Adsorption	NOM adsorbs to activated carbon, rapidly depleting the adsorption capacity of the carbon. Adsorption isotherms are much harder to predict in the presence of NOM.
Membranes	NOM adsorbs to membranes, clogging membrane pores and fouling surfaces, leading to a rapid decline in flux through the membrane.
Distribution	NOM can be biodegradable, leading to corrosion and slime growth in distribution systems (especially when oxidants are used during treatment).

**CHEMISTRY OF NOM**

Biological matter is composed primarily of four basic classes of organic compounds: carbohydrates, lipids, amino acids, and nucleic acids. Natural organic matter is composed of these chemicals and the products of biotic and abiotic chemical reactions between NOM molecules or between NOM and inorganic constituents of water. The wide array of biological activity in the environment leads to the production of thousands of different chemicals, so NOM is a complex mixture of different compounds with varying chemical properties, which may vary significantly from one water body to another as a result of local soil, climate, and hydrologic conditions. This complexity makes the characterization of the basic chemistry of NOM (such as functional groups or physical and chemical properties) difficult

**Figure 2-12**  
Ranges of TOC reported in a variety of waters. (Adapted from Rainwater and White, 1958.)

and causes NOM from different water bodies to have different effects when subjected to water treatment processes.

Natural organic matter is not volatile. It is fairly soluble and can be concentrated to greater than 1000 mg/L without precipitating. Most NOM molecules are negatively charged and many have multiple anionic functional groups, making them polyelectrolytic. The NOM molecules have a distribution of molecular weights, with about 90 percent of NOM between about 500 and 3000 Da. The elemental composition of NOM is about 45 to 60 percent carbon, 4 to 5 percent hydrogen, 35 to 40 percent oxygen, and 1 percent nitrogen (Thurman, 1985).

Based on their solubility in acid and alkali, aquatic humates are usually divided into two principal components: humic acid (HA), which is soluble in dilute alkaline solutions but is precipitated upon acidification, and fulvic acid (FA), which remains in solution at low pH. The structural features of HA and FA are similar, but the two fractions differ considerably in molecular weight and functional group composition. The molecular weight of fulvic acid varies from 200 to 1000 g/mol, whereas the molecular weight of HA ranges up to 200,000 g/mol. The FA fraction also possesses a higher content of oxygen-containing constituents per unit weight than humic acid. However, due to the arbitrary nature of this classification scheme, the term humic material is frequently used in reference to an aggregate of FA and HA.

#### MEASUREMENT AND CLASSIFICATION OF NOM

The complexity of NOM makes it impractical to routinely measure individual compounds. Instead, NOM is typically quantified using bulk parameters. The most common parameters in water treatment are TOC, dissolved

organic carbon (DOC), biodegradable dissolved organic carbon (BDOC), assimilable organic carbon (AOC),  $UV_{254}$  absorbance, and specific UV absorbance (SUVA). SUVA is calculated as

$$SUVA = \frac{UV_{254}}{DOC} \times 100 \quad (2-27)$$

where SUVA = specific UV absorbance, L/mg·m

$UV_{254}$  = UV absorbance at 254 nm,  $cm^{-1}$

DOC = dissolved organic carbon concentration, mg/L

Methods that have been used to quantify and characterize NOM are described in Table 2-7. For more detailed research, NOM can be characterized by separation into discrete fractions based on properties such as hydrophobicity, polarity, or molecular weight (Croue et al., 2000; Owen et al., 1993, 1995).

### Organic Compounds from Human Activities

Organic chemicals from industry, agriculture, and municipal effluents are routinely found in water supply sources and in trace amounts in many water supplies. Surface waters are especially vulnerable to these types of contaminants, but groundwater systems can also become contaminated. Contaminants that originate from a specific site are defined as *point source pollutants*, whereas substances that enter the aquatic environment over a broad area are referred to as *non-point source pollutants*. Groundwaters are most commonly subjected to point source contamination. By contrast, large-scale surface water basins may contain organic chemicals such as trichloroethene that cannot be traced to a single site.

#### USE OF SYNTHETIC ORGANIC COMPOUNDS

Industries that utilize large quantities of chemicals in manufacturing processes are major sources of organic pollutants. The vast majority of organic compounds used in industry are synthesized. Synthetic organic compounds (SOCs) comprise an extremely diverse group of compounds. A general classification according to polarity and volatility is illustrated on Fig. 2-13a. Typical compounds in each of the categories identified on Fig. 2-13a are presented on Fig. 2-13b. While generally found at very low concentrations in water, many SOC are of significant health concern. Among the sources of these compounds are the industrial and commercial facilities located in close proximity to major bodies of surface water. For example, the Mississippi and Ohio Rivers provide a plentiful supply of process and cooling water for a large fraction of the industries in the United States. Consequently, effluents from these activities can introduce a broad range of chemical contaminants to these river systems, depending on the nature of the materials being processed at each facility.

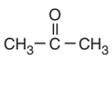

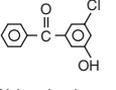

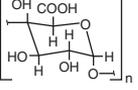

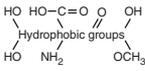

**Table 2-7**  
Methods for quantifying and characterizing NOM

Parameter	Description
<i>Aggregate Properties</i>	
Total organic carbon (TOC)	NOM is oxidized completely to CO <sub>2</sub> , which is stripped from the sample and measured in the gas phase. TOC is not equal to the NOM concentration but is a surrogate that gives an indication of the NOM concentration as long as the elemental composition does not change. The NOM concentration is typically 2 times the TOC concentration (based on the elemental composition).
Dissolved organic carbon (DOC)	The sample is analyzed identically to TOC after filtration through a 0.45- $\mu$ m filter. The DOC concentration is typically 80–90% of the TOC concentration.
Biodegradable dissolved organic carbon (BDOC)	Dissolved organic carbon that can be assimilated biologically. Final value depends on the specific test procedure employed. Important in assessing the potential for regrowth of microorganisms after disinfection in the distribution system.
Assimilable organic carbon (AOC)	The fraction of the BDOC that can be readily assimilated biologically as opposed to the total, which can be biodegraded over a longer period of time. In general, the methods used to determine the BDOC and AOC will yield different results.
UV <sub>254</sub> absorbance	The sample is filtered and the absorbance of UV light at a wavelength $\lambda$ of 254 nm is measured with a spectrophotometer. Like TOC and DOC, UV <sub>254</sub> absorbance is a surrogate for the NOM concentration. Specific molecular structures (chromophores) within NOM molecules absorb UV light, so the relationship between UV <sub>254</sub> absorbance and NOM concentration can vary between water bodies or seasonally because of differences in NOM composition. In addition, UV <sub>254</sub> absorbance may not be representative of NOM removal in a treatment process if the process removes molecules with chromophores differently than molecules without chromophores.
Specific UV absorbance (SUVA)	SUVA is calculated as the ratio of UV <sub>254</sub> absorbance to the DOC (TOC has also been used). SUVA has been correlated to the hydrophobic fraction of NOM and has been used as a guide for the treatability of NOM by some processes. For instance, water with a low SUVA value may not be amenable to enhanced coagulation.
<i>Specific Compound Classes and Individual Constituents</i>	
Molecular weight distribution	The molecular weight distribution of NOM can be determined by serial ultrafiltration or chromatographic methods. The most advanced method is high-performance size exclusion chromatography.
Hydrophobic and ionic fractions	NOM is separated into hydrophobic, hydrophilic, cationic, neutral, and anionic fractions by retention or passage through resin columns. The effect of these specific properties is then evaluated with respect to treatment processes.
Fluorescence	Fluorescence is strongly correlated with the molecular weight of NOM.

(continues)

**Table 2-7** (Continued)

Parameter	Description
Relative polarity	Compounds can be separated based on polarity by reverse-phase high-pressure liquid chromatography (RP-HPLC) or other chromatographic methods and compared to the polarity of a standard compound. Polarity affects the reactivity and fate of NOM in many environmental processes.
Compound class identification	Assays can be performed to measure the total protein or carbohydrate concentration in samples of water containing NOM.
Spectrometry	Spectrometric methods, such as nuclear magnetic resonance (NMR), Fourier transform infrared (FT-IR) spectrometry, solid-state cross-polarization magic-angle spinning (CPMAS), $^{13}\text{C}$ nuclear magnetic resonance spectrometry, electrospray ionization/mass spectrometry, and pyrolysis gas chromatography mass spectrometry (pyr-GC-MS) can be used to identify the primary functional groups or compound classes present in NOM.

		Volatility					Volatility				
		Volatile	Semivolatile	Nonvolatile			Volatile	Semivolatile	Nonvolatile		
Polarity	Polar	Alcohols Ketones Carboxylic acids	Alcohols Ketones Carboxylic acids Phenols	Polyelectrolytes Carbohydrates Fulvic acids	Polarity	Semipolar					
	Semipolar	Ethers Esters Aldehydes	Ethers Esters Aldehydes Epoxides Heterocyclics	Proteins Carbohydrates Humic acids			Polarity	Nonpolar	$\text{CH}_3\text{-CH}_2\text{-O-CH}_2\text{-CH}_3$		
	Nonpolar	Aliphatic hydrocarbons Aromatic hydrocarbons	Aliphatics Aromatics Alicyclics Arenes	Nonionic polymers Lignins Hymatomelanic acid					Polarity	Nonpolar

#### AGRICULTURAL PESTICIDES AND HERBICIDES

The quantity of agricultural pesticides used annually in the United States is extremely large. In California alone, over 4000 tonnes of chemicals is applied each year. The vast majority of these substances are organic chemicals. In general, pesticide treatments are distributed evenly over a large acreage. Modern agricultural practice has been directed toward the use of nonrefractory pesticides, such as organophosphates, that degrade rapidly in the environment following application. Use of nonrefractory pesticides has helped to minimize the risk of water contamination. Nevertheless, the use of such large quantities of agricultural chemicals requires that programs be developed to monitor water supplies subject to agricultural runoff.

#### MUNICIPAL WASTEWATER DISCHARGES

Municipal wastewater treatment plants are also a major point source of organic contamination. Even with effective secondary treatment, an ever-increasing number of organic compounds is being found in the effluent from treatment plants. The U.S. Geological Survey (USGS) has identified a number of compounds termed *emerging organic compounds* that are now being found in stream waters (USGS, 2000). Many of the emerging compounds are derived from veterinary and human antibiotics, human prescription and nonprescription drugs, and industrial and household wastewater products.

The processing of water for commercial applications and human consumption introduces a variety of organic compounds. More specifically, a variety of organic compounds can be formed through chemical transformations of NOM during water disinfection. For example, chlorine can efficiently convert humic substances (NOM) to trihalomethanes (THMs) and other organohalogen oxidation products under the reaction conditions encountered in water treatment systems. The formation and treatment of compounds formed during disinfection are considered in detail in Chaps. 13 and 19.

A variety of measures have been developed or adapted for the quantification of the array of synthetic and naturally occurring aquatic organic material. Two types of measures are in common use: (1) those measures that are used to quantify organic matter that is composed of an aggregate (nonspecific) of constituents with similar characteristics and (2) those measures that are used to quantify individual organic constituents (specific) from within the total organic compounds present. Aggregate measures are intended to quantify part or all of the organic content of a water. They include UV absorbance, TOC, total organic halogen (TOX), and trihalomethane formation potential (THMFP). The use of some of these measures for NOM was reported previously in Table 2-7.

**Organic  
Compounds

Disinfection**

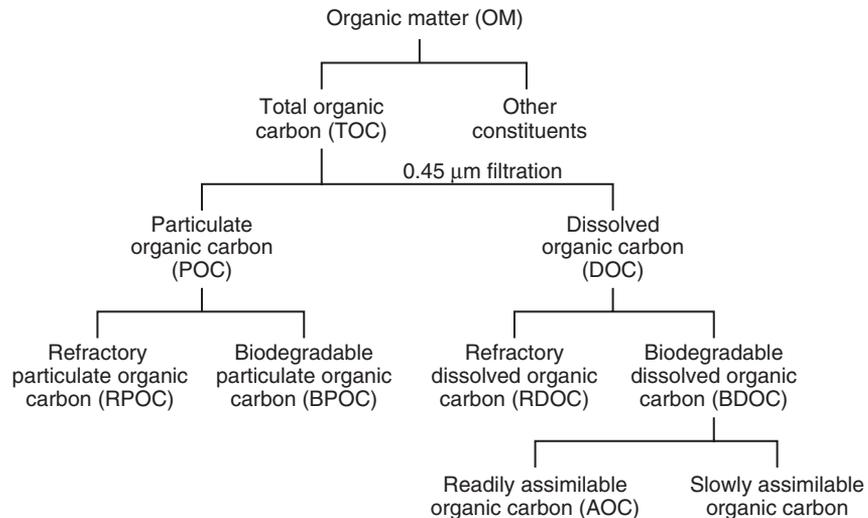

**Surrogate  
Measures  
for Aggregate  
Organic Water  
Quality Indicators**

**ULTRAVIOLET ABSORBANCE**

Organic substances absorb UV light, which is light that is beyond the visible spectrum at the violet end, generally defined as having a wavelength between 100 and 400 nm. Specific organic materials show definitive UV absorbance bands reflecting their particular unsaturation pattern and/or aromatic components. Such configurations desorb the short-wavelength/high-energy excitation of UV radiation, corresponding to excitation of electrons; increasingly shorter wavelengths are required to excite more stable molecules. Thus, simple aliphatic molecules will not tend to absorb UV light, whereas the complex multiaromatic, multiconjugated humic substances would be expected to absorb UV light very strongly. Ultraviolet absorbance at a wavelength  $\lambda$  of 254 nm is used as a surrogate measurement for the concentration of NOM, as described in Table 2-7. In some cases, UV absorbance at a wavelength  $\lambda$  of 285 nm has also been measured. In reporting the absorbance of a solution, the pH must be noted. The SUVA (see Table 2-7) is another measure that has been used to quantify the NOM in water.

**TOTAL ORGANIC CARBON AND DISSOLVED ORGANIC CARBON**

The TOC analysis is used to quantify the total amount of organic carbon contained in a sample by converting the dissolved organic compounds to a single chemical form while excluding inorganic carbon compounds from the analysis (see Fig. 2-14). Total organic carbon is a useful measurement because it provides an assessment of organic contamination and may be correlated to the amount of disinfection by-products (DBPs) that are produced during chlorination on a case-by-case basis. Dissolved organic carbon is the fraction of the TOC that passes through a 0.45- $\mu\text{m}$  filter, and

**Figure 2-14**

Classification of organic matter based on TOC method of analysis for total, particulate, and dissolved organic carbon. When different analytical methods of analysis are used, the term DOM is used in place of DOC. Refer to Table 2-7 for descriptions of these quantification methods.

the TOC of the material retained on the filter is defined as particulate TOC. As noted previously, the definition of DOC is operational, as a considerable amount of colloidal nondissolved material can pass through a 0.45- $\mu\text{m}$  filter.

#### **TOTAL ORGANIC HALOGEN**

Total organic halogen refers to the total mass concentration of organically bound halogen atoms ( $X = \text{Cl}, \text{Br}, \text{or I}$ ) present in water. From the standpoint of water quality, TOX is especially significant because it accounts not only for volatile halogen-containing compounds such as the THMs, trichloroethene, and tetrachloroethene but also includes the contribution of halogenated organic substances of high molecular weight that are also suspected health hazards. One commonly used method for TOX analysis involves the adsorption of organohalide solutes onto activated carbon (Dressman and Stevens, 1983). The particles of carbon are then washed to displace inorganic halides (predominantly  $\text{Cl}^-$ ). After treatment with nitrate, the carbon adsorbent is subjected to pyrohydrolysis, which converts the organically bound halogen to hydrogen halides (HX) and hypohalous acids (HOX). The aqueous effluent from the pyrohydrolysis step (pyrohydrozylate) can be analyzed for halide ion using a specific ion probe or by direct injection of the sample into a microcoulometric titration cell.

#### **TRIHALOMETHANE FORMATION POTENTIAL**

The THMFP is employed to assess the maximum tendency of the organic compounds in a given water supply to form THMs upon disinfection. Water supply sources with low THMFP values are considered to be superior when it becomes necessary to choose between alternative sources of water. The subject of THMFP is considered further in Chap. 19.

## 2-6 Taste and Odor

---

The human senses of taste and odor (smell) are stimulated by a myriad of chemical compounds, both inorganic and organic. Certain ones of these compounds are found occasionally in domestic water supplies and, more than any other factor, influence the palatability of the product. Many water treatment plants include facilities for the feeding of taste and odor control chemicals, adsorbents, or both. Additionally, some agencies employ preventative and control measures in raw-water reservoirs, lakes, and rivers. It is impossible to estimate accurately the annual expenditure, nationally, on taste and odor control measures. Recommended limits on odors are set by the U.S. EPA in the National Secondary Drinking Water Regulations. The purpose of this section is to (1) identify the sources of tastes and odors

in water supplies and (2) outline means to control their development or to remove them once they have appeared.

### **Sources of Tastes and Odors in Water Supplies**

Tastes and odors in water supplies can generally be attributed to two different causative elements: natural forces within the environment and the actions of human beings upon the aquatic environment. These sources of tastes and odors are not unrelated. For example, odors due to biological degradation of algae and their waste products may sometimes be traced to an upstream nutrient input of human origin. Sources directly responsible for taste and odor production in groundwater and surface water supplies are considered in the following discussions. The examination of these sources is essential when attempting to identify particular tastes or odors.

#### **TASTES AND ODORS IN SURFACE WATERS**

Taste and odor problems are proportionally more common in surface waters than in groundwaters largely because of the presence of algae. In addition, direct organic inputs such as autumnal leaf fall, stormwater runoff, and agricultural drainage provide ample nutrients for microorganisms that can often generate taste- and odor-producing compounds. Decaying vegetation from leaf fall and other sources may result in brown-colored, sweet-smelling water. These effects are due to suspended and dissolved glucosides, such as tannin, that originate in vegetative matter. Other suspended particulates, such as colloidal silts and clays, may render a water unpalatable if not removed in treatment.

#### **TASTES AND ODORS IN GROUNDWATER**

Most tastes and odors in groundwater supplies are natural in origin. For example, tastes and odors are caused by bacterial actions within the groundwater aquifers or the dissolution of salts and minerals as groundwater percolates and flows through geologic deposits. Intrusion of salt or mineral-bearing waters (such as seawater) may also result in taste or odor problems. Recently, tastes and odors in some groundwaters have been attributed to human sources, such as landfill leachate.

One of the most common odor problems in groundwater supplies is hydrogen sulfide ( $H_2S$ ). Hydrogen sulfide is frequently characterized as a rotten-egg odor, but at low concentrations it may also impart a swampy, musty odor. The odor threshold concentration of  $H_2S$  in water is less than 100 ng/L (0.0001 mg/L), and odors from waters containing 0.1 to 0.5 mg/L or greater are offensive (Lochrane, 1979; Pomeroy and Cruze, 1969). Sulfides in groundwater result from anaerobic bacterial action on organic sulfur, elemental sulfur, sulfates, and sulfites.

Reduced iron and manganese may also pose taste problems in groundwater. Although tastes due to dissolved iron or manganese are not particularly

noxious, they can render a water unpalatable and cause problems in pipelines, water services, and laundry facilities.

High salt content, as characterized by TDS or conductivity, can result in taste problems but does not usually result in objectionable odors. In general, consumers prefer waters with lower TDS content. The current widespread use of bottled mineral-bearing waters, however, may indicate that other psychophysical effects may affect taste preference.

Human-induced tastes and odors in groundwater occur as a result of chemical dumping, landfill disposal, mining and agricultural activities, or industrial waste disposal. A variety of synthetic organic chemicals have been identified in groundwater supplies. Examples include trichloroethylene (TCE), which has been found at objectionable concentrations in wells throughout the country.

Taste and odor prevention and control may be accomplished at the source, in the treatment plant, and to a certain extent in the distribution system. Ideally, the most satisfactory site for control in surface supplies is at the source. Source control generally involves controlling the growth of algae and related organisms. For groundwater supplies, source control must be accomplished through watershed management—a difficult task. For surface reservoirs, algaecides, destratification/aeration, and watershed management are used as control methods. Purveyors using continuous draft intakes with negligible raw-water storage or detention most often address taste and odor problems in-plant rather than at the source. Taste and odor can be treated by oxidation (Chap. 8) or adsorption (Chap. 15).

### **Prevention and Control of Tastes and Odors at the Source**

## 2-7 Gases in Water

---

Gases commonly found in water, as reported in Table 2-2, include nitrogen ( $N_2$ ), oxygen ( $O_2$ ), carbon dioxide ( $CO_2$ ), hydrogen sulfide ( $H_2S$ ), ammonia ( $NH_3$ ), and methane ( $CH_4$ ). The first three are common gases of the atmosphere and are found in all waters exposed to the atmosphere. The latter three are derived from the bacterial decomposition of the organic matter present in water. Although not found in untreated water, other gases with which the environmental engineer must be familiar include chlorine ( $Cl_2$ ) and ozone ( $O_3$ ), which are used for oxidation, disinfection, and odor control.

Gases in water can form bubbles, which may interfere with sedimentation processes, as the bubbles carry particles up through the water column and filtration, as gases accumulate and disrupt flow through the filter. Gas bubbles in water can also interfere with water quality measurements such as dissolved oxygen, ions measured with electrodes, and turbidity. The

quantity of a gas present in solution is governed by (1) solubility of the gas, (2) partial pressure of the gas in the atmosphere, (3) temperature, and (4) concentration of the impurities in the water (e.g., salinity, suspended solids). A discussion of the ideal gas law is presented below. The solubility of gases in water and Henry's law as applied to the gases of interest may be found in Chap. 14.

### Ideal Gas Law

The ideal gas law, derived from a consideration of Boyle's law (volume of a gas is inversely proportional to pressure at constant temperature) and Charles' law (volume of a gas is directly proportional to temperature at constant pressure) is

$$PV = nRT \quad (2-28)$$

where  $P$  = absolute pressure, atm

$V$  = volume occupied by gas, L,  $m^3$

$n$  = amount of gas, mol

$R$  = universal gas law constant,  $0.082056 \text{ atm}/(\text{mol/L}) \cdot \text{K}$

$T$  = temperature, K ( $273.15 + ^\circ\text{C}$ )

Using the universal gas law, it can be shown that the volume of gas occupied by 1 mole of a gas at standard temperature ( $0^\circ\text{C}$ ,  $32^\circ\text{F}$ ) and pressure (1.0 atm) is equal to 22.414 L:

$$\begin{aligned} V &= \frac{nRT}{P} \\ &= \frac{(1 \text{ mole}) [0.082056 \text{ atm}/(\text{mol/L}) \cdot \text{K}] [(273 + 0)\text{K}]}{1 \text{ atm}} = 22.414 \text{ L} \end{aligned}$$

The following relationship, based on the ideal gas law, is used to convert between gas concentrations expressed in  $\text{ppm}_v$  and  $\mu\text{g}/\text{m}^3$ :

$$\mu\text{g}/\text{m}^3 = \frac{(\text{concentration, ppm}_v)(\text{MW, g/mol of gas})(10^6 \mu\text{g/g})}{22.414 \times 10^{-3} \text{ m}^3/\text{mol of gas}} \quad (2-29)$$

The application of the Eq. 2-29 is illustrated in the following example.

### Naturally Occurring Gases

Gases that are commonly found in untreated water include nitrogen, oxygen, carbon dioxide, ammonia, hydrogen sulfide, and methane. Ammonia, hydrogen sulfide, and methane are typically formed during the anaerobic decomposition of organic matter (see Table 2-2). Dissolved nitrogen, oxygen, and carbon dioxide are generally present in natural waters from equilibration with the atmosphere; however, these gases also have biological origins, from processes such as atmospheric nitrogen fixation, photosynthesis, and respiration, respectively.

### Example 2-4 Conversion of gas concentration units

The gas released from a natural seep was found to contain 20 ppm<sub>v</sub> (by volume) of hydrogen sulfide (H<sub>2</sub>S). Determine the concentration in mg/m<sup>3</sup> and in mg/L at standard conditions (0°C, 101.325 kPa).

#### Solution

1. Compute the concentration in mg/L using Eq. 2-29.  
The molecular weight of H<sub>2</sub>S = 34.08 g/mol [2(1.01) + 32.06].

$$\begin{aligned} 20 \text{ ppm}_v &= \left( \frac{20 \text{ m}^3}{10^6 \text{ m}^3} \right) \left( \frac{34.08 \text{ g/mol H}_2\text{S}}{22.4 \times 10^{-3} \text{ m}^3/\text{mol of H}_2\text{S}} \right) \left( \frac{10^6 \mu\text{g}}{\text{g}} \right) \\ &= 30,429 \mu\text{g}/\text{m}^3 \end{aligned}$$

2. The concentration in mg/L is

$$\begin{aligned} 30,429 \mu\text{g}/\text{m}^3 &= \left( \frac{30,429 \mu\text{g}}{\text{m}^3} \right) \left( \frac{\text{mg}}{10^3 \mu\text{g}} \right) \left( \frac{\text{m}^3}{10^3 \text{ L}} \right) \\ &= 0.0304 \text{ mg/L} \end{aligned}$$

#### Comment

If gas measurements, expressed in mg/L, are made at other than standard conditions, the concentration must be corrected to standard conditions, using the ideal gas law, before converting to ppm.

## 2-8 Radionuclides in Water

Radionuclides are unstable atoms that are transformed through the process of radioactive decay. Radioactive decay results in the release of radioactive particles (radiation). Radionuclides are of interest because of the health effects resulting from exposure to radioactive particles and their occurrence in natural waters. A brief review of the fundamental properties of atoms, types of radiation, and units of expression is presented in this section.

An atom is composed of three basic subatomic constituents: protons (positive charge, located in the nucleus), neutrons (no charge, located in the nucleus), and electrons (negative charge, located in the outer shell or orbitals surrounding the nucleus). An element is defined by its atomic

### Fundamental Properties of Atoms

number, which is equal to the number of protons in its nucleus. Elements with the same number of protons and variable number of neutrons are known as isotopes. Radium, for example, has six isotopes,  $^{223}\text{Ra}$ ,  $^{224}\text{Ra}$ ,  $^{225}\text{Ra}$ ,  $^{226}\text{Ra}$ ,  $^{227}\text{Ra}$ , and  $^{228}\text{Ra}$ , all of which have an atomic number of 88 (88 protons) and atomic mass of 223 to 228 (88 protons, 135 to 141 neutrons). The isotope that decays is known as the parent, and the resulting element is known as the progeny or daughter. Radioactive decay is the spontaneous disintegration of an element, resulting in greater atomic stability through change of electron orbits or release of radioactive particles or radiation.

### Types of Radiation

The primary forms of radioactive decay are (1) alpha (particle) radiation, (2) beta (particle) radiation, and (3) gamma (ray) radiation. The release of alpha and beta particles transforms an isotope into a different element, while the release of gamma radiation reduces the energy of the element. Alpha, beta, and gamma radiations are known as ionizing radiation because of their ability to free electrons from their orbit in adjacent atoms.

Alpha particles are large, positively charged helium nuclei (two protons and two neutrons) released by certain isotopes during radioactive decay. Alpha particles are relatively slow and massive and are the least penetrating (may be stopped by the skin); however, when ingested, these particles can be very damaging to internal tissue and may cause cell mutation and possibly cancer. When an element emits an alpha particle, the element's atomic mass is reduced by 4 and its atomic number is reduced by 2. Beta particles are high-energy negatively charged particles released by certain elements during radioactive decay. Beta particles have smaller mass than alpha particles, which allows greater speed and penetration but creates less damage. The release of beta particles is characterized by the transformation of a neutron to a proton in the nucleus of an element and results in an increase of the atomic number. Gamma-ray emission, consisting of high-energy short-wave electromagnetic radiation (similar to x-rays) emitted from a nucleus, has tremendous penetrating power but has limited effect at low levels.

### Units of Expression

The units used to quantify radionuclides in water include expressions for activity, exposure/dose, and rate of decay. Activity refers to the amount of radiation being emitted from a radioactive agent. Exposure is a function of the activity, type of radiation, and pathway of human contact, while the dose is used to express the bodily uptake of radioactivity from a given exposure scenario. The life span of a radionuclide is estimated by its rate of decay, or half-life. Activity, adsorbed dose, and dose equivalent are described below.

#### ACTIVITY

Radionuclides have unique properties that require units other than milligrams or moles per liter. Because the emission of radioactivity is not dependent on the mass of the element, units that quantify the activity of

the element must be used. In the International System (SI) of units, the becquerel (Bq), equivalent to one disintegration or nuclear transformation (radioactive emission) per second, is the unit of radioactivity. In U.S. customary units, radiation is expressed in curies (Ci), 1 Ci is equivalent to  $3.7 \times 10^{10}$  disintegrations per second ( $37 \times 10^9$  Bq).

#### ADSORBED DOSE AND DOSE EQUIVALENT

Exposure to radionuclides through ingestion results in damage to internal organs as the element disintegrates. The amount of radiation that is imparted to the tissue is dependent on the number of particles emitted and is known as the absorbed dose. The SI unit for absorbed dose is the gray (Gy), where one gray equals one joule of radiation energy per kilogram of absorbing material. The corresponding U.S. customary unit is the radiation adsorbed dose (rad); 1 Gy is equal to 100 rad. Exposure to alpha, beta, and gamma radiation has different biological effects, so an exposure term known as the “dose equivalent” is used to quantify radiation that produces the same biological effect regardless of the type of radiation involved. The dose equivalent is determined by multiplying the adsorbed dose (in Gy or rad) by a quality factor. The quality factor is 1 for x-rays, gamma rays, and beta particles, and 20 for alpha particles. The units for dose equivalent is the sievert (Sv) in SI units and the Röntgen equivalent man (rem) in U.S. customary units ; 1 Sv is equivalent to 100 rem.

## Problems and Discussion Topics

---

- 2-1 Given the following test results, determine the mole fraction of calcium ( $\text{Ca}^{2+}$ ).

Cation	Concentration, mg/L	Anion	Concentration, mg/L
$\text{Ca}^{2+}$	40.0	$\text{HCO}_3^-$	91.5
$\text{Mg}^{2+}$	12.2	$\text{SO}_4^{2-}$	72
$\text{Na}^+$	15.1	$\text{Cl}^-$	22.9
$\text{K}^+$	5.1	$\text{NO}_3^-$	5.0

- 2-2 Determine the mole fraction of magnesium ( $\text{Mg}^{2+}$ ) for the water given in Problem 2-1.
- 2-3 Determine the mole fraction of sulfate ( $\text{SO}_4^{2-}$ ) for the water given in Problem 2-1.
- 2-4 Commercial-grade sulfuric acid is about 95 percent  $\text{H}_2\text{SO}_4$  by mass. If the specific gravity is 1.85, determine the molarity, mole fraction, and normality of the sulfuric acid.
- 2-5 If the UV intensity measured at the surface of a water sample is  $180 \text{ mW/cm}^2$ , estimate the average intensity in a Petri dish with an

average depth of 15 mm (used to study the inactivation of microorganisms after exposure to UV light, as discussed in Chap. 13). Assume the absorptivity of the water,  $k_A(\lambda)$  at  $\lambda = 254$  nm, is  $0.10 \text{ cm}^{-1}$  and that the following form of the Beer–Lambert law applies:

$$\ln\left(\frac{I}{I_0}\right) = -2.303k_A(\lambda)x$$

- 2-6 If the average UV intensity in a Petri dish containing water at a depth of 10 mm is  $120 \text{ mW/cm}^2$ , what is the UV intensity at the surface of the water sample? Assume the absorptivity of the water,  $k_A(\lambda)$  at  $\lambda = 254$  nm, is  $0.125 \text{ cm}^{-1}$  and that the equation given in Problem 2-5 applies.
- 2-7 If the transmittance is 92 percent and a photo cell with a 12-mm path length was used, what is the absorptivity?
- 2-8 Given the following data obtained on two water supply sources, determine the constants in Eq. 2-16 (power law density and slope coefficients) and estimate the number of particles in the size range between 2.1 and 5. Also, comment on the nature of the particle size distributions.

Bin Size, $\mu\text{m}$	Particle Count	
	Water A	Water B
5.1–10	2500	110
10.1–15	850	80
15.1–20	500	55
20.1–30	250	36
30.1–40	80	25
40.1–50	60	20
50.1–75	28	15
75.1–100	10	10

- 2-9 The following particle size data were obtained for the influent and effluent from a granular medium filter. Determine the constants in Eq. 2-16 (power law density and slope coefficients) and assess the effect of the filter in removing particles.

Bin Size, $\mu\text{m}$	Particle Count	
	Influent	Effluent
2.51–5	20000	101
5.1–10	8000	32
10.1–20	2000	6
20.1–40	800	3.2
40.1–80	400	1.2
80.1–160	85	0.34
160.1–320	40	0.12

- 2-10 Determine the alkalinity and hardness in milligrams per liter as  $\text{CaCO}_3$  for the water sample in Problem 2-1.
- 2-11 Given the following incomplete water analysis, determine the unknown values if the alkalinity and noncarbonate hardness are 50 and 150 mg/L as  $\text{CaCO}_3$ , respectively:

Ion	Concentration, mg/L
$\text{Ca}^{2+}$	42.0
$\text{Mg}^{2+}$	?
$\text{Na}^+$	?
$\text{K}^+$	29.5
$\text{HCO}_3^-$	?
$\text{SO}_4^{2-}$	144.0
$\text{Cl}^-$	35.5
$\text{NO}_3^-$	4.0

- 2-12 Given the following incomplete water analysis measured at  $25^\circ\text{C}$ , determine the unknown values if the alkalinity and noncarbonate hardness are 40 and 180 mg/L as  $\text{CaCO}_3$ :

Ion	Concentration, mg/L
$\text{Ca}^{2+}$	55.0
$\text{Mg}^{2+}$	?
$\text{Na}^+$	23.0
$\text{K}^+$	2.0
$\text{HCO}_3^-$	?
$\text{SO}_4^{2-}$	48.0
$\text{Cl}^-$	?
$\text{CO}_2$	4.0

- 2-13 Review the current literature and cite three articles in which the SUVA (specific UV absorbance) measurements were made. Prepare a summary table of the reported values. Can any conclusions be drawn from the data in the summary table you have prepared?
- 2-14 Review the current literature and prepare a brief synopsis of two articles in which the DOM (dissolved organic matter) was measured. What if any conclusions can be drawn from these articles about the utility of DOM measurements.
- 2-15 Determine the concentration in  $\mu\text{g}/\text{m}^3$  of 10  $\text{ppm}_v$  (by volume) of trichloroethylene (TCE) ( $\text{C}_2\text{HCl}_3$ ) at standard conditions ( $0^\circ\text{C}$  and 1 atm).
- 2-16 If the concentration of TCE at standard conditions ( $0^\circ\text{C}$  and 1 atm) is  $15 \mu\text{g}/\text{m}^3$ , what is the corresponding concentration in  $\text{ppm}_v$  (by volume)?

## Terminology for Microbiological Quality of Water

---

<b>Term</b>	<b>Definition</b>
Aerobic	Metabolic process carried out in the presence of free oxygen, where oxygen serves as the terminal electron acceptor.
Anaerobic	Metabolic process carried out in a reduced environment in the absence of free oxygen, where compounds such as $\text{SO}_4^{2-}$ and $\text{CO}_2$ serve as terminal electron acceptors.
Anoxic	Metabolic process carried out in a partially reduced environment in the absence of free oxygen, where compounds such as $\text{NO}_3^-$ , $\text{NO}_2^-$ , and Fe(III) serve as terminal electron acceptors.
Autotrophs	Organisms that produce complex organic compounds (such as carbohydrates, fats, and proteins) from simple inorganic molecules (e.g., $\text{CO}_2$ ) using energy from light (photosynthesis) or inorganic chemical reactions (chemosynthesis).
Cyst	Resting, nonmotile, encysted stage of amoeba or flagellate (e.g., <i>Entamoeba histolytica</i> , <i>Giardia lamblia</i> ).
Egg	Encysted form of helminths (e.g., <i>Ascaris</i> , Schistosomes).
Endemic	Condition where a disease is normally present in the population without external inputs.
Endospore	Dormant, highly resistant structure produced by some gram-positive bacteria (e.g., <i>Bacillus</i> , <i>Clostridium</i> ).
Enteric	In the gastrointestinal system (mouth, throat, stomach, duodenum, small intestine, large intestine, anus).
Epidemic	Condition where a disease is rapidly spreading in the population.
Facultative	Organisms that have metabolic processes that allow them to operate under aerobic, anoxic, and anaerobic conditions.
Fecal–oral route	Route of disease transmission from one person to another where a pathogen present in one person's feces is transmitted to another through the mouth (usually in food or water).

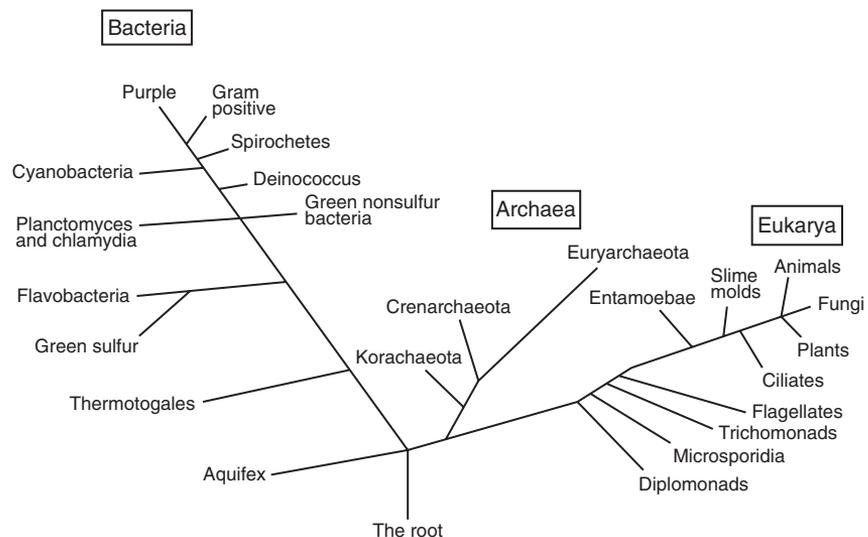

<b>Term</b>	<b>Definition</b>
Helminths	Parasitic worms.
Heterotrophs	Organisms that use organic chemicals as carbon source; can be aerobic, facultative, or anaerobic.
Metabolism	Biochemical cellular reactions involved in maintaining cell viability. Metabolism may occur under aerobic, anaerobic, anoxic, or facultative conditions.
Morbidity ratio	Fraction of infected persons who exhibit the symptoms of the disease.
Mortality ratio	Fraction of the persons who exhibit symptoms of the disease who ultimately die from it.
Oocyst	Encysted form resulting from fertilization during life cycle of sporozoa; indicates sexual reproduction (e.g., <i>Cryptosporidium</i> ).
Pandemic	Condition where an epidemic is expanding in several countries.
Parasite	Organism that draws its nutrients from another. A parasite cannot live independently.
Pathogens	Microorganisms capable of causing disease in humans, including bacteria, viruses, protozoa, helminths (worms), and algae.
Reproduction	Act of replication, either sexually or asexually. Some organisms reproduce by only one method, others can utilize either method. Microorganisms can reproduce sexually and asexually.
Virulence (pathogens)	Measure of the severity of the damage to the host.

The material on microbial quality presented in this chapter is designed as background material for subsequent chapters on treatment and disinfection. The specific objectives of this chapter are fourfold: (1) to provide an overview of the microbial world including the types of microorganisms and their characteristics, especially as they affect drinking water treatment, (2) an introduction to pathogens in drinking water and the routes of transmission of enteric disease, (3) a comprehensive discussion of bacteria, viruses, protozoa, helminthes (worms), and algae of concern in drinking water, and (4) a discussion of the issues related to bacterial monitoring of water supply sources. The following discussion presumes the reader, while trained in the sciences, does not specialize in microbiology. Additional information can be obtained from literature devoted to this subject.

### 3-1 Overview of the Microbial World

Since the middle of the nineteenth century, biologists have assumed that an evolutionary tree of life could be constructed. It was believed that the appearance and capabilities of organisms could be traced, in a linear way, up and down that evolutionary tree as organisms evolve from one to another. Until the introduction of genetic analytical techniques late in the twentieth century, the tree was constructed mostly on the basis of the morphology and behavior of organisms relative to other organisms. At the time, there were thought to be two fundamental branches to the tree, prokaryotic organisms and eukaryotic organisms, prokaryotes having only one outer cell membrane and eukaryotes being more formally structured.

In 1977, microbiologist Carl Woese constructed an evolutionary tree using genetic information and demonstrated a third domain, the archaea (Woese and Fox, 1977). The archaea are similar to bacteria, but their genetic makeup is different. Like bacteria, archaea lack a true nucleus, usually have one deoxyribonucleic acid (DNA) molecule suspended in the cell's cytoplasm contained within a cell membrane, and most also have a rigid outer cell wall. The name *archaea* is taken from the Greek word for "ancient" because these organisms do best under extreme environmental conditions, such as those when the earth was young, for example, the conditions found in hydrothermal vents. A modern phylogenetic tree of life is shown on Fig. 3-1. As shown on Fig. 3-1, the tree of life has three principal branches: bacteria, archaea, and eukarya. There are no known human pathogens among the archaea.

**Figure 3-1**  
Universal phylogenetic tree of life. (Adapted from Rittman and McCarty, 2001.)

The field of aquatic microbiology encompasses diverse organisms. Where drinking water is concerned, the groups of interest include bacteria, viruses, algae, protozoa, and helminths (worms). Each of these groups is discussed in this chapter. Some aspects of each group that are important in understanding aquatic microbiology are summarized in Table 3-1. These characteristics include size, surface charge, shape, oxygen requirements, carbon and energy requirements, motility, and the environmentally resistant stage for each.

Bacteria are single-celled organisms ranging in size from about 0.1 to 10  $\mu\text{m}$ . Even though their sizes range over two orders of magnitude, all bacteria have a relatively simple structure and composition. Bacteria have one key membrane structure—the membrane bounding the cell itself. The bacterial interior contains two major regions: the cytoplasm and the nuclear region, both relatively uniform in appearance. Cells of this simple type are termed prokaryotic. Cyanobacteria (also known as blue-green algae) are also prokaryotic. Other cells of algae, fungi, protozoa, plants, and animals are eukaryotic. Eukaryotic cells contain membrane-bound regions that are distinctive both morphologically and physiologically.

The simple appearance of the bacteria is deceiving; physiologically they are more diverse than any other biological group. Structural uniformity and physiological diversity make the classification of bacteria difficult. Typically, a bacterial genus is identified based on a combination of morphology and metabolic responses. For example, the genus *Escherichia* (including the species *Escherichia coli*) is described as unicellular, nonphotosynthetic, non-spore forming, straight, rod shaped, less than 2  $\mu\text{m}$  wide, gram negative, aerobic, heterotrophic, acid and gas producing from glucose and lactose within 48 h, methyl red positive, Voges–Proskauer negative, and catalase positive, with four species differentiated on the basis of pigmentation, utilization of citrate, and production of  $\text{H}_2\text{S}$ . As might be suspected, the classification of bacteria is constantly changing; for example, *E. coli* was previously assigned to the genus *Bacterium* as *Bacterium coli* and to the genus *Bacillus* as *Bacillus coli*. More recent classifications have been developed that are primarily based on the organism's genome. Genetic analysis is having a revolutionary impact on our understanding of the evolution of members of the microbial community.

The size, shape, motility, and surface charge of microorganisms can have important influences on their removal by water treatment processes. As discussed in Chaps. 9, 10, and 11, particles in the range of 1 to 10  $\mu\text{m}$  in diameter are more difficult to remove in conventional processes. Unfortunately, many important pathogens fall in this range, including most bacteria and the protozoan *Cryptosporidium parvum*. Size is a particularly important consideration in the treatment as well as in the detection of microorganisms. To put the microbiological world and some of its inhabitants in context, the relative sizes of a number of organisms are displayed on Fig. 3-2.

### Physical Characteristics of Microorganisms

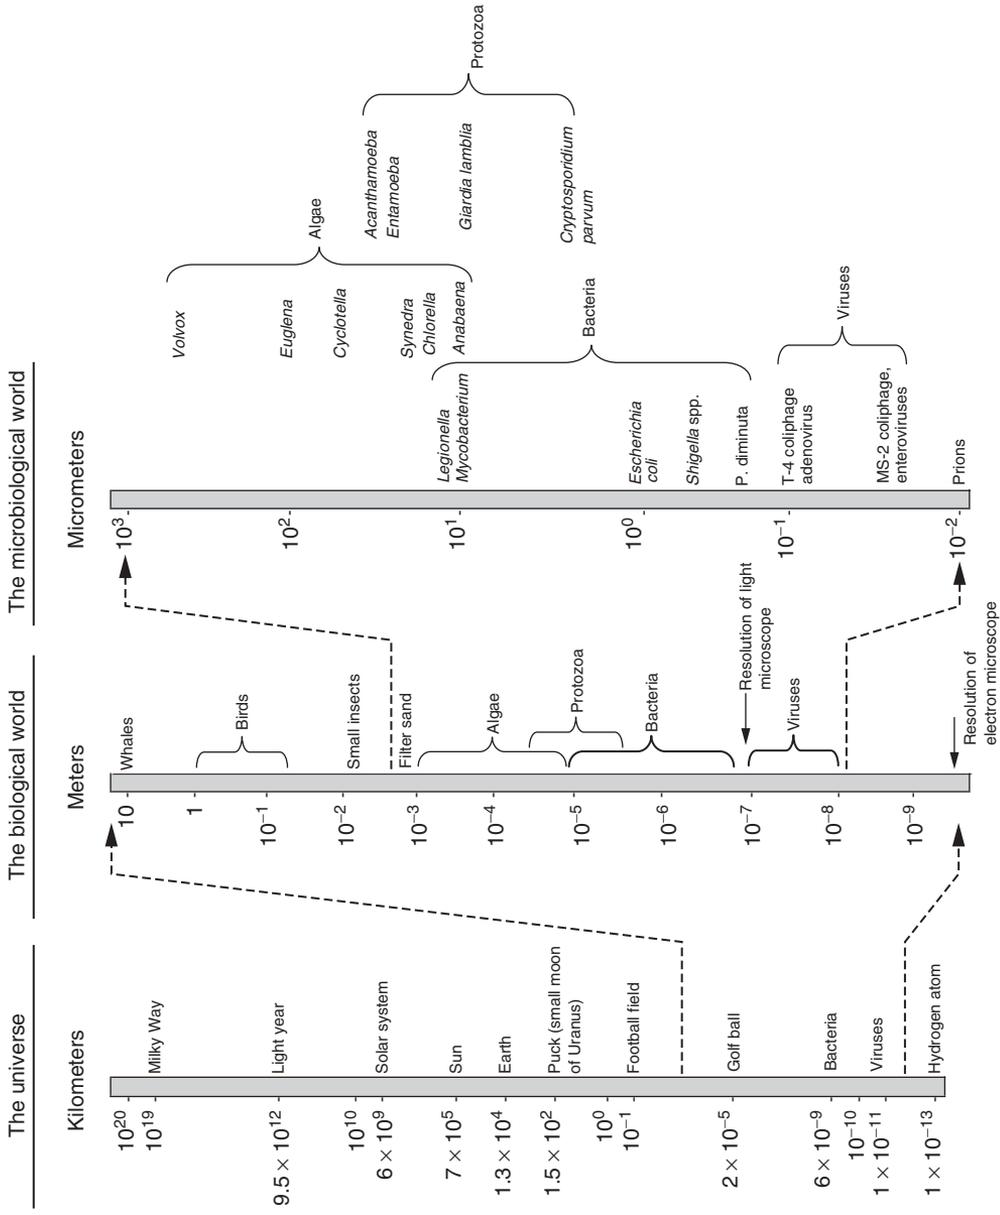

**Table 3-1**  
Important characteristics of classes of aquatic microorganisms<sup>a</sup>

Organism	Size, $\mu\text{m}$	Surface Charge	Shape	Oxygen Requirement	Carbon and Energy Requirement	Motility	Environmentally Resistant Stage
Viruses	$10^{-2} - 10^{-1}$	Negative	Variable, rod	NA	NA	None	Viron
Bacteria	$10^{-1} - 10$	Negative	Cocci, rod, spiral, comma	Aerobic, anaerobic, facultative	Chemoautotroph, <sup>b</sup> chemoheterotroph, <sup>c</sup> photoautotroph, photoheterotroph	Motile, nonmotile	Spores, cystlike
Blue-green algae	1	Negative	Cocci, filamentous	Aerobic	Photoautotroph	Gliding	Cysts
Green algae	$1 - 10^2$	Negative	Colloid pennatic	Aerobic	Photoautotroph	Motile, nonmotile	Spores, cysts
Protozoa	$1 - 10^2$	Negative	Variable	Aerobic, anaerobic	Chemoautotroph <sup>c</sup>	Motile, nonmotile	Cysts, oocysts
Fungi	$1 - 10^2$	Negative	Filamentous, coccoid	Aerobic, anaerobic	Chemoautotroph <sup>c</sup>	Nonmotile	Spores
Helminths	$1 - 10^5$	Negative	Variable	Aerobic	Chemoautotroph <sup>c</sup>	Motile	Eggs

<sup>a</sup>NA = not applicable.

<sup>b</sup>Typically obtain energy from inorganic compounds (also known as chemolithotrophic autotroph).

<sup>c</sup>Typically obtain energy from organic compounds (also known as chemoorganotrophic heterotroph).

**Figure 3-2** Relative sizes of universe, biological world, and microbiological world. On the left the biological world as a whole is compared with the rest of the universe, ranging from the hydrogen atom to the Milky Way. On the right the microbiological world is compared with the rest of the biological world.

The smallest inhabitants of the microbiological world are the prions, protein molecules of approximately 230 to 240 base pairs in length. *Volvox*, a species of algae formed by hundreds of cells, is among the largest members of the microbiological world.

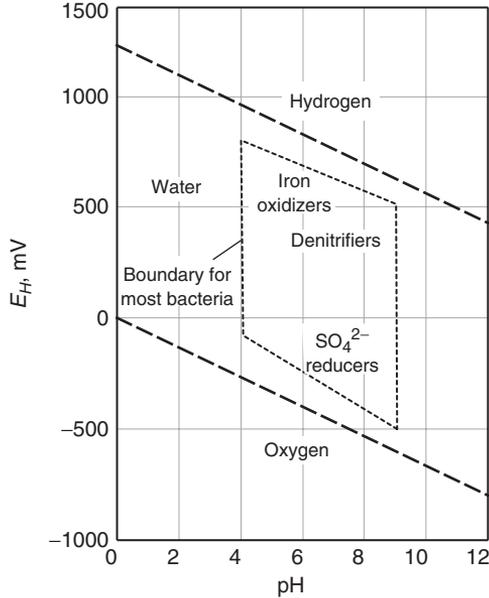

Many algae and helminths are visible to the unaided eye, while most bacteria can only be observed through a microscope. In 1683, Anton van Leeuwenhoek reported to the Royal Society of London on the observation of bacteria found in the plaque on his teeth using the microscope he had developed. However, serious work with bacteria and disease did not develop until Robert Koch had access to one of the innovative microscopes Carl Zeiss introduced into the market in 1883. Viruses are the smallest of waterborne agents, typically ranging in size from about 0.02 to 0.2  $\mu\text{m}$ . Viruses are too small to be seen with a light microscope but can be observed with an electron microscope.

Most, if not all, microbiological particles exhibit a negative surface charge over the range of pH of interest in water treatment, and so do most other aquatic particles and filter media. As a result, sedimentation and granular media filtration do not effectively remove pathogens unless a coagulant is used to address the forces of repulsion. Some organisms are motile, and experience has shown that these microorganisms are even more resistant to effective removal by granular media filtration. For these microorganisms, disinfection is first required to eliminate motility before coagulation and filtration can be effective.

### Oxidation– Reduction Potential ( $E_H$ ) and pH

The response of a microorganism to oxidation–reduction (redox) and pH conditions provides insight as to environments where the organism might be found. To survive under any conditions, a microorganism needs an electron acceptor and donor. When free hydrogen and oxygen are available, reducing the oxygen to water results in a transfer of electrons. As redox potential drops, other electron acceptors become important. Some of the more important conversions are the reduction of nitrate to nitrogen gas, manganese dioxide to Mn(II), ferric iron to ferrous iron, and sulfate to sulfide. Methane gas is generated under conditions of extremely low redox potential ( $E_H$ ). The stoichiometry of some of these reactions is given below:

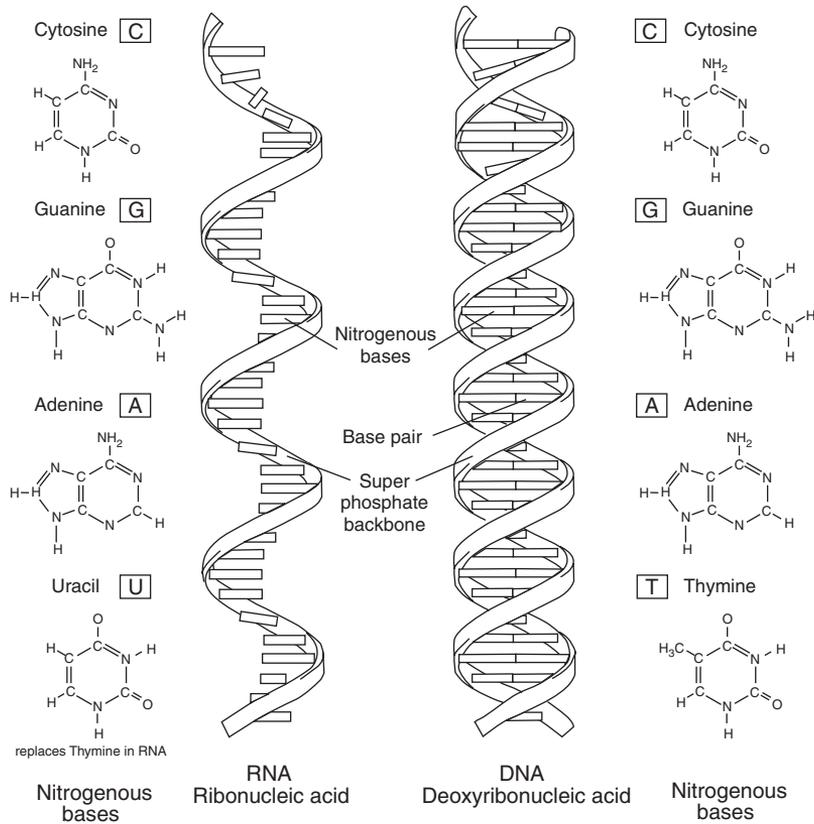

**Figure 3-3**  
Typical range for microorganisms as a function of  $E_H$  and pH.  
(Adapted from Rheinheimer, 1991.)

Most bacteria operate in an  $E_H$  range where the transformations they are designed for are easily accomplished. Thus iron bacteria prefer a low pH but high  $E_H$ . Sulfate reducers (e.g., *Desulfovibrio*) prefer a higher pH and a very low  $E_H$ . Denitrifiers operate well at a neutral pH and under mildly anoxic conditions. The availability of these electron acceptors to microorganisms is influenced not only by the redox potential but also by the pH. The regions of optimal redox conditions for many microorganisms on an  $E_H$ -pH plane are shown on Fig. 3-3. Most bacteria can operate in a pH range of 4 to 9 and function best in the range of pH 6.5 to 8.5, while some can tolerate pH values outside these boundaries. Thiobacilli can tolerate pH below 1.0 and function best between pH of 2 and 3.

During the past decade, significant advancements in the understanding of the chemistry of life have occurred. This revolution in understanding has its roots in the discovery of DNA, ribonucleic acid (RNA), and the role these chemicals play in the structure and growth of all living organisms.

Deoxyribonucleic acid is a double-stranded sugar-phosphate backbone with lattices made up of pairs of four nucleic acids. The sugar in the backbone is deoxyribose and the four nucleic acids are adenine, guanine, cytosine, and thymine. Ribonucleic acid is a single-stranded sugar-phosphate backbone whose lattices are also made up of pairs of four nucleic acids. The sugar in the backbone of RNA is ribose and three of the nucleic acids are the same as those in DNA, with uracil substituted for thymine. The DNA and RNA structures are shown, along with their key

## Biomolecular Revolution

**Figure 3-4**  
Basic structure of DNA  
and RNA and corresponding  
nitrogenous bases.

components on Fig. 3-4. The DNA serves as the library of life, the database of genetic information for the cell. The role of RNA is to govern metabolic processes.

The fact that DNA played an essential role in life's genetic structure was known from the early 1940s. It was Linus Pauling who proposed that DNA had a helical structure in 1948, but it was Watson and Crick with help from Wrinkle and Franklin who developed the correct details of the DNA structure in 1953.

During recent years, the technology required to support the determination of the genetic fingerprint of a given organism has undergone dramatic improvements, and the entire genomes of numerous organisms are rapidly appearing in the public domain. The availability of this information is already beginning to have fundamental impacts on the understanding of the relationship between organisms and their behavior. For example, in addition to the slow, vertical evolutionary changes up the tree of life that were introduced earlier, microorganisms (including pathogens) also have

considerable capacity for conducting more rapid horizontal exchanges in genetic material to facilitate useful evolutionary patterns.

Bacteria reproduce by binary fission, and in this process the chromosome in the original cell is duplicated in an identical daughter cell. For evolutionary changes to occur, changes to the chromosome in individual bacteria must take place, and these changes must then be passed on to future generations by the binary fission just described. The principal events and means that result in inheritable changes in the genome are (a) through the lysing and release of DNA from one organism, which when taken up by another organism can result in genetic transfer and recombination, (b) the direct transfer of genetic material through the exchange of plasmids from one organism to another, and (c) by mobile segments of DNA (often identified as *transposons*) that can move around to different positions in the genome of a single cell and thereby cause mutations.

Genetic transfer has been shown to occur when one cell dies and breaks up and another cell takes on a portion of its DNA. Such genetic transfer can also occur through the action of phage. Plasmids are small, circular, self-replicating units of genetic material that normally exist in the bacterial cell, but outside the chromosome itself. Some cells possess the ability to transfer their plasmids to other cells, transmitting genetic material in the process. Transposons are genetic elements that can move within the organism, from one plasmid to another and from plasmids to chromosomes.

All of these mechanisms of gene transfer have been demonstrated, but plasmid exchange is probably the best understood at the moment. Plasmids have been shown to transmit drug resistance (e.g., ampicillin, tetracycline, kanamycin, and chloramphenicol), resistance to UV light, resistance to metals (e.g., mercury, cobalt, magnesium, copper, and silver), resistance to bacteriocin (proteinaceous toxins given off by bacteria to inhibit the growth of similar bacterial strains), toxin production (both exotoxins and enterotoxins), the ability to metabolize specific sugars and hydrocarbons, and the ability to create tumors. The exchange of plasmids among bacteria is analogous to sexual processes. Some bacteria possess appendages called pilli, and through these pilli they are able to transmit plasmids to bacteria that do not have them.

### **Facilitation of Rapid Evolution among Bacterial Pathogens**

## 3-2 Pathogens in Drinking Water

---

From the beginning, the practice of drinking water treatment has been rooted in the need for removal of pathogens. This goal remains among the highest priorities today. Paul Ewald, a notable evolutionary microbiologist, recently said, “No other single intervention in the history of medicine has saved as many lives and reduced as much suffering as the provisioning of uncontaminated water” (Ewald, 1994; Ewald et al., 1998).

**Discovery  
of Waterborne  
Disease**

It is well documented that waterborne contamination can cause disease of epidemic proportions. However, there was a time when it was a common belief that diseases such as cholera and typhoid fever were primarily transmitted by other means, such as breathing miasma, vapors emanating from the decaying victim and transported through the open air during the night.

Studying the cause of London epidemics of Asiatic cholera in 1849 and 1853, Dr. John Snow demonstrated that the second epidemic, which killed nearly 500 people in a span of 10 days (victims often died within 36 h of exposure), was associated with contamination of the water at the Broad Street Well by water from a nearby cesspool. Snow was unable to identify the specific agent in the water, but he suspected that it was microbiological in character and that it somehow replicated itself in great numbers, exiting the victim's gastrointestinal tract (Snow, 1855). In that same year, Falipo Pacini identified the organism that caused cholera (Pacini, 1854; Bentivoglio and Pacini, 1995), but his discovery went largely unknown. A short time later, William Budd (1856) demonstrated that typhoid fever could be transmitted by the same means. In 1864 a Frenchman, Dr. Louis Pasteur, articulated the germ theory of disease. In 1880, Karl Eberth (1883) isolated the organism that caused typhoid fever (*Salmonella typhi*), and in 1883, Robert Koch, one of the most important figures in the history of public health microbiology, while working in Egypt and then in India, identified the comma-shaped bacillus responsible for Asiatic cholera (*Vibrio cholerae*) (Howard-Jones, 1984). It soon became clear that a number of important epidemic diseases were often waterborne—cholera, typhoid fever, and amoebic dysentery, among them.

In the nineteenth century, the term *cholera* was used to describe many warm-weather intestinal diseases associated with pain, vomiting, diarrhea, fever, and prostration. The term *Asiatic cholera* was used to distinguish a variety of cholera, usually fatal, that had remained endemic to Asia until around 1817 when the first of several *pandemics* resulted in its spread around the world. Because the disease was thought to originate in Asia and because it was so potent, it was called Asiatic cholera.

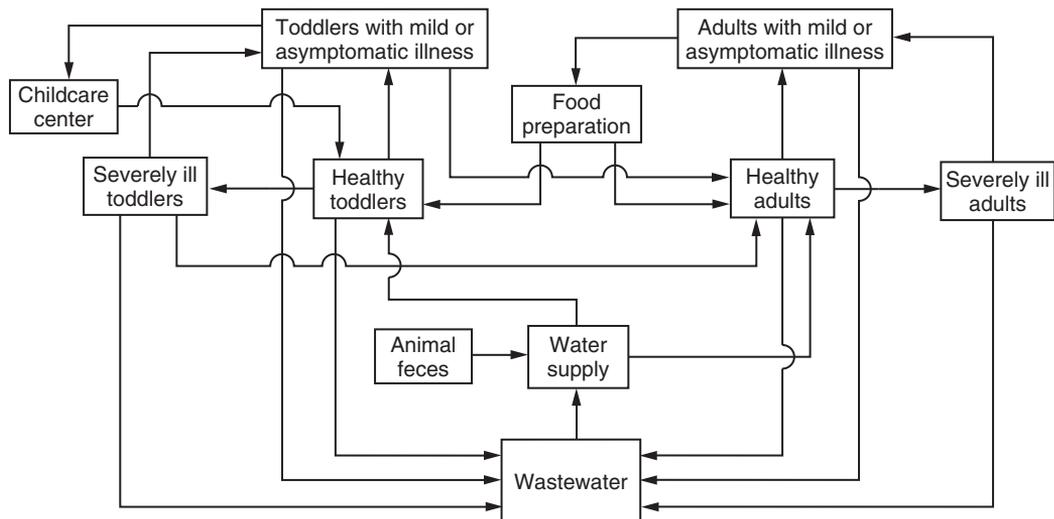

**Role of Water  
in Transmitting  
Disease**

Perhaps the most unique aspect of water as a vehicle for the transmission of disease is that a contaminated water supply can rapidly expose a large number of people. When food is contaminated with a pathogen, tens to hundreds of persons are commonly infected. If a large, centralized food-packaging facility is involved, thousands might be infected. However, when drinking water is contaminated with a pathogen, hundreds of persons are typically infected, and occasionally the number of persons infected can rise to the hundreds of thousands. For example, in the 1993 Milwaukee *Cryptosporidium* incident, it is estimated that 500,000 people became ill from contaminated drinking water (MacKenzie et al., 1994).

Another important consideration is that waterborne transmission can have an impact on the virulence of the pathogens themselves. *Virulence* is

a term used to describe the severity of the damage to the host (Casadevall and Pirofski, 1999). A pathogen that is more virulent causes more damage. Under normal conditions, pathogens are limited in the virulence they can exhibit because they depend on the mobility of their host for transmission.

The principal mechanisms for the transmission of enteric (intestinal) diseases are shown on Fig. 3-5. Suppose that, while it is infecting an adult, a pathogen evolves to a form that causes a severe, debilitating form of an enteric disease that immobilizes and seriously injures the infected person. The route of transmission can be analyzed using Fig. 3-5. If an adult with severe illness is too debilitated to prepare food, the organism cannot get into the food supply. However, the organism does get in the sewer, even if the sick person cannot get out of bed. Once in the sewer, the organism is then transported to the wastewater treatment plant. If the organism is not removed or inactivated at the wastewater treatment plant, it enters the receiving watercourse. If that watercourse serves as a water supply, then the organism has entered a water supply. If water treatment does not remove or inactivate the organism, both healthy toddlers and adults who drink the water are exposed and may get infected. A smaller number of individuals may also be exposed via contact with the infected persons. Thus, the entire population drinking the water supply is potentially exposed to the disease-causing agent. Under these conditions, an organism can successfully reproduce even if it causes a severe disease from which the host rarely recovers. According to some historical accounts, the classic form of Asiatic cholera that appeared in the middle of the nineteenth century behaved in this way.

**Figure 3-5**  
Schematic of routes of transmission for enteric disease.

The route of transmission can be interrupted by removing or inactivating the organism from the water in two places:

1. at the drinking water treatment plant
2. at the wastewater treatment plant

Organisms that evolve to cause mild disease or asymptomatic infections have different characteristics, as shown on Fig. 3-5. Examining the water route, again, as the disease is enteric, the organism will get into the wastewater. If it is not removed from the wastewater, it will also be in the water supply. And if it is not removed in water treatment either, it will also be in the drinking water—exposing both toddlers and adults. Some of these will then become mild or asymptomatic carriers. The infected toddlers will spread the disease at their childcare centers and directly to their adult caregivers if the caregivers do not exercise sufficient care. Either water treatment or wastewater treatment can intervene and stop the spread via this route.

Figure 3-5 can also be used to consider the spread of the asymptomatic disease via the food route. Adults with the disease, if they do not use adequate hygiene, may contaminate food when they prepare it. Both toddlers and adults who eat the contaminated food may then get infected. Some of those who get infected will be asymptomatic; others may exhibit mild symptoms. Infected adults may again prepare and contaminate food, and some infected toddlers will go to childcare centers. Toddlers in childcare centers will expose other toddlers who attend there. Again adult caregivers, who do not exercise sufficient hygiene, will also expose themselves while handling the sick toddlers. The drinking water has no connection to this route of communication, so treating the drinking water will not stop it. Training and regulating people working in food handling can largely eliminate transmission of the disease from an adult to others, but it seems likely that transmission among toddlers in childcare centers will be difficult to eliminate. The impact of a water treatment intervention is much greater where severe, debilitating disease is concerned.

It is not possible to eliminate diseases that are transmitted by the fecal-to-oral route. Such diseases will continue to be spread through the contamination of food, activities at daycare centers, and other endeavors of asymptomatic carriers. Eliminating the transport of pathogens through the drinking water route will result in the elimination of large-scale waterborne outbreaks. It will also make it much more difficult for organisms to survive if they produce symptoms that damage the host to the point where the host is forced to stay at home soon after contracting the disease.

An opportunistic pathogen is a microorganism that is not ordinarily able to overcome the natural defenses of a healthy human host. Under certain circumstances, however, such organisms are able to cause infection resulting in serious damage to the host. There are two circumstances when opportunistic pathogens are more successful: (a) when the immune

response of the host has been compromised [e.g., persons with human immunodeficiency virus (HIV), persons on drugs that suppress the immune system, the very elderly] or (b) when the host is exposed to such high levels of the organism in question that the infection becomes overwhelming before the body can develop a suitable immune response.

Water treatment and good sanitation practices are also necessary for successful application of antibiotic and vaccine therapies for gastrointestinal (GI) diseases. In developing countries with poor sanitation and inadequate water treatment, pathogens have wide and easy access to their human hosts. Under these circumstances, pathogenic bacteria can more successfully evolve to gain antibiotic resistance, and some pathogenic viruses have even evolved the capability to evade vaccine therapies.

It is widely known that some of humankind's worst scourges have been caused by waterborne disease. Until the last few decades of the twentieth century, water treatment technology focused on controlling diseases that were spread from one person to another by the fecal–oral route via drinking water. Diseases of this kind continue to occur throughout the world, and inadequate water treatment almost always plays a role. In parts of the world where the infrastructure for water and sewage is poorly developed, classic examples of these diseases (e.g., cholera and typhoid) still cause devastating epidemics. Even in more developed parts of the world, milder forms of gastroenteritis can become widespread when this infrastructure fails even for a short time. Clearly, preventing the spread of waterborne disease must remain the highest priority in water treatment.

New diseases have also come to the attention of the water treatment community that are not spread from one person to another via the drinking water. Most important among these are zoonotic diseases, which humans can contract from other animals. Also important are diseases caused by opportunistic pathogens, most of which are not associated with fecal contamination but instead live in various aquatic environments. While many of these diseases have come to our attention through the efforts of the medical profession to address the needs of individuals with suppressed immune systems, it has now become clear that some are important diseases for healthy individuals as well.

The most prominent zoonotic diseases of interest in water treatment at the present time are giardiasis and cryptosporidiosis. Both of these diseases are transmitted by the traditional fecal–oral route between humans but also from animals to humans. Zoonotic microorganisms of the gastrointestinal tract, such as *Salmonella* spp., infect animals as well as humans and cause a variety of human diseases and are responsible for the origins of new strains of pathogens, such as the flu (influenza viruses). It has been argued that most epidemic diseases of humans may originate from living in close community with animals (Diamond, 1999).

### **Pathogens of Importance to Water Treatment**

## Pathogenicity

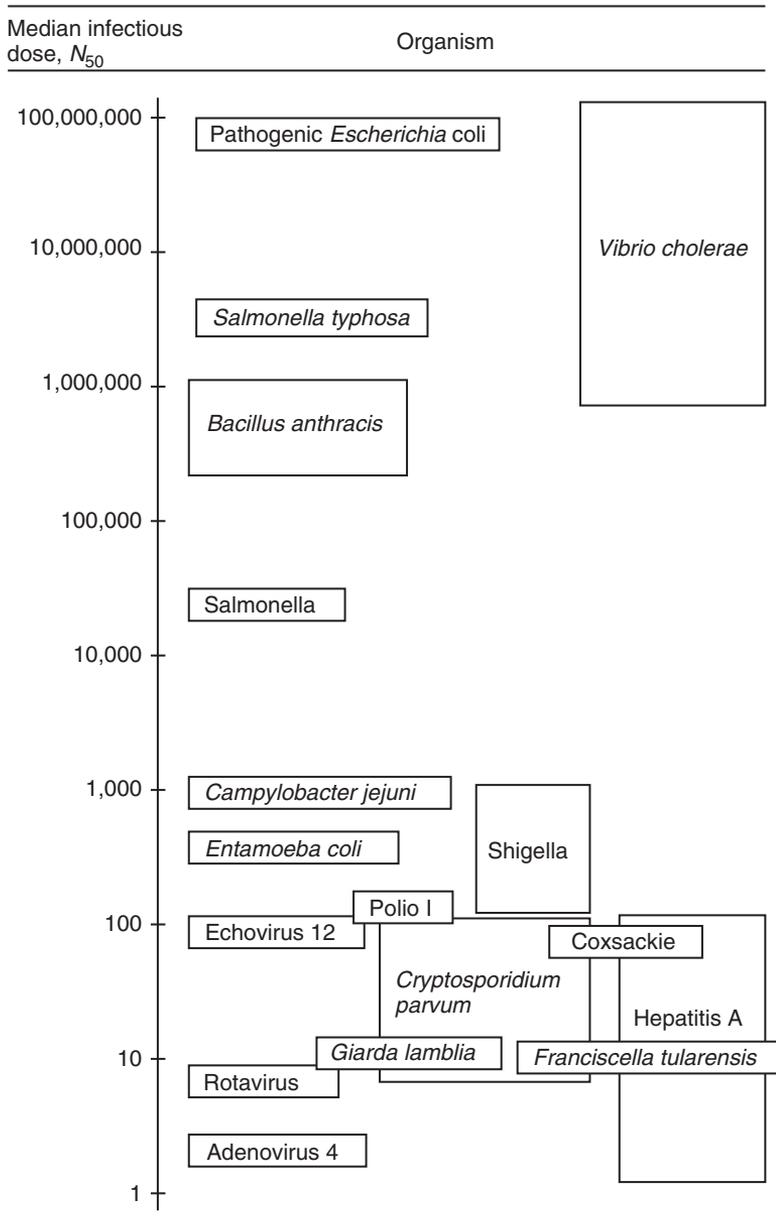

The microorganisms that are of most concern are the pathogens. The scientific community has not always used consistent terminology when discussing the concept of pathogenicity, partly because the behavior of microorganisms is extremely complex. One microorganism may colonize humans without causing disease or even have beneficial effects (commensalism). Another microorganism may colonize some humans without seeming to cause disease (asymptomatic infection) and yet colonize other humans and result in disease symptoms (symptomatic infection or infection resulting in disease). Casadevall and Pirofski (1999) discussed pathogenicity in depth, arguing that the unique property of pathogens is that they *damage* the host organism (i.e., cause disease).

The number of organisms that a human must be exposed to before infection varies a great deal from one pathogen to the next and also from one human to the next. The public health community uses the median infectious dose,  $N_{50}$ , as a measure of the “typical” dose required for infection in human beings. The methods for conducting such dose–response assessments are beyond the scope of this discussion but may be found in Haas et al. (1999). The wide variation in median dose from one pathogen to the next to bring about a response is illustrated on Fig. 3-6. On a mass basis, the pathogenic dose can be extremely low, as demonstrated in Example 3-1.

### INFECTION OUTCOMES

Pathogenicity is a complex phenomenon. Infection by a pathogen does not automatically translate to damage to the host. Infection means that the pathogen is successfully reproducing in the host. Depending on the pathogen and the individual host involved, such an infection can result in a variety of outcomes, including (1) asymptomatic infection (no symptoms or very mild symptoms—no damage to the host), (2) mild illness (mild symptoms—no permanent damage to the host), (3) acute illness (severe symptoms—often some permanent damage to host), or (4) death. The possible infection outcomes in a conceptual framework are summarized on Fig. 3-7a. Often the fraction of infections that result in asymptomatic infection is not well known because asymptomatic individuals do not seek medical care and special studies are required to determine if an individual not showing symptoms is infected. An organism, which often causes asymptomatic infection, is likely to have many routes of transmission beyond drinking water.

Hepatitis A virus is better understood than many other pathogens. The approximate likelihood of various outcomes with this pathogen is illustrated on Fig. 3-7b. Three out of four adults infected with the hepatitis A virus are asymptomatic. Persons who contract the disease experience the sudden onset of a flulike illness. After a few days of muscle aches, headache, anorexia, abdominal discomfort, fevers, and malaise, jaundice may set in. Full recovery usually takes 2 months, but 10 to 15 percent of the people

**Figure 3-6**  
Median dose of organisms required in drinking water to cause infection.

who contract the disease have a prolonged, relapsing course lasting up to 6 months (serious illness). Infection by the hepatitis A virus is fatal for about 0.075 to 0.15 percent of the persons who contract the disease, as demonstrated in Example 3-2.

### Example 3-1 Using Infectious Dose to Assess Mass-Based Toxicity of Pathogens

Estimate the mass dose in micrograms that will result in infection in 50 percent of the persons exposed for (a) pathogenic *E. coli* and (b) the pathogenic virus hepatitis A by using the  $N_{50}$  values from Fig. 3-6. In the case of hepatitis A, use the lower range of infectious doses reported. Assume that both organisms have a specific gravity of 1.1. The diameter of *E. coli* is approximately 1  $\mu\text{m}$ , and the diameter of hepatitis A is 25 nm. Assume both organisms are spherical in shape. Use 998  $\text{kg}/\text{m}^3$  for the density of water.

#### Solution: Part A—Pathogenic *E. coli*

1. Estimate the number of organisms. From Fig. 3-6,  $N_{50}$  is approximately  $10^{7.9}$  organisms.
2. Determine the dose on a mass basis: Assuming each organism is a sphere 1  $\mu\text{m}$  in diameter with a specific gravity of 1.1, the mass corresponding to the  $N_{50}$  is

$$\begin{aligned}\text{Mass dose} &= 10^{7.9} \left[ \frac{4}{3} \pi \left( \frac{1.0 \times 10^{-6} \text{ m}}{2} \right)^3 \right] (1.1)(998 \text{ kg}/\text{m}^3) (10^9 \mu\text{g}/\text{kg}) \\ &= 46 \mu\text{g}\end{aligned}$$

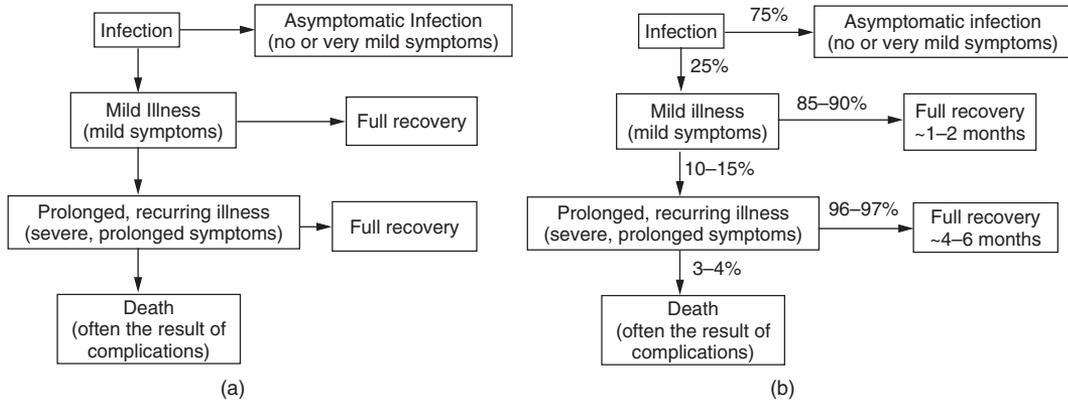

#### Solution: Part B—Pathogenic Virus Hepatitis A

1. Estimate the number of organisms. From Fig. 3-6, the lower range of  $N_{50}$  is approximately two organisms.
2. Determine the dose on a mass basis. Assuming each organism is a sphere 25 nm in diameter with a specific gravity of 1.1, the mass corresponding to the  $N_{50}$  is

$$\begin{aligned}\text{Massdose} &= 2 \left[ \frac{4}{3} \pi \left( \frac{0.025 \times 10^{-6} \text{ m}}{2} \right)^3 \right] (1.1)(998 \text{ kg}/\text{m}^3) (10^9 \mu\text{g}/\text{kg}) \\ &= 1.8 \times 10^{-11} \mu\text{g}\end{aligned}$$

#### Comment

These are truly low mass doses, especially when a single exposure to this level of organisms will cause infection in 50 percent of the persons exposed.

**Figure 3-7**

Alternative outcomes from pathogenic infection: (a) generalized representation and (b) approximate quantification of outcomes for pathogen hepatitis A.

### Example 3-2 Consequences of a hepatitis A epidemic

Due to a one-time contamination incident, hepatitis A enters into a water supply serving 10,000 persons at a concentration high enough to result in infections in 50 percent of the population. Estimate the number of persons for whom the infection is asymptomatic (no symptoms), the number who become mildly ill, the number who develop a prolonged illness, the number who recover from the prolonged illness, and the number who do not survive. Use the data presented on Fig. 3-7b to make the estimate. Use the upper bound for the ranges reported on Fig. 3-7b to estimate illness. Finally, what was the risk of dying from the disease to members of the community exposed?

#### Solution

1. Number of individuals who get infected:

$$10,000 \times 50\% = 5000$$

2. Number of individuals who are asymptomatic:

$$5000 \times 75\% = 3750$$

3. Number of individuals mildly ill:

$$5000 \times 25\% = 1250$$

4. Number of individuals with prolonged, recurring illness:

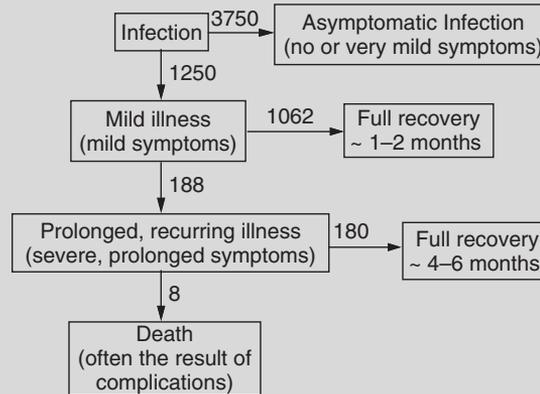

$$1250 \times 15\% = 188$$

5. Number of individuals who do not survive:

$$188 \times 4\% = 8$$

6. Risk of dying for members of community:

$$8/10,000 = 8 \times 10^{-4}$$

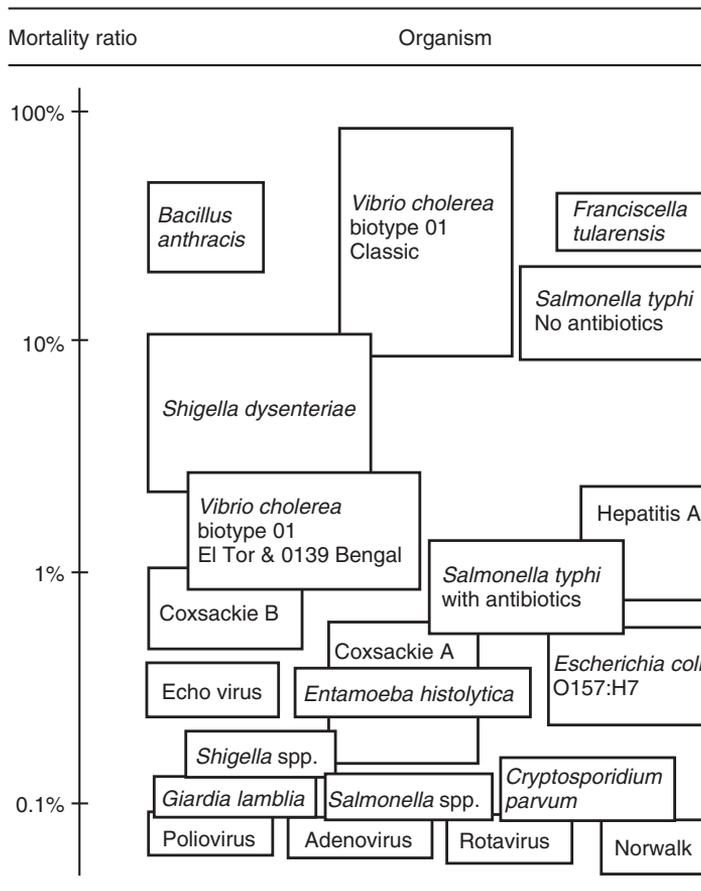

#### MORTALITY RATIO

Pathogens with a high probability of a fatal outcome are particularly important. A pathogen's effectiveness in causing damage to its host is referred to as virulence. The most common measure of virulence is the mortality ratio, which is the fraction of the persons who get ill to those who do not survive the disease. The mortality ratio for several pathogens is displayed on Fig. 3-8. Among the classic waterborne pathogens, the *V. cholerae* biotype 01 (Asiatic cholera) had one of the highest mortality ratios. There is evidence that contemporary strains of cholera (the El Tor and Bengal strains) are somewhat less virulent due to their dependence on asymptomatic carriers for transmission (Ewald et al., 1998). The other two organisms with the highest mortality ratio on Fig. 3-8 are *Franciscella tularensis* and *Bacillus anthracis*, organisms primarily known as agents of biological warfare.

#### Forms of Gastroenteritis

Gastroenteritis is the most important form of waterborne illness. Other forms are discussed in the following section. Gastroenteritis may be divided into three classes, as shown in Table 3-2: (1) noninflammatory gastroenteritis, (2) inflammatory gastroenteritis, and (3) invasive gastroenteritis. Noninflammatory gastroenteritis generally results from an organism or toxin that does not draw an immune response, such as in cases of food poisoning or from protozoan infections. Food poisoning of this kind can

**Figure 3-8**  
Mortality ratios for variety of pathogens.

result from the ingestion of mushrooms or food contaminated with a bacterial toxin, as is the case with *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium perfringens*, or *Clostridium botulinum*. These forms of gastroenteritis are not accompanied by a fever but most result in diarrhea and/or vomiting.

Inflammatory gastroenteritis results in redness, swelling, pain, and a feeling of heat in affected areas. In these circumstances, the organism may invade the epithelial layer of the GI tract and sometimes the lymph nodes but does not venture further. The immune response is designed to address the organism and its activities but results in no permanent damage to the host. Inflammatory gastroenteritis is associated with a number of bacteria, two viruses, and one protozoa. Symptoms include fever, diarrhea, and/or vomiting and fecal leukocytes (colorless white cells with a nucleus that are associated with the lymph system and blood).

Invasive gastroenteritis occurs when the organism responsible for the infection travels beyond the epithelial layer of the GI tract, invading other

**Table 3-2**

Association of pathogens with different forms of gastroenteritis

Gastroenteritis	Symptoms	Responsible Organisms
Noninflammatory gastroenteritis	Diarrhea and/or vomiting, no fecal leukocytes, no blood in stool, usually no fever.	Bacteria: <i>S. aureus</i> , <sup>a</sup> <i>B. cereus</i> , <sup>a</sup> <i>C. perfringens</i> , <sup>a</sup> <i>C. botulinum</i> <sup>a</sup>  Viruses: noroviruses Protozoa: <i>Giardia lamblia (intestinalis)</i> , <i>Cryptosporidium parvum</i> Algae: <i>Pfiesteria</i> spp. <sup>a</sup>
Inflammatory gastroenteritis	Diarrhea and/or vomiting, fecal leukocytes present, usually severe fever, no blood in stool.	Bacteria: <i>V. cholerae</i> , <sup>b</sup> enteropathogenic <i>E. coli</i> (EPEC), enteroaggregative <i>E. coli</i> (EAaggEC), <i>Clostridium difficile</i> , <i>Shigella</i> spp., enterotoxigenic <i>E. coli</i> (ETEC) Viruses: rotavirus, caliciviruses <sup>b</sup> Protozoa: <i>Entamoeba dispar</i>
Invasive gastroenteritis	Invasion past epithelial layer of GI tract, may not have any diarrhea or vomiting, dysentery may be present (mucus containing bloody feces), fecal leukocytes present, fever; may not have any GI tract problems but instead severe systemic problems.	Bacteria: <i>Salmonella</i> spp., <i>Campylobacter jejuni</i> , enteroinvasive <i>E. coli</i> (EIEC), enterohemorrhagic <i>E. coli</i> (EHEC), <i>Vibrio vulnificus</i> , <i>Yersinia</i> spp., <i>F. tularensis</i> , <i>B. anthracis</i> , <i>Helicobacter pylori</i> Viruses: unknown Protozoa: <i>E. histolytica</i>

<sup>a</sup>These microorganisms grow on food or in the environment and produce toxins that, when ingested, cause gastroenteritis a few hours later (only *Pfiesteria* spp. is of concern to drinking water).

<sup>b</sup>Often cited as not causing a fever.

organs and even the blood system itself. As a result, significant damage often results when these diseases are allowed to progress too far. Several bacteria and one protozoa are known to cause invasive gastroenteritis.

Waterborne pathogens include bacteria, viruses, protozoa, and helminths. Some of the more significant of each of these will be discussed in the following sections.

### 3-3 Bacteria of Concern in Drinking Water

Bacteria within water supplies are broadly classified into two groups: the autochthonous group (*autochthon* is from the Greek word for “one sprung from the land itself”) and the allochthonous group (*allos* from the Greek for “other”). Autochthonous bacteria thrive in natural water supplies, while allochthonous bacteria do not. Allochthonous bacteria end up in the water as a result of contamination, runoff, and rainfall. Allochthonous

bacteria normally have a limited life span in the natural water environment. Many bacteria of concern from the public health standpoint are classified as allochthonous. Allochthonous bacteria are more comfortable in the intestines of warm-blooded animals, and their presence in water is indicative of wastewater or fecal contamination. Outside of the warm, nutritionally rich environment of a human or animal gut, they die off rapidly. However, bacterial die-off is not an all or none response, so the rates of die-off and the initial bacterial concentrations in contaminated water are of interest.

Bacterial disease has always maintained a high profile where public health and water supply are concerned, and the situation is likely to remain that way for the foreseeable future. To provide some structure to the discussion of various bacterial pathogens, the bacteria have been divided into several broad categories. Classic waterborne pathogens, those that have plagued humans since the early understanding of waterborne illness such as cholera and typhoid fever are discussed first. Modern waterborne pathogens are those that have been the focus of health professional in more recent years. Pathogens that have been implicated in recent outbreaks but about which less is known, are considered to be pathogens of emerging concern. A final category of interest are pathogens that might be used to sabotage water systems.

Classic waterborne pathogens are those that have been associated with drinking water since the early development of water treatment practices. Cholera and typhoid fever are acute epidemic diseases that can, when transmitted via the water supply, infect a significant fraction of the community overnight. Typhoid fever is caused by *S. typhi*, a bacteria of the *Salmonella* genus. These and a variety of historic bacteria of interest in drinking water are characterized in Table 3-3. Characteristics of bacteria, the symptoms of the diseases they cause, and their relevance to water treatment are discussed below.

### Classic Waterborne Bacterial Pathogens

#### **VIBRIO CHOLERAEE**

*Vibrio* organisms are facultative anaerobic bacteria that are metabolically similar to Enterobacteriaceae and are one of the most common organisms in surface waters. *Vibrio cholerae* is the most ferocious of waterborne infectious pathogens because it is noninvasive and attacks the small intestine through secretion of an enterotoxin. The original classic *V. cholerae* (serotype 01) of the nineteenth century is thought to have been indigenous in India for many centuries. People exposed to this classic *V. cholerae* experienced explosive diarrhea and vomiting without fever. These initial symptoms usually occur 2 to 3 days or less after exposure. If left untreated, an infected individual with severe symptoms experiences dehydration, abnormally low blood pressure and temperature, muscle cramps, shock, coma, and eventually death. Often

**Table 3-3**  
Bacteria that cause classical waterborne diseases

Organism	Size, $\mu\text{m}$	Motile	Normal Habitat	Health Effects in Normal Persons	Evidence is Waterborne	Culturable
<i>Vibrio cholerae</i> O1 classical	$0.5 \times 1-2$	Flagella	Human stomach and intestines	Classic cholera	Classic studies	Classic studies
<i>V. cholerae</i> O1 El tor	$0.5 \times 1-2$	Flagella	Human stomach and intestines <sup>a</sup>	Milder but serious form of classic cholera	Several modern studies	Several modern studies
<i>V. cholerae</i> O139 Bengal	$0.5 \times 1-2$	Flagella	Human stomach and intestines <sup>a</sup>	Milder but serious form of classic cholera	Several modern studies	Several modern studies
<i>Salmonella typhi</i>	0.6	Yes	Human stomach and intestines	Typhoid fever: enteric fever	Classic studies	Classic studies
<i>Salmonella paratyphi A</i>	0.6	Yes	Intestines of warm-blooded animals	Enteric fever	Classic studies	Classic studies
<i>Salmonella schottmulleri</i>	0.6	Yes	Intestines of warm-blooded animals	Enteric fever	Classic studies	Classic studies
<i>Salmonella choleraesuis</i>	0.6	Yes	Intestines of warm-blooded animals	Gastroenteritis, <i>Salmonella</i> septicemia	Classic studies	Classic studies
<i>Salmonella typhimurium</i>	0.6	Yes	Intestines of warm-blooded animals	Gastroenteritis	Classic studies	Classic studies

<i>Salmonella enteritidis</i>	0.6	Yes	Intestines of warm-blooded animals	Gastroenteritis	Classic studies	Classic studies
<i>Shigella dysenteriae</i>	0.4	No	Human stomach and intestines	Bacillary dysentery: abdominal pain, cramps, diarrhea, fever, vomiting, blood and mucus in stools	Classic studies	Classic studies
<i>Shigella sonnei</i>	0.4	No	Human stomach and intestines	Bacillary dysentery: abdominal pain, cramps, diarrhea, fever, vomiting, blood and mucus in stools	Classic studies	Classic studies
<i>Shigella flexneri</i>	0.4	No	Human stomach and intestines	Bacillary dysentery: Abdominal pain, cramps, diarrhea, fever, vomiting, blood and mucus in stools	Classic studies	Classic studies
<i>Shigella boydii</i>	0.4	No	Human stomach and intestines	Bacillary dysentery: Abdominal pain, cramps diarrhea, fever, vomiting, blood and mucus in stools	Classic studies	Classic studies

<sup>a</sup>Also shown to grow in estuarial conditions.

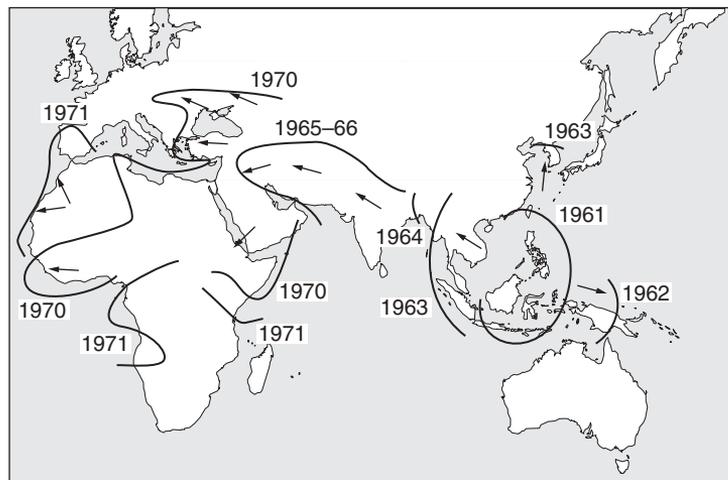

these symptoms occur in less than 18 h. Untreated cholera frequently results in death for 50 to 60 percent of those infected.

*Vibrio cholerae*'s rapid impact on its victims results from the activity of the cholera enterotoxin, which activates an enzyme in the intestinal cells, causing them to extract water and electrolytes from blood and tissue and move it into the intestine. The watery diarrhea that results is speckled with flakes of mucus and epithelial cells and contains enormous numbers of *V. cholerae*. Because of its grainy appearance, it is referred to as a "rice-water stool."

In 1817, *V. cholerae* moved beyond India, causing epidemics in several other countries. Thus began the first of six pandemics, starting in the nineteenth century and continuing into the first two decades of the twentieth century. During these pandemics, the disease moved around the world killing hundreds of thousands of people in each series of events. The last of these six classic epidemics was arrested in 1923. Between 1923 and 1960, it was believed that cholera would not return in pandemic form because water supplies had been improved worldwide.

Then in 1961 a new biotype of the classic serotype of *V. cholerae* (*V. cholerae* 01 also known as El Tor) emerged, producing a major epidemic in the Philippines and initiating a seventh pandemic. El Tor is now active on six continents (Ewald et al., 1998). The early development of this new pandemic is shown on the map on Fig. 3-9.

The evolutionary biologist Paul Ewald (Ewald et al., 1998) argues that, when faced with changes in their environment (such as better water treatment), pathogens will evolve to regain their survival advantage. There are three characteristics that El Tor has developed that allow it to succeed in this new environment: (1) a higher fraction of infections result in asymptomatic carriers (99.7 to 99 percent for El Tor vs. 50 to 75 percent

**Figure 3-9**  
Geographical development of the first 10 years of the seventh cholera pandemic.

for classic cholera), (2) a longer period of shedding, and (3) better survival outside the gut. Ewald argues that El Tor is largely successful where the classic cholera is not because it is a fundamentally milder disease with a much larger fraction of asymptomatic infections allowing for transmission of the disease by means other than water contamination (Ewald et al., 1998). Between 1969 and 1974, El Tor replaced the classic strains of endemic cholera originating from the Ganges River Delta of India. There were more than one million cases of El Tor in the Western Hemisphere in 1994.

In December 1992, a large epidemic of cholera began in Bangladesh, and large numbers of people have been infected. The organism has been characterized as *V. cholerae* serotype O139 “Bengal.” It is derived genetically from the El Tor pandemic strain, but it has changed its antigenic structure such that there is no existing immunity and all ages, even in endemic areas, are susceptible. The epidemic has continued to spread and Bengal has affected at least 11 countries in southern Asia. The emergence of this new strain illustrates the ability of this organism to evolve, as it must to succeed in a changing environment.

#### **SALMONELLA SPP.**

*Salmonella* bacteria are rod shaped, motile, non-spore-forming, and gram-negative bacteria (*S. gallinarum* and *S. pullorum* are not motile). There is a widespread occurrence of nontyphi *Salmonella* in animals, especially in poultry and swine. Several species of *Salmonella* cause gastrointestinal illness, but, of these, *S. typhi*, which causes typhoid fever, is the most notorious. Evidence suggests that typhoid fever has been with humankind from the beginning—so long that part of the population has developed resistance to the disease’s most damaging effects. A Roman physician, Antonius Musa, achieved fame 2000 years ago by treating Emperor Augustus with cold baths when he fell ill with typhoid. It was Dr. William Budd who, in 1856, first demonstrated that typhoid could be waterborne and Karl Eberth who isolated the organism responsible for the disease from the organs of its victims. The incubation period for typhoid fever is usually 10 to 14 days. Early symptoms are fever [the temperature rises to 39 to 40°C (103 to 104°F)], headaches, malaise, and abdominal pain. Diarrhea is common, but many patients experience constipation. As the disease advances, *S. typhi* invades the GI cells and infects the bloodstream (many individuals of European descent have a genetic trait that interferes with the organism’s effort to conduct this invasion). The bacteria then concentrate in the lymph nodes, the liver, the spleen, and the gall bladder. The bacteria often show up on the surface of the skin concentrated in “rose spots,” approximately a dozen dark red spots on the abdomen and chest about 1 mm in diameter.

Asymptomatic carriers are common and have been known to shed *S. typhi* from their gall bladder for years. Typhoid Mary, the infamous food handler and restaurant worker who infected hundreds if not thousands of patrons in New York City, was a notable example of this malady. Other species of

*Salmonella* have similar but less severe effects. Probably the most well known *Salmonella* spp. causing an enteric fever similar to *S. typhi* is *S. paratyphi* (paratyphoid fever). Other *Salmonella* species cause acute gastroenteritis without fever, which occurs within a few days of exposure and usually lasts several days to a week. Until 1948, when the antibiotic chloramphenicol was introduced, little could be offered to typhoid victims but supportive care. Without antibiotics the mortality rate can be as high as 15 percent. Through the use of antibiotics the mortality rate can be reduced to about 1 percent, but only if recognized and treated early in the infection.

It is important to understand that, in the long term, antibiotics are no substitute for good sanitation. In countries with poor sanitation, drug resistance to *Salmonella* began to emerge in the 1970s, and by the late 1970s the rate of drug resistance among strains of *Salmonella* had reached 75 percent in Vietnam, for example. By comparison, the resistance in industrialized countries was on the order of 5 percent. Drug resistance among strains of enteric pathogens continues to be a problem in countries with poor sanitation (Isenbarger et al., 2002). Once again, these observations are consistent with the theories of evolutionary biology. In environments where pathogens have easy access to victims and constant exposure to drug therapy, they can afford the less efficient metabolic machinery required for drug resistance (Ewald et al., 1998). Good water treatment is an essential element of controlling this family of pathogens. Sanitary practices provide effective intervention, making the drug therapies more effective.

#### **SHIGELLA SPP.**

*Shigella* spp. organisms are gram-negative, nonmotile, non-spore-forming, rod-shaped bacteria (bacilli). Some of the more important species are *Shigella dysenteriae*, *S. sonnei*, *S. boydii*, and *S. flexneri*. *Shigella* is named after the Japanese scientist, Kiyoshi Shiga, who identified the organisms in 1897. The species *S. dysenteriae* is responsible for bacillary dysentery, a disease often associated with crowded, unsanitary conditions. Other species of *Shigella* usually produce milder forms of diarrheal disease. Most people who are infected with *Shigella* develop diarrhea, fever, and stomach cramps starting a day or two after exposure. The diarrhea is often bloody, the distinguishing characteristic of dysentery. *Shigella dysenteriae* is the only cause of epidemic bacterial dysentery.

*Shigella*, like *Salmonella* and *E. coli*, is a member of the family Enterobacteriaceae. *Shigella* differs from other members of that family by having genes in a large “virulence” plasmid that codes for epithelial cell invasion and the formation of enterotoxins. In contrast to *S. flexneri*, *S. sonnei*, and *S. boydii*, *S. dysenteriae* can also cause cell death by the production of Shiga toxin.

*Shigella* spp. organisms are primarily human pathogens, although they can be found in some primates such as monkeys and chimpanzees but rarely occur in other animals. *Shigella* normally affects the distal ileum or

colon and is usually confined to the mucosa, but it can spread through the intestinal wall and lead to perforation. The disease is caused when virulent *Shigella* organisms attach to and penetrate epithelial cells of the intestinal mucosa. After invasion, they multiply by spreading from one epithelial cell to the next, resulting in tissue destruction. Unlike *Salmonella*, *Shigella* is acid tolerant. As a consequence, gastric acidity provides little protection against infection. Effective natural defenses include the normal flora, secretory immunoglobulin A (antibodies found in the saliva, sweat, and tears), and phagocytes. In contrast to the invasive *S. typhi*, *Shigella* rarely invades beyond the intestinal mucosa or local lymph nodes.

Contamination is usually through the fecal–oral route. Fecally contaminated water and unsanitary practices of food handlers are the most common causes of this contamination. The most commonly associated foods are salads (potato, tuna, shrimp, macaroni, and chicken), raw vegetables, milk and dairy products, and poultry. The milder forms of *Shigella* spp. infections are also spread in childcare centers in developed countries.

*Shigella dysenteriae* has caused epidemics of dysentery throughout the world. *Shigella dysenteriae*, *S. flexneri*, and *S. boydii* are the species most commonly found in developing countries. *Shigella sonnei* is more common in developed countries, and in these countries *S. dysenteriae* is quite rare. *Shigella dysenteriae* caused a 4-year epidemic in Central America beginning in 1968 that resulted in an estimated 500,000 cases and 20,000 deaths. No epidemics have occurred in the region since then, but *S. dysenteriae* continues to occur sporadically in the Western Hemisphere. *Shigella dysenteriae* also spread down the African continent as a major pandemic. It was first reported in eastern Zaire in 1981 and since then has been reported in Rwanda, Burundi, and Tanzania. It was first identified in the province of KwaZulu-Natal, South Africa, in March 1994 and simultaneously noted in the northern part of South Africa. Since then it has spread throughout sub-Saharan Africa. An estimated 300,000 cases of shigellosis occur annually in the United States, but these are largely infections of *S. sonnei* and some *S. flexneri*, both spread by food and oral sex. Worldwide, it is estimated that *Shigella* spp. organisms are the cause of more than 600,000 deaths annually.

As with *Salmonella*, drinking water treatment and sanitation play a major role in the ecology of *Shigella* in two ways. In countries with poor sanitation, pandemics of the most harmful species, *S. dysenteriae*, occur beyond control, whereas in more developed countries milder species such as *S. sonnei* dominate. Another related observation is the development of resistance to antibiotics among *Shigella* spp. in countries with poor sanitation. *Shigella dysenteriae* has shown that it can quickly develop antibiotic resistance. In a country with poor sanitation, antibiotics are often effective against *S. dysenteriae* for only 1 or 2 years after being introduced; resistance has even been observed to develop during the course of a single epidemic.

**Modern  
Waterborne  
Bacterial  
Pathogens**

The classical bacterial pathogens in the preceding discussion have been associated with waterborne disease for the public health community for some time. In recent years, progress in science has brought new waterborne bacterial pathogens to the forefront. Bacterial pathogens that have been shown to cause waterborne disease in recent years are summarized in Table 3-4. Most of these bacteria cause a form of diarrhea, and none presents a threat to community comparable to the cholera epidemics 100 years ago; however, they do sometimes have serious health consequences. Any serious diarrhea can be life threatening to some members of the population, especially in a poor country, and some invasive forms of these diseases have other important health consequences as well.

**PATHOGENIC *E. COLI***

The largest group of bacteria discussed in Table 3-4 is the pathogenic *E. coli*. *Escherichia coli* belongs to the family Enterobacteriaceae and is almost invariably enteric. *Escherichia coli* is a facultative anaerobe, gram-negative rod that lives in the intestinal tracts of warm-blooded animals. A number of genera in Enterobacteriaceae are human intestinal pathogens (e.g., *Salmonella*, *Shigella*, and *Yersinia*). Several others are normal inhabitants of the human gastrointestinal tract (e.g., *Escherichia*, *Enterobacter*, and *Klebsiella*), but these bacteria may be associated with disease if they harbor virulence factors that make them capable of causing a disease.

*Escherichia coli* colonizes the GI tract of warm-blooded animals during the first few days after birth. The human bowel usually shows evidence of colonization in less than 4 days. *Escherichia coli* can adhere to the intestine or to the mucus overlying it. Once a strain of *E. coli* resides in an animal's colon, it remains there, undisturbed for weeks, months, or even years until disturbed by an enteric infection or antimicrobial drugs. Normally, *E. coli* serves a useful function in the body by suppressing the growth of harmful bacterial species and by synthesizing appreciable amounts of vitamins. The entire DNA sequence of the *E. coli* genome has been determined for two strains of this bacterial species and is available to the public.

While there is wide agreement that certain varieties of *E. coli* are pathogenic and that these play an important role in waterborne disease, information on these organisms continues to develop and, consequently, their classification is evolving as well. The most widely recognized groupings are the enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), and enterohemorrhagic *E. coli* (EHEC). The EHEC group consists of the well-known bacteria *E. coli* O157:H7. Newer but less widely accepted groupings are the enteropathogenic *E. coli* (EPEC) and the enteroaggregative *E. coli* (EaggEC). These organisms are implicated in waterborne disease outbreaks, and all of them have unique methods for adhering to the mucus and/or wall of the intestines of warm-blooded animals. Exactly how they adhere is related to their pathogenic nature, which is determined by which virulence genes they possess.

**Table 3-4**  
Bacteria recently associated with waterborne disease

Organism or Bacteria	Size, $\mu\text{m}$	Motile	Health Effects in Healthy Persons	Evidence of Waterborne Pathway	Culturable
Enteropathogenic <i>Escherichia coli</i> (EPEC)	0.3 – 0.5 × 1 – 2	No	Traveler's diarrhea	Numerous waterborne outbreaks	<i>E. coli</i> test
Enteroaggregative <i>E. coli</i> (EaggEC)	0.3 – 0.5 × 1 – 2	No	Childhood diarrhea and diarrhea among immunocompromised	Numerous waterborne outbreaks	<i>E. coli</i> test
Enteroinvasive <i>E. coli</i> (EIEC)	0.3 – 0.5 × 1 – 2	No	Childhood diarrhea	Numerous waterborne outbreaks	<i>E. coli</i> test
Enterohemorrhagic <i>E. coli</i> (EHEC, e.g., <i>E. coli</i> O157)	0.3 – 0.5 × 1 – 2	No	Bloody diarrhea, occasionally hemolytic uremic syndrome (HUS)	Six waterborne outbreaks, notably Cabool, MI, and Walkerton, Ontario	<i>E. coli</i> test at 37.5°C
Enterotoxigenic <i>E. coli</i> (ETEC)	0.3 – 0.5 × 1 – 2	No	Traveler's diarrhea	Numerous waterborne outbreaks	<i>E. coli</i> test
<i>Helicobacter pylori</i>	0.5 – 1 × 2.5 – 4	Yes	Dominant cause of peptic and duodenal ulcers; associated with gastric carcinoma	Some indirect evidence	No
<i>Yersinia enterocolitica</i>	0.3 – 0.5 × 1 – 2	No	Fever, abdominal pain, gastroenteritis with diarrhea and vomiting	Outbreaks associated with contaminated spring water	Yes
<i>Campylobacter jejuni</i>	0.3 × 1 – 5	Yes	Diarrhea, abdominal pain, nausea, fever, malaise	Numerous outbreaks	Yes, but methods are difficult and insensitive

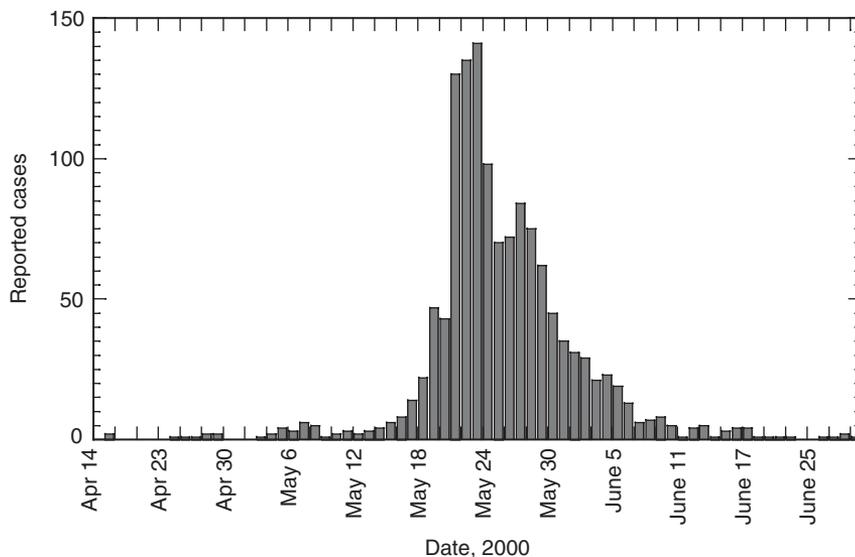

Both ETEC and EPEC are thought to be a major cause of endemic and traveler's diarrhea in underdeveloped countries. Both result in abdominal cramps and a watery diarrhea. Enterotoxigenic *E. coli* does so through the generation of toxins that lead to secretion without invading the epithelial wall and hence causes only low-grade fever. Enteropathogenic *E. coli* causes abdominal discomfort through the production of a "Shiga-like" toxin, but also by invading the epithelial wall. Its invasive character results in significant inflammation and fever.

Enteroinvasive *E. coli* does not produce toxins, but it does adhere to the colon wall and then penetrates and grows in the epithelial cells of the colon. The result is severe inflammation, fever, and bacillary dysentery, much like the symptoms of *S. dysenteriae*. The disease is also found in the same conditions of poor sanitation associated with *Shigella*. In many genetic and physiological respects, *S. dysenteriae* and EIEC are very similar bacteria.

Enteroaggregative *E. coli* is not as well studied as some of the others. The distinguishing feature of EaggEC is its ability to attach to tissue culture cells in an aggregative manner. Enteroaggregative *E. coli* is associated with persistent diarrhea in young children and immunocompromised patients. Like ETEC, EaggEC adheres to the intestinal mucosa and causes watery diarrhea without inflammation or fever. The role of EaggEC strains in human disease is less clear than the other pathogenic *E. coli* discussed in this section.

Enterohemorrhagic *E. coli*, of which *E. coli* O157:H7 (the "O" is a letter) is a main member, is a unique variety of *E. coli* that produces a Shiga-like toxin (verotoxin) that is closely related or identical to the toxin produced by *S. dysenteriae*. As a result, infection with EHEC produces hemorrhagic colitis, an illness characterized by severe cramping and diarrhea that is initially watery but becomes bloody, occasionally vomiting, and fever that is either low grade or absent. The illness is usually self-limited and lasts for an average of 8 days. Some victims develop hemolytic uremic syndrome (HUS), a rare condition affecting mostly children, characterized by destruction of red blood cells, damage to the lining of blood vessel walls, and in 10 percent of the cases kidney failure. It is uniquely but not exclusively connected to *E. coli* O157:H7. In the elderly, thrombotic thrombocytopenic purpura (TTP) can occur (HUS plus high fever and neurological symptoms), and under these conditions, TTP can have a mortality rate as high as 50 percent.

Enterohemorrhagic *E. coli* was identified as the cause of a significant waterborne outbreak in Walkerton, Ontario, in May and June 2000. The incident was caused by contamination of a well in the local water system by EHEC, and *C. jejuni* contained in manure leached into the well from a nearby farm. The EHEC was found in the manure on the farm, in the water distribution system, and in the stools of infected patients (Bruce-Grey-Owen Sound Health Unit, 2000). During the outbreak, estimates are that more than 2300 persons were ill, as shown graphically on Fig. 3-10. Of the 1346 cases that were reported, 1304 (97 percent) were

**Figure 3-10**  
Number of illness cases reported during Walkerton, Ontario, disease outbreak of 2000. (Data from Bruce–Grey–Owen Sound Health Unit, 2000.)

considered to be directly due to the drinking water. Based on stool samples, about an equal number were infected with *E. coli* O157:H7 and *C. jejuni*. Sixty-five persons were hospitalized, 27 developed HUS, and 6 died.

### CAMPYLOBACTER JEJUNI

*Campylobacter jejuni* is a gram-negative, slender, curved, and motile rod-shaped bacterium. Cell motility is achieved through polar flagella that emanate from a spiral-shaped bacterium. The unique shape of the cell and flagella are helpful in Gram stain identification. *Campylobacter jejuni* prefers conditions with reduced levels of oxygen (microaerophilic conditions).

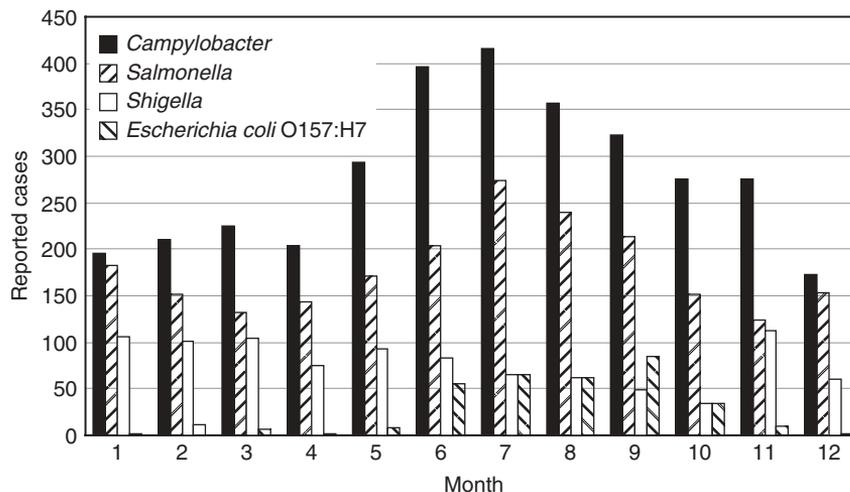

*Campylobacter* is found in natural water sources throughout the year. The presence of *Campylobacter* is not clearly correlated with indicator organisms for fecal contamination (i.e., *E. coli*). The organism survives substantially better in a cold environment. It has been reported that, when stressed, *Campylobacter* enters a “viable but nonculturable state” but can still be transmitted to animals.

*Campylobacter* has been known a long time, but its significance to public health has changed over time. As early as 1886, Escherich observed organisms resembling campylobacters in stool samples of children with diarrhea. In 1913, McFaydean and Stockman identified *Campylobacter* (called related *Vibrio*) in fetal tissues of aborted sheep. In 1957 King described the isolation of related *Vibrio* from blood samples of children with diarrhea, and in 1972 clinical microbiologists in Belgium first isolated *Campylobacter* from stool samples of patients with diarrhea (Kist, 1985).

The development of selective growth media in the 1970s permitted more laboratories to test stool specimens for *Campylobacter*. Soon, *Campylobacter* spp. was established as a common human pathogen. *Campylobacter jejuni* infections are now the leading cause of bacterial gastroenteritis reported in the United States (Blaser et al., 1983). In 1996, 46 percent of laboratory-confirmed cases of bacterial gastroenteritis reported in the Centers for Disease Control and Prevention (CDC)/U.S. Department of Agriculture/Food and Drug Administration Collaborating Sites Foodborne Disease Active Surveillance Network were caused by *Campylobacter* species. Campylobacteriosis was followed in prevalence by salmonellosis (28 percent), shigellosis (17 percent), and *E. coli* O157:H7 infection (5 percent), as shown on Fig. 3-11.

*Campylobacter jejuni* is commonly present in the GI tract of healthy cattle, pigs, chickens, turkeys, ducks, and geese and may occasionally be isolated from streams, lakes, and ponds. The closely related species *Campylobacter coli* and *Campylobacter upsaliensis* may also cause disease in humans.

Typical symptoms of *C. jejuni* illness include severe abdominal pain, diarrhea, fever, nausea, headache, and muscle pain. A majority of cases are mild and do not require hospitalization or treatment with antibiotics; however, *C. jejuni* infection can be severe. The disease is rarely fatal, less than 1 death per 1000 cases. Children under the age of 5 and young adults aged 15 to 29 are the age groups most frequently affected. The incubation period is typically 2 to 5 days, but onset times of up to 11 days have been reported. The illness usually lasts about 1 week, with severe cases persisting for up to 3 weeks. However, *Campylobacter* infection may be followed by Guillain–Barré syndrome (GBS), a rare but serious form of neuromuscular paralysis in a small proportion of cases. Many of those suffering from GBS have antibodies to *Campylobacter*, indicating a recent infection. *Campylobacter* has also been

**Figure 3-11**  
Cases of foodborne gastroenteritis in the United States in 1996. (Adapted from Altekruze et al., 1999.)

isolated from the stools of patients stricken with GBS. Although not everyone who is infected with *Campylobacter* will develop GBS, the association between *Campylobacter* and GBS makes this bacterium more significant.

Infections caused by strains of *C. jejuni* that are resistant to antibiotics make clinical management more difficult. Antibiotic resistance can compromise treatment of patients with bacteremia. Once again, antibiotic resistance of *C. jejuni* fits Ewald's theory of microbial evolution (Ewald et al., 1998). Resistance is highest in the developing world, where sanitation is poor, the bacteria have easy access to their hosts, and the use of antibiotics is the principal means employed to address disease. A 1994 study found that most clinical isolates of *C. jejuni* from U.S. troops in Thailand were resistant, even to ciprofloxacin, which is one of the antibiotics considered a last line of defense. Additionally, nearly one-third of isolates from U.S. troops located in Hat Yai were resistant to azithromycin (Murphy et al., 1996). Evidence also demonstrates that fluoroquinolone-susceptible *C. jejuni* becomes drug resistant in chickens receiving drug therapy.

#### **HELICOBACTER PYLORI**

*Helicobacter pylori* is a spiral-shaped, gram-negative rod approximately  $0.5 \times 3.0 \mu\text{m}$  in size, with sheathed flagella attached to one pole that allow for motility. *Helicobacter pylori* is linked to GI disease in humans. It was first identified in Australia by Dr. Barry Marshall in 1983 as a potential cause of peptic ulcers. *Helicobacter pylori* lives in the stomach and duodenum (section of intestine just below the stomach). Today it is understood to be the most common cause of gastritis in humans.

*Helicobacter pylori* makes its home in the mucous lining of the stomach, using its flagella and spiral shape to drill through the mucous layer in the stomach. *Helicobacter pylori* produces adhesions that bind to membrane-associated lipids and carbohydrates. The adherence of *H. pylori* to plasma membranes of surface epithelial cells has been shown using electron microscopy. *Helicobacter pylori* protects itself from the stomach's acidity by releasing the enzyme urease, which converts the urea in the stomach to bicarbonate and ammonia, creating a pH-neutral microenvironment around the cell, a benefit to the spiral bacteria but not the epithelial cells to which it is attached.

The organism's location against the stomach lining also leads to isolation from the immune system, which cannot penetrate the lining itself. Nevertheless the immune system can sense the presence of *H. pylori* and, over time, tries to respond. The immune response results in the development of a peptic ulcer. Greater than 90 percent of duodenal ulcer patients are infected with *H. pylori*. Ulcer patients without *H. pylori* infection are typically those who have taken nonsteroid anti-inflammatory drugs, such as aspirin and ibuprofen, which can commonly cause ulcers. Eradication of the bacterium from a person greatly reduces the recurrence of ulcers. There is also a strong correlation with *H. pylori*, peptic ulcers, and stomach

cancer. It is estimated that *H. pylori* infection increases the risk of gastric cancer sixfold.

*Helicobacter pylori* is believed to be transmitted orally by means of fecal matter through the ingestion of waste-tainted food and/or water. As a result, the organism is considered a potential waterborne pathogen. Although the actual mode of transmission has not been proven, the ability to culture the bacterium from stool is supporting evidence for a fecal–oral mode of transmission, hence its consideration as a potential waterborne pathogen. Drug therapies are available to eliminate the infection.

#### YERSINIA ENTEROCOLITICA

*Yersinia pestis* was the cause of the plague, but that disease was transmitted by fleas, not by contaminated water. Its relative, *Y. enterocolitica*, also a small rod-shaped, gram-negative bacterium, is often isolated from clinical specimens such as wounds, feces, sputum, and lymph nodes near the GI tract. However, it is not part of the normal human flora. Another cousin, *Yersinia pseudotuberculosis*, has been isolated from the diseased appendix of humans. Both *Y. pseudotuberculosis* and *Y. enterocolitica* are associated with diseases of the GI tract, but only *Y. enterocolitica* has been connected with ingestion of contaminated water. *Yersinia enterocolitica* can be identified through its ability to grow in cold temperatures and its motility at room temperature. *Yersinia enterocolitica* is also most comfortable at neutral to alkaline pH. As a result, the use of antacids is contraindicated.

*Yersinia enterocolitica* is an invasive pathogen that can penetrate the intestinal lining and enter the lymph nodes, causing a systemic infection. *Yersinia enterocolitica* causes intestinal inflammation called yersiniosis via the release of enterotoxins that can cause severe pain similar to that found in patients with appendicitis.

Fever and abdominal pain are the hallmark symptoms of *Y. enterocolitica* infections. Four syndromes are also associated with *Y. enterocolitica*: (1) enterocolitis—diarrhea, low-grade fever, abdominal cramps; (2) pseudoappendicitis—pain in the same area as the appendix along with leukocytosis; (3) extraintestinal focal infection—infections in the urinary tract, pneumonia, pharyngitis, and so on; and (4) bacteremia—entrance of organisms into the bloodstream. Enterocolitis is common in young children, pseudoappendicitis in young adults, and bacteremia in diabetics, alcoholics, and others with compromised conditions. Most infections are uncomplicated and resolve completely. Occasionally, some persons develop joint pain, most commonly in the knees, ankles, or wrists. These joint pains usually develop about 1 month after the initial episode of diarrhea and generally resolve after 1 to 6 months. A skin rash called erythema nodosum may also appear on the legs and trunk. *Yersinia enterocolitica* has been associated with reactive arthritis, which may occur even in the absence of obvious symptoms. The frequency of such postenteritis arthritic conditions is about

2 to 3 percent. Nevertheless, infections of *Y. enterocolitica* are relatively rare, and the organism is an infrequent cause of diarrhea and abdominal pain.

The *Y. enterocolitica* strains that cause human illness also reside in pigs, but other strains are found in other animals, including rodents, rabbits, sheep, cattle, horses, dogs, and cats. In pigs, the bacteria are most likely to be found on the tonsils. *Yersinia enterocolitica* has been detected in environmental and food sources, such as ponds, lakes, meats, ice cream, and milk. Isolates from environmental samples are not always pathogenic. Poor sanitation and improper techniques by food handlers, including improper storage, cannot be overlooked as contributing to food contamination.

A number of pathogens have emerged in recent years that are of concern in drinking water because they are transmitted by the fecal–oral route or have been implicated in recent waterborne outbreaks. Some of these are opportunistic pathogens that grow and thrive in natural waters and in the soil environment. Four of the more significant emerging pathogens are shown in Table 3-5.

### Bacterial Pathogens of Emerging Concern

#### LEGIONELLA PNEUMOPHILA

*Legionella pneumophila* is a motile, rod-shaped, gram-negative, aerobic bacterium—a “facultative parasite.” In 1976 it was discovered as the cause of a mysterious pneumonia-like disease among a group of elderly men attending an American Legion Convention in Philadelphia, Pennsylvania (hence the name). *Legionella* does not grow well in the laboratory with typical culture methods. Special media and pretreatment methods are required for its cultivation. *Legionella* has many species and serogroups. The strain responsible for Legionnaire’s disease is *L. pneumophila* serogroup 1, or the *Pontiac strain*.

*Legionella* thrives in warm aquatic environments with rust, algae, and organic particles. It has been known to survive in tap water at room temperature for over a year. *Legionella* prefers to grow inside other organisms; for example, *L. pneumophila* has been associated with protozoa, *Hartmannella vermiformis*, *Tetrahymena thermophila*, and *Acanthamoeba castellanii*. *Legionella* grows inside these amoebae and multiplies intracellularly using the amoeba as a resource for reproduction.

*Legionella* bacteria are transmitted to humans via aerosols, such as those generated by air-conditioning cooling towers. Successful transport is favored by a high relative humidity because it enables them to survive while airborne.

The most susceptible hosts are elderly men, smokers, and persons with suppressed immune systems (diabetics, HIV patients, organ transplant recipients, alcoholics, kidney patients, patients on steroids for allergy control, etc.).

Infection begins with the inhalation of *L. pneumophila*. In the lung, the *L. pneumophila* comes in contact with alveolar macrophage. The probability

**Table 3-5**  
Bacterial pathogens of emerging concern in drinking water

Organism	Size, $\mu\text{m}$	Motile	Normal Habitat	Health Effects in Healthy Persons	Modes of Transmission	Evidence of Waterborne Pathway	Culturable
<i>Legionella pneumophila</i>	0.3 – 0.9 $\times$ 2 – 20	Yes	Warm water	Legionnaire's disease, Pontiac fever	Aerosols	Outbreaks associated with warm-water aerosols	Routine media
<i>Aeromonas hydrophila</i>	0.3 – 1.0 $\times$ 1.0 – 3.5	Yes	All freshwaters	Gastroenteritis (controversial)	Water exposure	Drinking contaminated water; water in open wounds	Yes on agar medium with sheep's blood
<i>Mycobacterium avium</i> <i>intercellulare</i>	0.2 – 0.6 $\times$ 10	No	Soil, dust, water, and animals	Lung infection, fatigue	Inhalation or ingestion	Increasing incidence of GI in AIDS patients	Yes
<i>Pseudomonas aeruginosa</i>	0.5 – 0.8 $\times$ 1.5 – 3	Polar flagellum	Inhabitant soil and water; opportunistic human pathogen	Infections of urinary tract, respiratory system, and soft tissue; dermatitis, bacteremia, and systemic infections	Contact with compromised tissue	Only for immunocompromised patients	Yes

of success in this venture increases with the dose and decreases with the competence of the host immune system. At this point, the macrophage takes the bacteria into a food vacuole inside the cell where *L. pneumophila* takes over, directing processes in the macrophage to produce more of its own kind (*L. pneumophila*), eventually lysing the cell and moving on to others. *Legionella pneumophila*'s ability to succeed in this mission depends on a number of special properties the organism has developed that allow it to move into a host cell, take over, reproduce itself, and then lyse the cell and seek other targets. As this process goes forward, it results in lung damage in a number of complicated ways.

Infection by *L. pneumophila* results mainly in Legionnaire's disease. However, some strains have also been known to manifest a disorder called Pontiac fever, a mild infection with influenza-like symptoms. Incidents of Legionnaire's disease have increased over the past decade, partly because of better diagnosis and partly because there are more environments that favor its occurrence. The first symptoms of Legionnaire's disease occur between 2 and 10 days, typically 5 or 6 days, postinfection. The primary indication is pneumonia; however, anorexia, malaise, sore muscles, and headaches are some early indicators. The majority of patients that develop Legionnaire's disease eventually become delirious. The major effect of Legionnaire's disease is respiratory failure. Other complications are acute renal failure, hypotension, and shock. Fifteen percent of hospitalized cases are terminal.

It might seem that keeping *L. pneumophila* out of water distribution systems would be an effective method of preventing the spread of this disease. In this regard, the current practice of maintaining a distribution system residual is helpful. Chlorine residual minimizes the spread of the organism through showerheads and similar home equipment, but keeping a residual in the distribution system is not enough. Incidences of *L. pneumophila* infection are generally associated with exposure to air-conditioning equipment, institutional hot-water supplies, and other hot-water environments that, by design, create conditions that are ideal for *L. pneumophila* development. Moreover, there are plenty of opportunities for equipment of this kind to get its *L. pneumophila* seed directly from the air supply. Taking special care in the design and operation of this kind of equipment so that the growth of *L. pneumophila* can be avoided is more likely to have a material impact. For example, regular use of oxidizing disinfectants could prevent the formation of heavy slime layers that support *L. pneumophila*, and the use of materials that do not corrode and that minimize access to nutrients can also be of help.

#### **AEROMONAS HYDROPHILIA**

*Aeromonas hydrophilia* and other *Aeromonas* species are straight, gram-negative, motile, non-spore-forming, facultatively anaerobic rods or coccobacilli. They appear singly and are motile with a single polar flagellum. The organisms are heat sensitive, being easily destroyed by pasteurization or equivalent heat processes.

*Aeromonas* causes illness through the use of a number of virulence factors, including heat-sensitive enterotoxins. The enterotoxin *A. hydrophilia* produces an effect similar to cholera toxin. Some other *Aeromonas* spp. strains also produce cytotoxins. As a result, patients infected with *A. hydrophilia* sometimes have watery diarrhea similar to that caused by *V. cholera*, although, on occasion, the diarrhea may contain mucus and blood. In addition to diarrheal illness, *Aeromonas* spp. has been associated with a number of severe and persistent infections, with symptoms varying depending on the site of infection. Severe inflammation is a common complaint.

*Aeromonas hydrophilia* has long been recognized as an opportunistic pathogen in immunocompromised hosts (patients on drug therapy, elderly, young). The illness can be severe, especially in the immunocompromised. Its connection with disease in normal hosts is more recent, and although *A. hydrophilia* has been associated with some chronic disease, it is not yet clear how significant *A. hydrophilia* is among the various causes of gastroenteritis.

*Aeromonas* spp. organisms are water loving and inhabit fresh or seawater. They are widely distributed in nature, but water is their main reservoir or source. They can be found in sinks, taps, or drainpipes. *Aeromonas* spp. is easily found in source water and also has been found in treated drinking water. There is evidence that *Aeromonas* is present in biofilms in water distribution systems. *Aeromonas hydrophilia* is found widely in fresh and brackish waters and may be present in the stools of healthy individuals. *Aeromonas hydrophilia* is usually transmitted through drinking contaminated water but may also be transmitted in foods that are in contact with contaminated water.

#### **MYCOBACTERIUM AVIUM COMPLEX**

*Mycobacterium avium* complex (*M. avium* and *M. intracellulare*) is an acid-fast, rod-shaped, aerobic, non-spore-forming, nonmotile family of bacilli. *Mycobacterium avium* complex (MAC) is also sometimes called MAI, which stands for *M. avium intracellulare*. These organisms are ubiquitous in soil, food, and water. *Mycobacterium avium* complex colonizes water systems as well, although it is found at much higher levels in soil (LeChevallier et al., 1991).

*Mycobacterium avium* complex organisms are opportunistic pathogens. In healthy individuals, when MAC causes infection, it usually causes attacks in the respiratory tract. For immunocompromised individuals, MAC is a serious bacterial infection related to tuberculosis. Symptoms can include weight loss, fevers, chills, night sweats, swollen glands, abdominal pains, diarrhea, and overall weakness. In these patients, MAC usually affects the intestines and inner organs first, causing liver test results to be high and swelling and inflammation to occur. Frequently with these patients, MAC infections also become disseminated. When this occurs, almost any organ system can be involved, especially those with many mononuclear phagocytes (e.g., the

liver, spleen, and bone marrow). Signs and symptoms of disseminated MAC are generally nonspecific, such as fever, night sweats, weight loss, weakness, and anorexia. Diarrhea, malabsorption, and abdominal pain may indicate GI involvement; enlargement of the liver and spleen is common. The exact nature of the transmission of the disease is not well established, but because GI infection is often present, introduction through food or drink must be considered.

Members of the MAC are able to grow in water samples without any additional substrate and are resistant to chlorination. They can also grow over a wide range of temperatures and salinities. The cell walls of these bacteria contain high levels of lipid (waxy) material; hence they are hydrophobic and find it easy to colonize the wet surfaces in water systems (LeChevallier et al., 1991).

Some connections with water supply have also been more directly implicated. *Mycobacterium avium* strains were found in water samples (e.g., ice machines, faucets, toilets, sinks) taken from patient care sites in some Boston area hospitals. These isolates were serologically similar to clinical isolates at those same patient care sites (DuMoulin and Stottmeier, 1986). In Los Angeles, *M. avium* strains from infected patients were shown to be genetically related to isolates recovered from patients exposed to the water through drinking or bathing (Glover et al., 1994; Von Reyn et al., 1994). An epidemiological study of 290 HIV patients in San Francisco found *M. avium* complex in 4 of 528 water samples, 1 of 397 food samples, and 55 of 157 soil samples taken from potted plants (Yajko et al., 1995).

#### **PSEUDOMONAS AERUGINOSA**

*Pseudomonas aeruginosa* is a gram-negative, aerobic rod belonging to the bacterial family Pseudomonadaceae. *Pseudomonas aeruginosa* is also motile by means of a single polar flagellum. In fact, *Pseudomonas* is one of the most vigorous, fast-swimming bacteria seen in hay infusions and pond water samples. *Pseudomonas aeruginosa* can live in a sessile biofilm form or in a planktonic form as a free-swimming cell. *Pseudomonas* can usually be found in soil and water, showing up regularly on the surfaces of plants and occasionally on the surfaces of animals. *Pseudomonas* is better known to microbiologists as pathogens of plants rather than animals.

*Pseudomonas aeruginosa* is the epitome of an opportunistic human pathogen. The bacterium almost always infects tissue that has been compromised; however, there is hardly any tissue that it cannot infect once a compromise has taken place.

*Pseudomonas aeruginosa* typically produces three colony types; isolates from soil or water usually produce a small, rough colony. Clinical samples yield one of two smooth colony types. One type has an elevated fried-egg appearance, with large, smooth, flat edges. The other type has a mucoid appearance characteristic of urinary tract infections, and its shape is attributed to the production of alginate slime. The smooth and mucoid

colonies are presumed to be due to factors that play a role in colonization and virulence.

*Pseudomonas aeruginosa* is primarily a pathogen acquired during hospitalization. According to the CDC, the overall incidence of *P. aeruginosa* infections in U.S. hospitals averages about 0.4 percent, and the bacterium is the fourth most commonly isolated nosocomial pathogen (a pathogen acquired during hospitalization), accounting for 10 percent of all hospital-acquired infections. For an opportunistic pathogen such as *P. aeruginosa*, the disease process begins with some alteration or circumvention of normal host defenses. The pathogenesis of *Pseudomonas* infections is multifactorial, as suggested by the number and wide array of virulence determinants possessed by the bacterium. Multiple and diverse determinants of virulence are, in part, responsible for the wide range of diseases it causes. Most *Pseudomonas* infections are both invasive and toxinogenic.

The ultimate *Pseudomonas* infection may be seen as composed of three distinct stages: (1) bacterial attachment and colonization, (2) local invasion, and (3) disseminated systemic disease. However, the disease process may stop at any stage. Particular bacterial determinants of virulence mediate each of these stages and are ultimately responsible for the characteristic syndromes that accompany the disease.

The fimbriae of *Pseudomonas* (the small hairlike protrusions surrounding the cell) adhere to the epithelial cells of the upper respiratory tract and, by inference, to other epithelial cells as well. These adhesions appear to bind to specific receptors on epithelial cells. Colonization of the respiratory tract by *Pseudomonas* requires fimbrial adherence and may be aided by production of a protease enzyme that degrades fibronectin to expose the underlying fimbrial receptors on the epithelial cell surface. Tissue injury may also play a role in colonization of the respiratory tract since *P. aeruginosa* will adhere to tracheal epithelial cells of mice infected with influenza virus but not to normal tracheal epithelium (opportunistic adherence), and it may be an important step in *Pseudomonas* inflammation of cornea and urinary tract infections as well as infections of the respiratory tract. *Pseudomonas aeruginosa* also produces a mucoid exopolysaccharide referred to as alginate. Alginate slime forms the matrix of the *Pseudomonas* biofilm that anchors the cells to their environment and, in medical situations, protects the bacteria from the host defenses, such as lymphocytes, phagocytes, the ciliary action of the respiratory tract, antibodies, and so on. Once a *P. aeruginosa* strain takes on the mucoid form, it is less susceptible to antibiotics than in its planktonic state. Mucoid strains are also associated with cystic fibrosis.

*Pseudomonas aeruginosa* can produce disease in any part of the GI tract from the oropharynx to the rectum. As in other forms of *Pseudomonas* disease, those involving the GI tract occur primarily in immunocompromised individuals. The organism has been implicated in perirectal infections, pediatric diarrhea, typical gastroenteritis, and necrotizing enterocolitis. The GI tract is also an important portal of entry in *Pseudomonas* septicemia.

The versatile pathogen can also be responsible for endocarditis, respiratory infections, bacteremia, central nervous system infections, ear infections, eye infections, bone and joint infections, and urinary tract infections.

*Pseudomonas aeruginosa* is notorious for its resistance to antibiotics, and this makes it a particularly dangerous pathogen. The bacterium is naturally resistant to many antibiotics due to the permeability barrier afforded by its outer membrane. Also, its tendency to colonize surfaces in a biofilm form makes the cells impervious to therapeutic concentrations of antibiotics. Because its natural habitat is the soil, living in association with actinomycetes and molds, it has developed resistance to a variety of their naturally occurring antibiotics. Moreover, *Pseudomonas* maintains antibiotic resistance plasmids and resistance transfer factors (Todar, 2003), and it is able to transfer these genes by means of the bacterial processes of transduction and conjugation.

It is clear that *P. aeruginosa* is an effective pathogen, and there is little doubt that it can be waterborne. What remains to be established is if drinking water is an important means of transmission for any disease associated with this organism. The organism is not only versatile but virtually omnipresent. It is not clear that removing the organism from drinking water would significantly reduce the exposure of the human population to its aggressive activity.

Since the terrorist attacks on the United States on September 11, 2001, water utilities have a special interest in understanding organisms that might be considered in attempts to sabotage water systems, particularly when the objective is to create fear in the population. Although most serious bioterrorism efforts have focused on aerosols as delivery systems, there is also reason for concern that all, or a portion of, the municipal water system could be used to affect a large part of the population. The ideal pathogen for this use would be one that has an extremely low infectious dose (see Fig. 3-6), a very high mortality rate (see Fig. 3-8), and a high resistance to disinfectants. Organisms with a high mortality ratio include some of the classic waterborne pathogens, such as *V. cholerae* and *S. typhi*, but also some organisms less commonly associated with water, such as *B. anthracis* (anthrax) and *F. tularensis* (rabbit fever). None of these is outstanding where infectious dose is concerned. Some of their characteristics are summarized in Table 3-6 and a brief discussion of *B. anthracis* and *F. tularensis* follows.

#### **BACILLUS ANTHRACIS**

*Bacillus anthracis* is a gram-positive, nonmotile bacillus typically having squared ends. *Bacillus anthracis* produces an endospore, easily seen via methylene blue or India ink stains. Capsule formation differentiates *B. anthracis* and other nonpathogenic bacilli. The endospores are ellipsoidal, located centrally in the sporangium. The spores refract light and resist staining. *Bacillus anthracis* is about 1  $\mu\text{m}$  wide and 3  $\mu\text{m}$  long and is

### **Bacteria and Terrorism in Water Supplies**

**Table 3-6**

Bacterial pathogens of interest in terrorism

Bacterium	Size, $\mu\text{m}$	Motile	Normal Habitat	Health Effects in Healthy Persons	Modes of Transmission	Evidence of Waterborne Pathway	Culturable
<i>Bacillus anthracis</i>	1 – 1.2 $\times$ 3 – 5	No	Found in soil habitats	Anthrax	Inhalation or ingestion of spores	Only of interest in bioterrorism	Ordinary nutrient medium
<i>Francisella tularensis</i> A	Small	No	Small mammals	Tularemia (rabbit fever)	Insect bites	Only of interest in bioterrorism	Difficult on standard media; diagnosis by serology

usually straight. Anthrax bacilli form long chains and appear similar to streptobacilli in culture. Anthrax in the spore stage can exist indefinitely in the environment. Optimal growth conditions result in a vegetative phase and bacterial multiplication.

*Bacillus anthracis* forms a capsule that consists of a poly-D-glutamate polypeptide. The capsule protects the organism against the bactericidal components of serum and phagocytes and also against engulfment by the phagocytes themselves. The capsule is important when infection is being established. It is less important during the terminal phase of the disease, which is dominated by the anthrax toxins. Anthrax has been around a long time and is described in the early literature of the Greeks, Romans, and Hindus. The fifth plague described in the book of Genesis may be an early description of anthrax.

The toxic nature of *B. anthracis* was not understood until the mid-1950s. Before then, it was assumed that death was due to blockage of the capillaries, popularly known as the “log-jam” theory. This theory came about because so many bacilli were found in the blood of animals dying of the disease ( $10^9$  bacteria/mL of blood has been observed). Since then it has been demonstrated that, on the order of  $10^6$  cells/mL can result in death of an animal, and the blood of animals dying from anthrax was found to contain a toxin. Finally, injection of the toxin into guinea pigs caused anthrax symptoms. Thus, it was understood that anthrax toxin is important to pathogenesis. The lethal mode of action of anthrax toxin is not completely understood at this time. Anthrax victims appear to die as a result of oxygen depletion, secondary shock, increased vascular permeability, respiratory failure, and cardiac failure. Death frequently occurs suddenly and unexpectedly. The level of the lethal toxin in the blood supply increases rapidly quite late in the disease. It seems to closely parallel the concentration of organisms.

Susceptibility to anthrax varies considerably among animal species. Limited data are available on the dose required for infection. For inhalation, the infectious dose is thought to be on the order of  $10^5$  organisms. There is reason to believe that the infectious dose for the GI tract would have to be substantially higher, but no quantitative information is available. As shown on Fig. 3-6, the infectious dose has been set between  $2 \times 10^5$  and  $10^6$  organisms. There is no evidence of person-to-person transmission of anthrax.

Anthrax ordinarily attacks herbivores (e.g., cattle, sheep, goats, and horses). Pigs are more resistant, as are dogs, cats, and rats. Birds usually are very resistant to anthrax. Buzzards and vultures are not vulnerable to anthrax, but they are thought to transmit the spores. Humans are relatively resistant to cutaneous invasion by *B. anthracis*, but the organisms can infest tears in the skin.

There are two manifestations of the disease that are relevant to exposure through ingestion: oropharyngeal anthrax, a disease where the mouth and throat are infested, and intestinal anthrax, where lesions are found throughout the GI tract.

Oropharyngeal anthrax typically occurs 2 to 7 days after exposure. The lesion at the site of entry into the oropharynx resembles a cutaneous ulcer. Patients with oropharyngeal anthrax may complain of a sore throat and difficulty swallowing. If the disease is allowed to progress unabated, death may result from asphyxiation due to neck edema and/or toxemia.

Intestinal anthrax occurs 2 to 5 days following ingestion. Patients with intestinal anthrax complain of nausea, vomiting, malaise, anorexia, abdominal pain, hematemesis, and bloody diarrhea. The disease is accompanied by a fever.

Primary intestinal anthrax predominantly affects the saclike first section of the large intestine, just beyond the point at which the lower part of the small intestine (ileum) joins the large intestine and produces a local lesion similar to that which results from cutaneous anthrax. In advanced cases, multiple ulcerative lesions are found throughout the GI tract secondary to hematogenous spread. Intestinal anthrax is difficult to recognize, and shock and death may occur 2 to 5 days after onset if it is not properly addressed.

With either disease a malignant pustule develops at the site of the infection. This pustule is a central area of coagulation necrosis (ulcer) surrounded by a rim of vesicles filled with bloody or clear fluid. A hard, black plaque covering an ulcer implying extensive tissue necrosis forms at the ulcer site. Extensive swelling surrounds the lesion. The organisms multiply locally and may spread to the bloodstream or other organs (e.g., the spleen). Dissemination from the liver, spleen, and kidneys back into the bloodstream can result in bacteremia. In bacteremic anthrax, hemorrhagic lesions may develop anywhere on the body. Usually, bacteremia is associated only with inhalation anthrax. Intestinal anthrax results in death in 25 to 60 percent of the cases.

**FRANCISCELLA TULARENSIS**

*Franciscella tularensis* is a small, nonmotile, gram-negative, strictly aerobic, non-spore-forming coccobacilli. *Franciscella tularensis* has been divided into two subspecies: (1) *F. tularensis* biotype tularensis (Type A) and (2) *F. tularensis* biotype palaeartica (Type B). Organisms isolated in North America are usually Type A. They are virulent in both animals and humans. In Europe and Asia, human tularemia isolates are usually Type B and much less virulent.

Tularemia is a zoonosis, also known as rabbit fever or deerfly fever. Natural reservoirs include small mammals such as rabbits, mice, ground hogs (woodchucks), ground squirrels, tree squirrels, beavers, coyotes, muskrats, opossums, sheep, and various game birds. Human-to-human transmission has not been documented. Human infections normally occur through a variety of mechanisms, such as bites of infected arthropods; handling infected animal tissues or fluids; direct contact or ingestion of contaminated water, food, or soil; and inhalation of contaminated aerosols. The infectious dose of *F. tularensis* is so low that examining an open culture plate can cause infection (see Fig. 3-6). The disease, tularemia, was first described in Japan in 1837. Its name relates to the description in 1911 of a plaguelike illness in ground squirrels in Tulare county, California (hence the name tularemia), and the extensive work subsequently done by Dr. Edward Francis, after whom it was subsequently named (*Franciscella tularensis*).

Symptoms of tularemia vary, depending on the route of introduction. In those cases where a person becomes infected from handling an animal carcass, symptoms can include a slow-growing ulcer at the site where the bacteria entered the skin (usually on the hand) and swollen lymph nodes. If the bacteria are inhaled, a pneumonia-like illness can follow. Those who ingest the bacteria may report a sore throat, abdominal pain, diarrhea, and vomiting. Advanced tularemia is accompanied with high fever, acute septicemia, and toxemia. Oral infection results in typhoidlike symptoms. In bites, a local abscess at the site of infection is followed by septicemia followed by rapid spread to the liver and spleen. Thirty percent of untreated tularemia patients die. Symptoms can appear between 1 and 14 days after exposure, typically in 3 to 5 days.

*Franciscella tularensis* is a particularly notorious candidate for biological warfare. During World War II, the Japanese and the United States and its allies all worked on its use for this purpose. The U.S. military stockpiled *F. tularensis* in the late 1960s and then destroyed it in 1973. The Soviet Union continued the production of biological weapons production into the early 1990s, including antibiotic-resistant strains of *F. tularensis*.

### 3-4 Viruses of Concern in Drinking Water

---

Although the existence of viruses has been known for some time and some classic diseases such as smallpox and rabies are known to be of viral origin, less is known about these pathogens when compared to bacteria. Viruses

have a simpler structure than other organisms. All viruses are true parasites in that they are totally dependent on their host for the resources required for survival. Viruses can survive outside of the host, in some instances, longer than bacteria because they do not have metabolic requirements. Viruses of various kinds use animals, plants, bacteria, fungi, and algae as their hosts. The size of the viruses relative to other organisms was shown on Fig. 3-2. A basic virus consists of a core of nucleic acid (either DNA or RNA) surrounded by a protein coat. Some have protective lipid envelopes. Despite this straightforward morphology or, in some ways, because of it, viruses are more host specific. Animal viruses do not infect bacteria and vice versa. Many viruses can infect only one species of another organism.

Because of their small size, viruses could not be detected until the advent of the electron microscope (EM) in 1931. Their presence prior to that time had, however, been postulated, and they were referred to as filterable agents because they would pass through standard filters used to retain bacteria.

Even with the use of the advanced electron microscopic techniques currently available, viruses are still difficult to detect in environmental samples. Except in raw or partially treated wastewaters where their numbers may exceed 10,000 virus units per liter, large-volume sampling and subsequent concentration techniques are required. Even in untreated supplies used for drinking water, where their numbers may reach 1 to 100 units/L, samples of 100 to 1000 L must be processed to achieve significant recovery. Further sophistication is required to identify viruses collected. Given these problems, it is not surprising that definitive association of waterborne viruses with specific disease occurrences is not common. In fact, until recently infectious hepatitis was the only epidemiologically established waterborne viral disease (Grabow, 1968). However, the circumstantial evidence linking viruses to various disease outbreaks is increasingly persuasive. As discussed below, enteric viruses are regularly shed in animal and human feces; they are ubiquitous in untreated surface waters around the world, and although water treatment plants are typically effective in removing incoming viruses, inadequate treatment or temporary breaks in treatment effectiveness can allow some to survive.

Some of the more important characteristics of viruses that are associated with waterborne disease are summarized in Table 3-7. As mentioned earlier, the viruses that cause poliomyelitis and hepatitis A are probably the ones that have been documented to be associated with waterborne transmission for the longest time. But most viruses that infect the GI system are now known to be or are strong candidates for waterborne transmission. These include the viruses just mentioned as well as all the others shown in Table 3-7. For example, poliovirus, coxsackie, echo, and other enteroviruses have been known to be present in wastewater effluent for some time. More recently, rotaviruses, caliciviruses (Norwalk-like viruses or human caliciviruses), and adenoviruses have also been shown to have this association. Finally, the

**Table 3-7**

Characteristics of viruses of interest in water

Species	Type or Strain	Size, nm	Shape	Nucleic Acid <sup>a</sup>	Genome Length, kb <sup>a</sup>

hepatitis E virus is now known to be an important agent of waterborne disease.

### **Nongastrointestinal Viruses**

**POLIOVIRUS**  
Fifty years ago poliomyelitis was one of the most feared diseases in the developed world. To Americans that lived through the age of polio epidemics, the iron lung is perhaps the most profound symbol.

Poliovirus is an enterovirus. The virus appears in three serotypes, of which Type I is the most common cause of the epidemic disease. Humans are the only natural hosts for poliovirus Type I. The infection occurs through oral–fecal contact and the virus is highly contagious.

Today, extensive use of vaccines has greatly reduced the incidence of the disease, even in developing countries. Because the virus has no animal host, it may be possible to eliminate polioviruses entirely through the use of vaccines, as was done for smallpox in 1980. Consequently, the World Health Organization (WHO) has a Global Polio Eradication Initiative underway to accomplish that goal.

The clinical forms of poliomyelitis vary, but the two basic patterns are the minor illness and the major illness (paralytic myelitis). The minor illness, which accounts for 80 to 90 percent of infections, mostly affects young children. The disease is mild and does not involve the central nervous system. Symptoms are a lot like the flu—a slight fever, malaise, headache, sore throat, and vomiting, which develop 3 to 5 days after exposure. Recovery typically occurs within 24 to 72 h.

Symptoms of the major illness include fever, severe headache, stiff neck and stiff back, deep muscle pain, and, occasionally, increased sensitivity of the skin or the sensation that limbs are falling asleep. Often the disease stops at this point, and complete recovery is still the probable outcome.

In other cases, the disease continues, becoming paralytic myelitis, causing loss of reflex in selected locations, weakness on one side, or paralysis of muscle groups, including those required for breathing (hence the iron lung). The major illness sometimes follows the minor illness after a few days of recovery, but, more commonly, the disease proceeds directly, particularly in older children and adults.

In paralytic poliomyelitis, slightly less than 25 percent of victims suffer severe permanent disability, about 25 percent have mild disabilities, and a little more than 50 percent eventually recover with no residual paralysis. The greatest return of muscle function occurs in the first 6 months, but improvements may continue for 2 years.

The virus enters the body through the mouth and begins to multiply in the intestinal tract. Oral transmission is the most common means of contracting the disease, but it can also be contracted by direct contact with a person who is carrying the disease. Ironically, serious poliomyelitis epidemics are a phenomenon of developed countries. Near the turn of the last century, the countries with the highest standards of hygiene suffered most (e.g., United States, Denmark, Australia, Great Britain). Today transmission is most intense where population density is high and sanitation levels are low.

Recognizing that polio is transmitted by the fecal–oral route, waterborne transmission has been suspected for some time. Nonetheless, the proposition was hard to prove at the time when polio was an important epidemic disease in the United States, and definitive results came years after the Salk

vaccine (1954) and the Sabin vaccine (1958). The virus was first found in wastewater in the early 1940s (Kling et al., 1942; Paul et al., 1940; Trask and Paul, 1942). But a clear demonstration of waterborne transmission was accomplished much later (Mosley, 1967). Recently, it has been argued that better understanding of the viruses and their behavior would lead to different conclusions about earlier epidemics as well (Knolle, 1995).

Polio has been eradicated in North and South America, in most northern and southern African countries, in almost all of Eastern and Western European countries. The Western Pacific and China are nearly free of polio. Eradication of the disease in Europe is expected by the time of the publication of this book.

Nevertheless, the disease continues to strike in Africa, southeast Asia, the Indian subcontinent, and the Near East. On the order of 30 countries still report outbreaks with 15 countries reporting a total of 784 confirmed polio cases in 2003. Reservoir countries include Bangladesh, the Democratic Republic of Congo, Ethiopia, India, Nigeria, and Pakistan. A high risk of infection also exists in war-ravaged countries such as Angola, Somalia, and Sudan.

The global effort to eradicate polio stands little chance of success through the use of vaccination alone. Safe water and good sanitation and hygiene practices will be required as well. In an environment where access to new hosts is an uncommon event, the only forms of the virus that will be able to survive are those that do not cause profound symptoms in the host and are able to stay with the host for a long time. In the environments present in today's reservoir countries, opportunities for the virus to gain exposure to new hosts are myriad. In this environment, a seemingly harmless form of the virus loses no advantage in its evolutionary competition by evolving into a form that can cause serious disease. Indeed, there is some evidence that this sort of evolution is taking place in some vaccine strains being used in these countries today (Anonymous, 2001; Cherkasova et al., 2002; Kew et al., 2002; Landaverde et al., 2001).

### HEPATITIS

Hepatitis is an inflammation of the liver sometimes accompanied by jaundice, a yellowish color change of skin and mucous membranes. Hippocrates first described epidemic jaundice. By the eighth century it was known to be infectious, and outbreaks were reported in military and civilian populations in the seventeenth, eighteenth, and nineteenth centuries. Early on it was proposed that the infectious jaundice was caused by a virus. Although there had been some evidence to the contrary, until World War II the disease was thought to be infectious in nature, but, during the war, a number of new outbreaks occurred as a result of vaccinations for yellow fever and measles. As a result, in 1947 MacCallum proposed that hepatitis be classified into two types: Type A—infectious hepatitis—and Type B—serum hepatitis (MacCallum, 1947). The former could be contracted from one individual

to the other via the fecal–oral route, and the latter could be contracted only through direct exposure of the blood serum (e.g., blood transfusion, contaminated vaccines, contaminated drug needles, or anal sex). In the mid-1960s Blumberg found an antigen in Australian aborigines that later turned out to be the antigen for serum hepatitis (Blumberg et al., 1965). Since that time, three more viruses causing serum hepatitis have been identified. They are hepatitis virus Types C, D, and G (Choo et al., 1989; Linnen et al., 1996; Rizzetto, 1977). A second virus, Type E, causing infectious hepatitis was also identified in connection with epidemics occurring in India (Balayan et al., 1983; Tandon et al., 1985). This virus was also connected to contaminated water (Belabbers et al., 1985) and was found in wastewater (Jothikumar et al., 1993).

In summary, several different viruses cause hepatitis. They are the hepatitis virus Types A, B, C, D, E, and G (at this point a consensus has not been developed on the F candidate). All of these viruses cause acute, or short-term, viral hepatitis. The hepatitis B, C, D, and G viruses can also cause chronic hepatitis, in which the infection is prolonged, sometimes lifelong. This response is also consistent with the theory espoused by evolutionary biologists who would argue that serum hepatitis viruses must develop the ability to persist in the host for long periods because the opportunities for transfer from one host to the other are more limited. The virus causing the infectious disease, on the other hand, depends on its transmission characteristics in the environment for survival and would find long persistence in the host a more limited advantage (Ewald et al., 1998).

There have been a number of outbreaks of infectious hepatitis that have been classified serologically as non–Type A. Often these are presumed to have been outbreaks of hepatitis Type E. On the other hand, even using more up-to-date technology, some cases of viral hepatitis still cannot be attributed to the hepatitis A, B, C, D, or E viruses. This “non–A-through-E” hepatitis is sometimes called hepatitis X. The virus causing hepatitis X has not yet been identified, and it is not clear if this form of hepatitis is infectious or not.

Hepatitis A is a well-documented waterborne disease. The first study demonstrating it as a waterborne disease was conducted in 1945 (Neefe and Strokes, 1945), and newer studies using more up-to-date technologies have confirmed those conclusions in subsequent outbreaks (Sobsey et al., 1985). About 23,000 cases of hepatitis A are reported annually in the United States. These represent just under 40 percent of all hepatitis cases reported. Infectious hepatitis usually resolves on its own over a period of several weeks, but some people are asymptomatic (do not show the symptoms of the hepatitis) until the disease is advanced. Hepatitis A is often a mild disease, which explains why it is so widely spread, even in developed countries with safe water and a high standard of living. Hepatitis A has a worldwide distribution occurring in both epidemic and endemic fashion.

Due to the number of asymptomatic carriers, the mild character the disease often exhibits, and the activity of the disease in developed countries, it is clear that good water treatment will not be enough to control this disease. Nevertheless, it does appear that safe water combined with good sanitation and hygiene can keep the disease at very low endemic levels.

Hepatitis E occurs in both epidemic and sporadic-endemic forms, usually associated with contaminated drinking water. Major waterborne epidemics have occurred in Asia and North and East Africa. To date no U.S. outbreaks have been reported for this type of hepatitis. The disease is most often seen in young to middle-aged adults (15 to 40 years old). Pregnant women appear to be prone to severe disease, and high mortality (20 percent) has been reported in this group. Major waterborne epidemics have occurred in India (1955 and 1975 to 1976), USSR (1955 to 1956), Nepal (1973), Burma (1976 to 1977), Algeria (1980 to 1981), Ivory Coast (1983 to 1984), and Borneo (1987). While no outbreak has occurred in the United States, imported cases were identified in Los Angeles in 1987. Serological tests suggest that most U.S. residents have not acquired immunity to hepatitis E, but about 1 to 3 percent of the U.S. population is positive for antibodies. While hepatitis E transmission via contaminated water is well established, transmission from person to person is not common. Considering this and other data, it seems likely that the lower levels in the United States are due to the fact that this virus can be controlled by levels of sanitation infrastructure that are not successful in controlling hepatitis A (Mast and Krawczynski, 1996). Effective water treatment may be the critical component in controlling the spread of this disease.

### **Viral Gastroenteritis**

Diarrhea remains one of the major causes of death in young children. This is especially so in Asia, Africa, and Latin America, where it causes millions of deaths in children under 4 years of age. The main long-term driving forces for high incidence and mortality are unsafe water or inadequate sanitation. The development and operation of much better physical and institutional infrastructure will be required to eliminate these driving forces. The short-term causes are a variety of pathogenic microorganisms. A number of bacteria and protozoa that cause diarrhea have been identified: enterotoxigenic *E. coli*, *Salmonella*, *Shigella*, cholera, other *Vibrio* bacteria, *Giardia* and *Cryptosporidium*, for example. These pathogens account for a large part, but not all of the investigated cases and outbreaks (Lee et al., 2002).

It was not until the seventh decade of the twentieth century that technology was developed that would allow the detection and identification of viruses that cause diarrhea. As a result, an etiological agent could be found for only a limited fraction of gastroenteritis patients. Once these technologies began to develop, researchers began to recognize that a number of viruses were also etiological agents, particularly the rotaviruses and the Norwalk and Norwalk-like viruses (NLVs). Even with some of the causative

agents identified, early techniques, which largely involved the use of electron microscopy, were too expensive for routine use when examining stool specimens collected from outbreaks.

In the following decade more efficient techniques were developed using immunological assays. These techniques were more effective for identifying causative agents so they brought with them new information and new understanding. On the other hand, the materials required to conduct the immunological assay are difficult to obtain. Consequently, outbreaks were still not fully investigated, and a substantial number of cases were still labeled as being of unknown etiology. One of the things the immunological assays did show is that the diversity of NLVs was substantial, and this of course only made the problem more difficult to study and characterize. To some extent, the same is true of the rotaviruses.

During the last decade of the twentieth century, breakthroughs in cloning and sequencing of diarrhea-causing viruses led to the development of sensitive molecular assays, and now information is being gathered at a rapid pace. It now appears that NLVs and rotaviruses cause most outbreaks of viral diarrhea. The rotavirus group appears to cause the majority of incidents in poor countries and the very young, and the NLVs appear to be responsible for the bulk of incidents in the United States and other developed countries (MMWR, 2001), where illness occurs in both adults and children. In an underdeveloped country either of these diseases can be life threatening, primarily as a result of lack of adequate treatment for serious cases.

#### **ROTAVIRUS**

Considering the globe as a whole and the severity of the disease that results, the most important viruses causing diarrhea are probably the rotavirus family. Rotaviruses have been estimated to cause 30 to 50 percent of all cases of severe diarrheal disease in humans. There are several groups of rotaviruses (A through G), but only three groups are of interest in human gastroenteritis: groups A, B, and C. The group A subtypes 1, 2, 3, and 4 are the leading cause of severe diarrhea among infants and children and account for about half of the cases requiring hospitalization. Group A rotaviruses are endemic worldwide. Group B normally infects pigs and rats, but group B rotavirus, also called adult diarrhea rotavirus, has caused major epidemics of severe diarrhea, affecting thousands of people in Asia, the Indian subcontinent, and North Africa. Group C rotavirus has been associated with sporadic cases of diarrhea in children in the United Kingdom and Japan.

The rotaviruses are round particles about 80 nm in diameter having the appearance of little wheels when viewed by electron microscopy (EM) with negative staining—hence the name *rota*. The virus particles enclose double-stranded RNA in two concentric protein shells (capsids). The human virus has been difficult to culture in vitro, although those belonging to group A are culturable with specialized techniques.

Human rotaviruses were once thought to be limited to the group A rotaviruses, whereas other groups (B to E) were thought to be strictly zoonotic. In the early 1980s, millions of people in China became infected in an epidemic of group B rotaviruses (Hopkins et al., 1984). Subsequent to that event, smaller group B outbreaks have occurred. Studies of immunoglobulin pools from Shanghai suggest that the Chinese population had been exposed to this pathogen in the past (Hung et al., 1987). Because group B rotavirus is a common diarrheal pathogen for swine and because all rotaviruses have a segmented genome, they may be somewhat like the influenza virus, capable of antigenic changes through reassortment of genes. Some have suggested that this human group B epidemic came about through changes that allowed the swine virus to reconfigure itself so that it could propagate in the human gut (Bridger, 1988).

The gastroenteritis caused by rotavirus exhibits the symptoms of vomiting, watery diarrhea, and low-grade fever. The disease can range from mild to serious. People are sometimes hospitalized, and in countries with limited infrastructure, it can be fatal, particularly in infants. The incidence of disease peaks among children aged less than 36 months. Children at this age are also at the greatest risk for severe disease, requiring hospitalization. The disease is normally self-limiting, meaning there is no cure beyond the human immune system. Persons with the disease often excrete large numbers of viruses ( $10^8$  to  $10^{10}$  infectious units/mL of feces) and the infective dose is on the order of 10 to 100 infectious units. As a result, the disease is easily transmitted via contaminated hands, food, water, or utensils.

A significant fraction of the population infected with rotavirus is asymptomatic but still excrete infective particles. As a result of this and the virus's low infectious dose, rotavirus infections are nearly ubiquitous. In both developed and undeveloped countries, 95 percent of children are infected by 5 years of age. Although water treatment can help eliminate the most lethal strains, endemic disease appears to continue even in the presence of a full complement of modern sanitation and hygiene practices. Rotavirus persistence may be related to the high level of virus shedding by infected persons (as much as a trillion viruses per gram of feces), the many other routes of fecal–oral transmission, the many different rotavirus strains that infect infants and young children, and the lack of long-lasting immunity resulting from infection. The natural immunity, which appears in the older part of the population, suggests that vaccination may also be a useful tool to achieve effective control of this disease. Vaccine development is well underway but has been set back by the occurrence of unacceptably high rates of bowel obstruction as a complication resulting from immunization (Parashar et al., 1998).

#### **HUMAN CALICIVIRUSES**

The Norwalk and Norwalk-like agents are members of the family Caliciviridae, containing several hundred viruses that have been connected with

waterborne and foodborne outbreaks and share certain common characteristics. Norwalk is the pathogen that was associated with the cruise ship epidemics during the winter of 2002 to 2003. Generally they are small, round structured viruses about 35 to 39 nm in diameter, with about 7.7 kb (kilobase pairs) of single-stranded RNA and a capsid containing one major protein of about 60,000 Da. The taxonomy of the caliciviruses has been systematized recently and now uses a standard nomenclature consisting of A/B/C/D/X/Y/Z. The NLVs consist of two genogroups (GI and GII), each of which contains several subgroups (clusters or clades) of closely related but not identical viruses. The prevalence of NLVs varies in time and place among the two main genogroups and among the clades within them. Genogroup II viruses have predominated in the last several years. Another group of human caliciviruses, the Sapporo-like viruses (SLVs), is genetically distinct and has a lower prevalence than the NLVs. The serological or antigenic relationships among the NLVs remain unclear, but new antigens expressed from cloned capsid genes of these viruses are helping to establish antigenic relationships and the role of immunity in susceptibility to infection. The hepatitis E virus discussed earlier is structurally similar to the members of Caliciviridae, but it is placed in a separate virus family.

The Norwalk and NLVs cause viral gastroenteritis, acute nonbacterial gastroenteritis, food poisoning, and so-called winter vomiting disease. Symptoms are nausea, vomiting, diarrhea (not bloody), and abdominal cramps. Headache and low-grade fever may also occur, but diarrhea and vomiting are relatively prevalent among adults, whereas a higher proportion of children experience vomiting. The infectious dose is low, with perhaps 10 to 100 virus particles constituting a 50 percent infectious dose. The disease has an incubation time of 1 to 2 days and is usually self-limiting in less than 4 days. However, virus shedding can continue for 2 weeks postinfection and after symptoms of illness have disappeared. In contrast to the rotaviruses, this disease primarily affects adults and older children. Children younger than 2 years are affected, although prevalence rates are still uncertain. In the United States, illness is most commonly reported among persons of school age and older. Persons exposed to the disease develop immunity but not a long-lasting one.

The NLVs were first identified in the stool filtrates of a patient with diarrhea using EM in 1972 (Kapikian et al., 1972). Since that time they have been widely associated with both waterborne and foodborne disease. However, some instances associated with contaminated food have also been shown to be related to contaminated drinking water as well (Beller et al., 1997). Norwalk-like agents probably create a low background level of infection in a community until an infected individual contaminates a common source and an outbreak occurs. Although secondary cases can multiply the number of persons affected, outbreaks are generally limited to 1 to 2 weeks.

Like rotavirus A, the Norwalk-like agents are endemic even in the most developed countries probably due to the relatively mild character of the disease and to the large number of asymptomatic carriers, including those who just had the disease and still shed the virus particles, both of which result in more spread of the disease by personal contact.

#### **OTHER VIRUSES IMPLICATED IN GASTROENTERITIS**

Both the rotaviruses and the NLVs have been demonstrated to appear in the feces of patients with gastroenteritis; have been found in wastewater, raw water, and drinking water; and have been tied to specific waterborne outbreaks. There are also other viruses associated with gastroenteritis for which the waterborne connection, though likely, has not yet been clearly proven. Notable among these are the astroviruses and adenoviruses.

##### *Astroviruses*

The astroviruses are members of the family Astroviridae and the genus *Astrovirus*. There are several species, of which seven serotypes have been identified as human astroviruses. Astroviruses are spherical particles about 28 to 30 nm in diameter surrounded by a protein capsid but with no envelope. The name “astro” derives from the fact that the virus particles take on the appearance of a five- or six-pointed star when seen under the electron microscope. Astroviruses have a positive, single-stranded RNA genome with a length of about 7.5 kb. They are fastidious but have been successfully grown in cell culture.

Human astrovirus infections are not yet well understood. The co-occurrence of diarrhea and shedding of astrovirus in feces and the identification of astrovirus in the epithelial cells of diarrhea patients suggest that replication occurs in the human intestine (Phillips et al., 1982).

Low incidence rates of astrovirus infection among young children with diarrhea were verified with early EM studies (Kapikian et al., 1972). The development of enzyme-linked immunosorbent assay (ELISA) and reverse-transcriptase polymerase chain reaction (RT-PCR) have subsequently revealed that astroviruses are strongly associated with viral gastroenteritis in children worldwide (Cruz et al., 1992; Glass et al., 1996; Herrmann et al., 1991; Lew et al., 1991). Human astrovirus serotype 1 is the most predominant serotype worldwide, while serotypes 2, 3, and 4 also appear to be fairly common and serotypes 5, 6, and 7 appear more infrequently.

After exposure, astroviruses typically exhibit a 1- to 4-day incubation period before symptoms occur. The main symptom is typically watery diarrhea, and the disease is usually seen in young children 6 months to 2 years of age. It can also be associated with anorexia, fever, vomiting, and abdominal pain. Astrovirus infections do not normally result in serious dehydration or hospitalization, but individuals experiencing poor nutrition, immunodeficiency, severe mixed infections, or another underlying gastrointestinal disease may experience complications.

Immunity to astrovirus infection is not well understood. Young children and the institutionalized elderly are usually the populations that develop the disease, suggesting that an antibody acquired early in childhood provides protection through adult life and wanes late in life (Glass et al., 1996). Data from the limited studies that have examined the age distribution of astrovirus infection show that the majority of people acquire antibodies by the time they are 5 years of age.

At temperate latitudes, astrovirus infections are more common in the winter, while at tropical latitudes the infections tend to occur during the rainy season. This seasonal pattern of infection is similar to that of rotavirus.

Electron microscopy has long been the method of choice for identification of these viruses, but the technique is too costly and too insensitive for environmental samples. Astroviruses were first observed by EM in stool specimens from infants with gastroenteritis (Appleton and Higgins, 1975; Madeley and Cosgrove, 1975). Using cell culture and more recent molecular techniques, the viruses are frequently found in environmental samples. In data collected for the Information Collection Rule, astroviruses were found in 15 of 29 surface water samples examined using a RT-PCR-nested protocol (Chapron et al., 2000).

Astroviruses are transmitted from person to person by the fecal–oral route. Fecal–oral transmission has been verified by volunteer studies (Kurtz et al., 1979; Midthun et al., 1993). Although most transmission is probably person to person among children, contaminated water and shellfish have given rise to outbreaks. Asymptomatic shedding has also been demonstrated. To date, there has been no clear demonstration of transmission by the water route in the United States, although it is probable that such a demonstration will occur in the future.

#### *Adenoviruses*

Adenoviruses are large, nonenveloped viral particles. They are the only human enteric viruses that contain double-stranded DNA rather than single- or double-stranded RNA. Adenoviruses are widely recognized causes of infections in the lungs, eyes, urinary tract, and genitals, but adenoviruses 40 and 41 are thought to affect the intestines.

Adenovirus particles have been shown to be more common among patients with gastroenteritis than with the general population (Wadell et al., 1986). However, in numerous studies examining the victims of gastroenteritis for the presence of adenovirus types 40 and 41, the viruses have been identified in only a minority of the stools examined (Cruz et al., 1990; De Jong et al., 1993; Grimwood et al., 1995; Jarecki-Kahn et al., 1993; Wadell et al., 1986). Peak incidence of adenovirus particles in stools of diarrhea patients occurs among children less than 2 years of age, but older children and adults may be infected. Infections occur throughout the year with no clear peaks. Incubation is between 3 and 10 days, with shedding

lasting longer than or equal to 1 week. Long-term immunity is thought to be acquired during childhood infection.

Person-to-person transmission is presumably the principal mechanism for the spread of infection. Neither food nor water has been demonstrated as a means of transmission, although adenoviruses have been reported as possible agents in waterborne outbreaks (Kukkula et al., 1997) and adenoviruses have been found in raw and finished drinking water (Chapron et al., 2000; Murphy et al., 1983).

### **Other Viruses Associated with Fecal–Oral Route**

As the name implies, the enteroviruses are regularly found in feces and in wastewater, and all are considered capable of infecting the human gut. There is also evidence of many of these appearing in surface water and groundwater supplies. However, with the possible exception of the poliovirus, there is little conclusive evidence of waterborne transmission based on documented outbreaks. There are a number of possible reasons for this situation. For example, many of these viruses may cause asymptomatic effects or chronic rather than acute disease, where the association of the organism with disease is more difficult to make. They may also be responsible for mild diseases that do not reach the attention of the medical community. In any case, as they are residents of the gut, they are certainly candidates for waterborne transmission. Even if waterborne transmission is not their primary vehicle of transmission, their ultimate elimination will not be accomplished without effective water treatment playing a role. Other possible enteric viruses are parvoviruses, which are small, round, featureless viruses containing DNA. They have been implicated in foodborne illness in the United Kingdom, but their role as waterborne pathogens is uncertain.

## **3-5 Protozoa of Concern in Drinking Water**

---

The protozoans are a group of unicellular, nonphotosynthetic organisms probably derived from various groups of unicellular algae. They are motile, moving via use of flagella (flagellates), amoeboid locomotion (amoeba), or cilia (ciliates). Two other groups of protozoa, the coccidians and the microsporidia, are nonmotile. Several protozoa are parasites transmitted by the fecal–oral route. Protozoan organisms and a description of their associated diseases are summarized in Table 3-8.

Inside the host, parasitic protozoa excystate, meaning “living stages,” such as trophozoites (*Giardia*) and sporozoites (*Cryptosporidium*) are released. Only the hardy resting stages, such as cysts, oocysts, and spores (of microsporidia), can survive outside the host. For some parasites, such as *Giardia*, the life cycle is simple and involves primarily cell division (binary fission) and the formation of cysts. For *Cryptosporidium*, the life cycle of the organism is more complex and includes both asexual and sexual stages.

**Table 3-8**  
Parasitic protozoa that infect humans and that may be of concern in drinking water

Protozoa	Organism	Reservoir	Disease	Transmission	Occurrence
<i>Acanthamoeba castellanii</i>	Trophozoite is amoeba 25–40 $\mu\text{m}$ with thornlike radiations, aerobic, mobile, sluggish, polydirectional. Cyst double-walled 15 – 28 $\mu\text{m}$ polygon.	Warm stagnant water, ponds, power plant cooling ponds	Causes <i>Acanthamoeba</i> keratitis in soft contact lens wearers. Can produce a rare but serious form of encephalitis in immunosuppressed.	Gains entry through abrasions, ulcers, and as secondary invader during other infections.	Ubiquitous phagotroph in aquatic habitat. Rare endoparasite in eye or central nervous system.
<i>Balantidium coli</i>	Trophozoite: Ciliated amoeba (50 – 80 $\times$ 40 – 60 $\mu\text{m}$ ) with two nuclei, a macronucleus and a micronucleus. Cyst: round, 55 $\mu\text{m}$ .	Pigs (primarily), primates, humans	Most asymptomatic. Symptoms, when present: diarrhea, occasionally dysentery, abdominal pain, weight loss. Symptoms can be severe in debilitated persons.	Waterborne transmission tied to poor sanitation or contamination with swine feces; human infection rate is low.	Worldwide. Infections occur more frequently in areas where pigs are raised.
<i>Entamoeba histolytica</i>	Trophozoite: 15–60 $\mu\text{m}$ , avg. 25- $\mu\text{m}$ amoeba with distinct nuclear envelope and small central endosome. Cyst: 10–20 $\mu\text{m}$ , avg. 12 $\mu\text{m}$ , four nuclei, central endosomes.	Humans	Most asymptomatic, occasionally dysentery. Usually limited to GI tract, occasional invasions with serious complications.	Fecal–oral. Fecally contaminated food or water is the primary mode of transmission. Vegetables are a problem in endemic areas.	Worldwide distribution with a higher prevalence in tropical and subtropical countries.

(Continued)

Table 3-8 (Continued)

Protozoa	Organism	Reservoir	Disease	Transmission	Occurrence
<i>Entamoeba dispar</i>	Trophozoite: 15–60 $\mu\text{m}$ , avg. 25- $\mu\text{m}$ amoeba with distinct nuclear envelope and small central endosome. Cyst: 10–20 $\mu\text{m}$ , avg. 12 $\mu\text{m}$ , four nuclei, central endosomes.	Humans	Most asymptomatic, mild diarrhea.	Fecal–oral. Fecally contaminated food or water is the primary mode of transmission. Vegetables are a problem in areas.	Worldwide distribution with a higher prevalence in tropical and subtropical countries.
<i>Giardia lamblia</i>	Trophozoite a single-celled flagellated protozoa (9–21 $\mu\text{m}$ long, 5–15 $\mu\text{m}$ wide, and 2–4 $\mu\text{m}$ thick), “teardrop” shape, contains two nuclei at anterior and five flagella, tumbling motility; forms environmentally resistant cysts in the colon (13 $\mu\text{m}$ long, oval shape, and two nuclei).	Beavers, bears, muskrats, dogs, cats, humans, maybe others	Giardiasis—asymptomatic in most; in some, sudden diarrhea with foul-smelling, greasy-looking stool with no mucus or blood; often abdominal cramps, bloating, fatigue, and weight loss; restricted to upper small intestine with no invasion; normally illness lasts 1–2 weeks; chronic infections can last months to years.	Person-to-person, fecal–oral route; infected food handlers; contaminated water or food.	Worldwide; especially areas of poor sanitation; outbreaks more common in children; waterborne outbreaks common where unfiltered waters are contaminated; childcare centers; traveler’s diarrhea; most frequent cause of nonbacterial diarrhea in North America.

<i>Naegleria fowleri</i>	<p>Three forms: amoeba, cyst, and flagellate.</p> <p>Trophozoites: 7–20-<math>\mu</math>m amoeba with single nucleus, large karyosome, and no peripheral chromatin. Cysts have a single nucleus that is almost identical to that seen in the trophozoite. Morphologically resembles <i>Acanthamoeba</i> spp.</p>	Soil water, decaying vegetation	Primary amoebic meningoencephalitis.	Nasal inhalation with subsequent penetration of the nasopharynx by flagellate form, then transformation to amoeba in brain; exposure from swimming in freshwater lakes.	Worldwide. On the soil, in warm, stagnant bodies of water, lakes, rivers, hot springs, unchlorinated pools, and power plant pools.
<i>Cryptosporidium parvum</i> type 1	Oocyst: ellipsoidal 3–5 $\mu$ m, sporozoite and merozoites: wormlike 10 $\times$ 1.5 $\mu$ m; shizont, microgametes (biflagellated, 5 $\mu$ m), macrogametes.	Humans	Often asymptomatic; symptoms: cryptosporidiosis—diarrhea, abdominal pain, nausea or vomiting, and fever.	Person-to-person, fecal–oral route; common in childcare centers, infected food handlers; contaminated water or food, especially water and vegetables.	Worldwide.
<i>C. parvum</i> type 2	Oocyst: ellipsoidal 3–5 $\mu$ m, sporozoite and merozoites: wormlike 10 $\times$ 1.5 $\mu$ m; shizont, microgametes (biflagellated, 5 $\mu$ m), macrogametes.	Cows, goats, sheep, pigs, horses, dogs, mule deer, humans	Often asymptomatic, symptoms: cryptosporidiosis—diarrhea, abdominal pain, nausea or vomiting, and fever.	Person-to-person, fecal–oral route; common in childcare centers, infected food handlers; contaminated water or food, especially water and vegetables.	Worldwide.

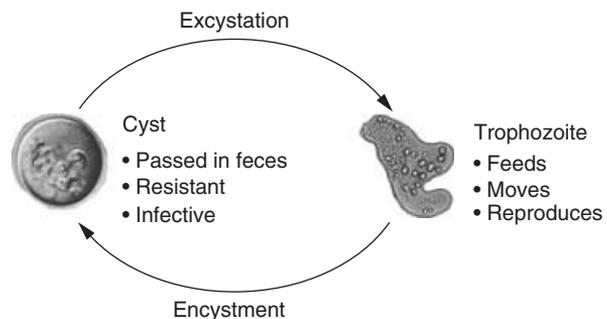

From the standpoint of waterborne disease the organisms of greatest importance are *Entamoeba histolytica*, *Entamoeba dispar*, *Giardia lamblia*, and *Cryptosporidium parvum*.

## Entamoeba

Entamoebas are single-celled parasitic amoeboid protozoa. Trophozoites range in size from 20 to 40  $\mu\text{m}$  in diameter. Sporozoites are spherical cysts measuring 10 to 16  $\mu\text{m}$  in diameter with four nuclei, on rare occasions as many as eight. The morphology of the nuclei is similar in both the trophozoites and the sporozoites. Locomotion is rapid gliding, by means of a single well-defined pseudopodium, often extended explosively, without conspicuous differentiation between ecto- and endoplasm. It is fairly difficult to distinguish between the various species of *Entamoeba*, although such speciation is important because only some species are pathogens.

Humans can be host to at least six species of *Entamoeba* in addition to several amoebae belonging to other genera. However, only one species of *Entamoeba* infecting humans is known to cause a serious disease, *E. histolytica*. If untreated, infections of *Entamoeba* can last for years. Infection is often asymptomatic. The most common symptoms to occur are vague GI distress or dysentery (hence the name amoebic dysentery). Most infections occur in the digestive tract, but other tissues may be invaded. The amoebae's enzymes help it to penetrate and digest human tissues, and it can also secrete toxic substances. Complications include ulcerative and abscess pain and, rarely, intestinal blockage. Onset time is highly variable. Severe ulceration of the GI mucosal surfaces occurs in less than 16 percent of cases. In fewer cases, the parasite invades the soft tissues, most commonly the liver. Only rarely are masses formed (amoebomas) that lead to intestinal obstruction. Fatalities are infrequent.

The life cycle of *Entamoeba* spp. is illustrated on Fig. 3-12. Infection by *Entamoeba* spp. begins with the ingestion of mature cysts from fecally contaminated food, water, or hands. Once they reach the small intestine, the cysts excyst, releasing trophozoites, which migrate to the large intestine. The trophozoites multiply by binary fission and produce cysts with protective walls, which are passed in the feces. The cysts can survive a long time in the

**Figure 3-12**

Basic model of life cycle of protozoan parasites transmitted by oral–fecal route.

external environment and are responsible for transmission. In many cases, the trophozoites remain confined to the intestinal lumen (a noninvasive infection), which is typical of *E. dispar*. Individuals with infections of this kind have no symptoms (asymptomatic carriers); however, cysts are still passed in their stool.

In some patients the trophozoites invade the intestinal mucosa (intestinal disease), resulting in amoebic dysentery. In other patients the trophozoites also travel through the bloodstream to extraintestinal sites such as the liver, brain, and lungs (extraintestinal disease), resulting in serious complications.

In recent years invasive and noninvasive forms of the disease have been associated with two separate species, *E. histolytica* and *E. dispar*. The two species are morphologically indistinguishable.

In 1857, Lösch demonstrated that amoeba can cause dysentery, naming the organism *Amoebae coli*. In 1903, Schaudinn renamed the species that caused the disease Lösch studied to *E. histolytica*. It soon became evident that the vast majority of persons infected with *Entamoeba* spp., did not show the more serious conditions Lösch spoke of, and in 1925 Brumpt suggested that two species be considered, one that caused pathogenic infections (*E. histolytica*) and another whose infections were not pathogenic (*E. dispar*). In the last three decades of the twentieth century, a number of developments made it clear that *E. histolytica* and *E. dispar* are very similar organisms but with different virulence factors (Bhattacharya et al., 2000; Diamond and Clark, 1993; Gilchrist and Petri, 1999; Jackson and Ravdin, 1996).

In recent years a new understanding of this organism has led to the recognition that there are in fact two species within what has previously been known as *E. histolytica*. Of these two organisms, *E. histolytica* is the cause of all invasive disease while the other, *E. dispar*, is not capable of invading tissue. These organisms were previously known as *pathogenic E. histolytica* and *nonpathogenic E. histolytica*, respectively, and these names will be encountered in the literature. The relative prevalence of these two species is not yet fully known, but it is clear that in most parts of the world *E. dispar* is easily the more common of the two. The two species are morphologically identical, and differentiating between the two is accomplished with relatively sophisticated methods: isoenzyme, antigen, and/or DNA analyses.

*Entamoeba* infects predominantly humans and other primates. Other mammals such as dogs and cats can become infected but usually do not shed cysts (the environmental survival form of the organism) with their feces and therefore do not constitute a significant reservoir leading to transmission.

The disease has a worldwide distribution with a higher prevalence in tropical and subtropical countries. Ten percent of the world population carries either *E. histolytica* or *E. dispar*. The infection is not unusual in the tropics and arctics or in any crowded situation with inadequate

water treatment and sanitation/hygiene infrastructure in temperate zone urban environments. *Entamoeba* spp. is also frequently diagnosed among homosexual men.

Amebiasis is transmitted by fecal contamination of drinking water and foods but also by direct contact with dirty hands or objects as well as by sexual contact. Perhaps the most dramatic incident in the United States was the Chicago World's Fair outbreak in 1933 caused by contaminated drinking water. Defective plumbing allowed wastewater to contaminate the drinking water. There were 1000 cases and 58 cases were ultimately fatal. In recent times, food handlers are suspected of causing many scattered infections, but there has been no single large outbreak. In October 1983, the Los Angeles County (California) Department of Health Services was notified by a local medical laboratory of a large increase in the laboratory's diagnoses of intestinal amebiasis (*E. histolytica* infection). Thirty-eight cases were identified from August to October. The laboratory staff estimated that, before August, they had diagnosed approximately one *E. histolytica* infection per month. A preliminary investigation failed to identify a common source of the infection.

### **Giardia lamblia**

A pathogenic flagellated protozoa, *G. lamblia*, is one of the most primitive eukaryotic, or nonbacterial, organisms. It does not have a typical endoplasmic reticulum or Golgi apparatus. The organism has no mitochondria. This lack of mitochondria has been taken as evidence that these organisms existed before the endosymbiosis event. The endosymbiosis event is an important landmark in evolution, which is thought to have occurred 100 million years ago and to have created mitochondria. Organisms created before that event do not have mitochondria. Although *Giardia* lacks these organelles, it still has ways of accomplishing many of the functions these organelles normally serve. *Giardia* has bilateral symmetry, a unique feature among organisms at its evolutionary level.

*Giardia* can exist either as a sporozoite (a cyst) or a trophozoite. As a trophozoite, it takes on a pear-shaped look from the front and a spoon-shaped look from the side. It is about 10 to 15  $\mu\text{m}$  long and 4 to 8  $\mu\text{m}$  wide. It is motile through the use of its flagellum, and its motion is similar to that of a leaf falling or rolling around. The trophozoite has two nuclei and eight flagella (four lateral, two ventral, and two caudal). The nuclei are so placed that, along with the other characteristics of the organism, they give it the appearance of a "monkey face." Another distinctive feature is the special adhesion surface the organism uses to attach to the wall of the intestine (like a suction cup). This adhesive disc is a sophisticated structure with microtubules and microribbons that allow it to firmly attach to the host organism.

As cysts, *Giardia* organisms take on an oval, ellipsoidal, or spherical shape about 11 to 14  $\mu\text{m}$  long and 7 to 10  $\mu\text{m}$  wide. Cysts are not motile but do include flagellar axonemes that lie diagonally across their long axis. When

first formed, the cysts exhibit two nuclei, like the trophozoite. Mature cysts include four nuclei, all displaced to one pole. The life cycle of *G. lamblia* may also be described as shown on Fig. 3-12, except that it is not associated with either of the invasive stages of infection associated with *E. histolytica*.

Members of the genus *Giardia* are found in colonies attached to the intestinal linings of animals (trophozoite), in the feces of infected individuals (cyst form), or in contaminated water (cyst form). They can survive temperature extremes ranging from the internal temperature of an animal body to freshwater down to 4°C.

The two stages in the life cycle of *G. lamblia* are well adapted to survival in the environment. Exposure of cysts to gastric acid during their passage through the stomach activates excystation, although the trophozoite does not emerge from the cyst until it passes into the small intestine. The act of emergence is triggered by the milder pH in the small ileum, the small intestine just downstream of the bile ducts. The emerging parasite quickly divides into two equivalent binucleate trophozoites that use their adhesion surface or foot to attach to and colonize the small intestine. Trophozoites use their four pairs of flagella to swim in the intestinal fluid and also to assist in adhering to mucous strands. They also penetrate the mucous layer to attach to intestinal epithelial cells via their unique adhesive disc. Few other microbes normally colonize the complex and variable environment at the upper end of the small intestine. Trophozoites may continue in the small intestine for weeks to years; however, when they are carried downstream by the flow of intestinal fluid, they take the form of a cyst, as they cannot survive outside the host as a trophozoite.

Infection with *G. lamblia* causes diarrhea and abdominal pain and is implicated in a chronic fatigue syndrome that is difficult to diagnose. Giardiasis is an important contributor to the burden of human diarrheal disease. Nonetheless, the basic biology of this parasite is not well understood. *Giardia lamblia* trophozoites are not invasive and secrete no known toxin; nevertheless, they are capable of causing severe and protracted diarrhea. On the other hand, about half the persons infected with *G. lamblia* do not exhibit any symptoms (are asymptomatic). Also, in normal persons, a *G. lamblia* infection usually resolves spontaneously. Thus, both the duration and symptoms of giardiasis vary in normal people.

There are many species of *Giardia*, and they are named based on their normal host. *Giardia lamblia* (also called *Giardia duodenalis*) inhabits humans, *Giardia muris* inhabits rodents, and *Giardia ardeae* inhabits birds. Only *G. lamblia* can inhabit humans. Parasites from one animal typically exhibit a high degree of host specificity; that is, they cannot infect other animal hosts. For example, humans are not infected by *G. muris*. However, some strains appear to be able to infect more than one host. Specifically, there is evidence to suggest that *G. lamblia* can infect beavers and possibly muskrats as well as humans, making all of these a possible reservoir for

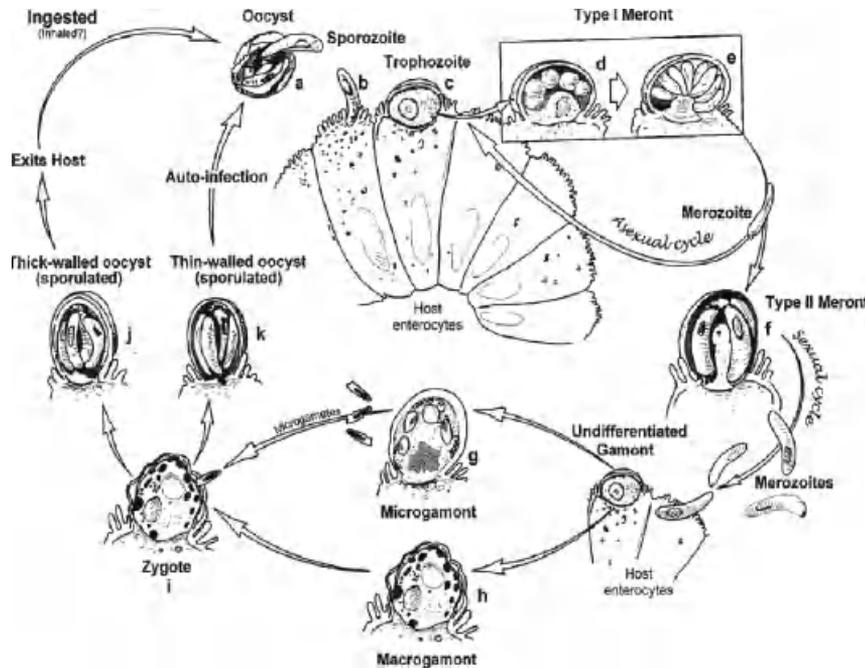

the organism. Other reservoirs of *Giardia* capable of infecting humans are calves and other agricultural animals.

*Giardia lamblia* causes intestinal infection throughout the world. In both industrialized and developing countries, endemic giardiasis is an important cause of illness in children and adults. *Giardia lamblia* cysts have been identified in persons with gastroenteritis numerous times, they are always present in wastewater and, despite the poor quality of analytical procedures, are regularly found in surface water supplies as well. *Giardia lamblia* has also been tied to several outbreaks of waterborne disease around the world. Clearly *G. lamblia* is a pathogen of concern in drinking water treatment. As mentioned earlier, the organism was the principal target of the U.S. EPA's original Surface Water Treatment Rule (U.S. EPA, 1989). However, *G. lamblia* is endemic through both the developed and the developing world and water treatment, while a necessary measure for controlling major outbreaks, will not eliminate the disease entirely. Based on endemic levels in both animal and human populations, this disease organism is likely to be around for a long time.

### **Cryptosporidium**

*Cryptosporidium parvum* is a single-celled protozoan and an obligate intracellular parasite. It infects the epithelial cells on the intestinal wall and travels from one host to the next as an oocyst, excreted in the feces. The infectious agent, or oocyst, is about 3 to 7  $\mu\text{m}$  in diameter, about half the size of a normal red blood cell.

The life cycle of *C. parvum* is illustrated on Fig. 3-13. It is much more complex than the life cycles of the protozoa discussed in the preceding sections because it involves both sexual and asexual developmental stages. Development begins with the ingestion of the sporulated oocyst, the resistant stage found in the environment. Each oocyst contains four infective sporozoites. Sporozoites exit from a suture located along one side of the oocyst. The preferred site of infection is the ileum, the small intestine just downstream of the duodenum and the bile ducts. Sporozoites penetrate individual epithelial cells in this region. The parasites were once thought to just attach to the outside surface of the epithelial layer, but it is now known that they establish themselves inside a membrane containing a thin layer of host cell cytoplasm on the surface of epithelial cells. A unique attachment/feeder organelle, plus accessory foldings of the parasite membranes, develops at the interface between the parasite proper and the host cell cytoplasm. This organelle is called a meront. Multiple fission occurs, resulting in the formation of eight merozoites within the meront. Once the meronts reach maturity, they rupture open, freeing the merozoites. The merozoites are very similar in appearance to sporozoites but represent a different stage of development. Like the sporozoites before them, the merozoites penetrate new cells where they also form additional meronts. In fact, some merozoites develop into meronts of exactly the same type as the sporozoites, with the same outcome. Others form a meront that

**Figure 3-13**  
Life cycle of *C. parvum*.  
(Courtesy of the National  
Centers for Disease  
Control and Prevention,  
National Center for  
Infectious Diseases.)

matures in a different way. This second type of meront (Type II meront) contains only four merozoites, unlike the Type I meronts, which contain eight. When these four Type II merozoites are released, they form two different sexes. Some enter cells, enlarge, and form macrogametes. Others enter cells, undergo multiple fission, and form microgametocytes, which mature to contain 16 nonflagellated microgametes. When they reach maturity, the microgametocytes rupture, releasing microgametes that then seek out and penetrate the macrogametes, mating and forming a zygote. As the zygote matures, a resistant oocyst wall forms around them. Some form a thin wall and others a very thick protective wall. Inside the zygote, meiosis occurs, and four sporozoites are formed in the process. Most of the thin-walled oocysts excyst and continue the cycle in the gut. The thick-walled oocysts are passed into the environment in the feces.

The genus *Cryptosporidium* is a member of the family Cryptosporidiidae, which is assigned to the order Eucoccidiorida and to the phylum Apicomplexa. The parasite infects a wide range of vertebrates, including humans. The species *C. muris* infects the gastric glands of rodents and several other mammalian species but, under normal circumstances, not humans. The species *C. parvum*, however, infects the small intestine of an unusually wide range of mammals, including humans. It is a zoonotic species and is the agent that causes cryptosporidiosis in humans. Although numerous other species of the genus have been described over the years, the majority of

those reported from mammals are synonyms of *C. parvum*. There do appear to be a number of genotypes of *C. parvum* that are more specialized.

Two genotypes of the *C. parvum* species are of special interest. So far genotype 1 (sometimes labeled genotype H for “human”) has only been found to infect humans. Genotype 2 (or genotype C for “calf”) occurs in a wide range of animals, including humans. Genotype 1 tends to be more aggressive in humans. Genetic markers on different chromosomes reveal there is little or no mixing between the genotypes, suggesting that these may actually be two separate species that possess the same morphology. The two isolates have a very different host range, but, at the present time, it is not known if they cause different pathology. Either genotype may cause an outbreak; however, preliminary information suggests that genotype 1 is predominant in human infections, including all seven isolates examined in the 1993 outbreak in Milwaukee.

Although there has been recent success in culturing genotype 1 in piglets and genotype 2 in vitro, virtually all the available data on infectious dose, disinfection resistance, and removal requirements are based on genotype 2 grown in calves. The inability to continuously propagate *C. parvum* in vitro is probably the most significant obstacle to developing a better understanding of the organism. Although genotype 2 isolates can be and have been maintained in calves, in vivo propagation is costly and the separation of the oocysts from the rest of the fecal matter is labor intensive. As a result, information on *C. parvum* in general and of the genotype 1 subgroup in particular is limited.

Symptoms of cryptosporidiosis include diarrhea, a loose or watery stool, stomach cramps, an upset stomach, and a slight fever. A number of persons who are infected have no symptoms (i.e., are asymptomatic). *Cryptosporidium* is a common cause of human diarrhea, although less common than diarrhea caused by human viruses. Severe infections are more common in the young, both in animals and in humans. However, people of all ages are susceptible. Childcare centers, with a large susceptible population, frequently report outbreaks.

Symptoms generally begin between 2 and 10 days after being infected. The intestinal disease is self-limiting in most healthy individuals, with watery diarrhea lasting between 2 and 4 days, the rest of the symptoms lasting no more than 2 weeks. In some outbreaks at childcare centers, diarrhea can persist for nearly a month. Occasionally the patient appears to improve for a few days, then gets worse again, before the illness finally ends.

The widespread use of highly active antiviral therapy (HAART) for patients with HIV, in particular combination therapy with protease inhibitors, has led to an overall decline in the incidence of opportunistic illnesses in persons with HIV infection. Despite this decline, cryptosporidiosis in persons with acquired immunodeficiency syndrome (AIDS) is still common. It is unlikely that HAART will be available to the vast majority of persons with HIV infection who live in countries that cannot afford these

expensive therapies. In the end, a healthy immune system is the only truly effective means of eliminating the parasite.

Some data is available on infectious dose of *C. parvum*. So far these studies have been conducted on the Type 2 organism. The range of the dose to cause infection in 50 percent of the subjects ( $ID_{50}$ ) reported in these studies is from 9 to 1042 oocysts (Okhuysen et al., 1999). Considering that such a high fraction of the isolates from humans have been Type 1, it seems likely that the infectious dose for this organism is on the low end of this range (i.e., *C. parvum* is an effective infectious agent). A conclusion that is consistent with the organism's weak immune defense is explained in the following paragraph.

*Cryptosporidium* appears to make little effort to evade the immune system of the host. Many of the surface proteins, glycoproteins, and phospholipids of *Cryptosporidium* are of such a nature that they stimulate the immune system, and many molecules on the surface of both sporozoites and merozoites will react with two or more different immune responses. To succeed, *Cryptosporidium* must develop rapidly and swamp the intestine with oocysts. In fact, the infectious nature of this parasite is such that, if its stay in the body were prolonged, it would kill the host through dehydration and electrolyte imbalance. This sort of activity might eliminate the host species. Given *Cryptosporidium*'s excellent ability to survive outside the host, evolution favors the strains of *Cryptosporidium* that can get in and get out again quickly, generating a lot of oocysts in the environment without seriously damaging the host.

As the first case of cryptosporidiosis in humans was reported in 1976, *Cryptosporidium* can be considered an emerging pathogen. Since then it has been recognized as a major cause of GI illness worldwide, especially in developing countries and among the immunocompromised. Outbreaks of cryptosporidiosis have been reported in several countries, the most remarkable being a waterborne outbreak in Milwaukee in 1993 that affected more than 400,000 people (Edwards, 1993). Enough surveys have been conducted to gain some idea about prevalence of the parasite among different portions of the human population. Somewhere around 0.4 percent of the U.S. population appears to be passing oocysts in their feces at any one time. Of those patients admitted to U.S. hospitals for diarrhea, 2 to 2.5 percent are reported to pass oocysts. However, the seroprevalence in the population appears to be much higher. Between 30 and 50 percent of the U.S. population have antibodies to *C. parvum*. In developing countries, this measure is higher, between 60 and 85 percent of people in these regions of the world testing positive for *C. parvum* antibodies.

The ability of *C. parvum* to infect such a broad spectrum of warm-blooded animals gives it a tremendous advantage in evolutionary competition. Consider that *C. parvum* Type 2 infects not only humans but also cows, goats, sheep, pigs, horses, dogs, and cats—even wild animals, such as the mule deer. A high environmental concentration of oocysts is expected, given the survival characteristics and broad range of hosts.

However, the numbers of *Cryptosporidium* oocysts reported by various groups from public water samples are not reliable (neither precise nor accurate). Concentration techniques for oocysts in environmental samples are poor, resulting in underestimates, and detection methods often cross-react with algae or other debris, potentially resulting in overestimates. Numerous species and strains of *Cryptosporidium* incapable of infecting humans occur in the environment and may cross-react in diagnostic tests. As a result, laboratories performing diagnostic testing on *Cryptosporidium* oocysts in water have widely varying degrees of reliability (precision and accuracy). Finally, today's methods are not capable of estimating oocyst viability. Many oocysts detected are probably not viable due to age, freezing, sunlight, or other environmental effects that have inactivated them.

*Cryptosporidium* is primarily transmitted from one individual to the other by the fecal–oral route. Oocysts may be found in soil, food, water, or surfaces that have been contaminated with the feces from infected humans or animals. The disease is not spread by contact with blood. As demonstrated by the experience in Milwaukee, but also in many other instances, cryptosporidiosis can be a waterborne disease. Eliminating this route of exposure is important because other measures for controlling the disease cannot succeed if the drinking water route is available. Moreover, as with other organisms, ready transport through the drinking water enables more debilitating forms of the disease to spread more effectively. For example, as better water treatment becomes available, it may be found that Type 1 *C. parvum* is isolated less frequently. However, cryptosporidiosis is the sort of disease that will never be controlled by water treatment alone for the following reasons: (1) unlike many waterborne diseases, it has a large reservoir of infections in the nonhuman mammal population; (2) *C. parvum* has a low infectious dose; it develops a number of asymptomatic carriers who can expose the rest of the population during their period of patency, the period of time when the infected person sheds oocysts in his or her feces; and (3) it is already clear that there are essentially permanent reservoirs in the human population, such as childcare centers, that water treatment will not address.

### Other Protozoa of Concern in Water Supply

*Entamoeba histolytica*, *G. lamblia*, and *C. parvum* are well-established causes of waterborne disease, and all three are a potential risk throughout much of the globe. *Balantidium coli* is also a waterborne pathogen of the conventional fecal–oral route. It is normally associated with exposure to pig wastes contaminating the water supply and is thus a zoonotic disease. The disease is often asymptomatic or takes the form of a mild amoebic dysentery. In immunosuppressed persons, the disease is likely to be more serious. Waterborne outbreaks are rare, but effective water treatment can play an important role in reducing the risks from this route.

*Acanthamoeba castellanii* and *Naegleria fowleri* are both opportunistic pathogens that are virtually ubiquitous in the aquatic environment. These

are not pathogens of the fecal–oral route and the GI system is not their primary target. In both cases, serious infections can occur that involve the central nervous system. *Acanthamoeba*, which is ubiquitous in water, soil, dust, and so on, can result in serious infections for persons using contact lenses but not practicing adequate hygiene. It is not clear that drinking water treatment has much of a role to play in controlling either of these two organisms.

### 3-6 Helminths of Concern in Drinking Water

---

Parasitic worm infections are not a widespread problem in the United States. However, some types do still regularly occur, particularly in southeastern United States. Ascariasis, an infection of the small intestine, occurs worldwide and is still relatively common, especially among children in the southern United States. In more tropical countries and/or in countries with less developed wastewater treatment systems or sanitation practices, certain types of helminth infections are endemic. Schistosomiasis, a disease caused by *Schistosoma* infections of the liver or urinary system, is endemic in parts of Africa and also occurs in the Arabian peninsula, South America, the Middle East, India, and Asia. Fortunately, human schistosomiasis has been eliminated in the continental United States.

Transmission of helminths occurs in a variety of ways: via contaminated drinking water or vegetables and through body contact with contaminated irrigation water, biosolids, and/or soils. Information on some of the common helminths in the United States and worldwide is summarized in Table 3-9. The primary mode of control is through effective treatment and disposal of wastewater or human feces. If contamination of a drinking water supply does occur, conventional treatment will generally remove the helminth eggs, which are denser than water and larger than filter pores. However, some of the adult worm stages can pass through the pores of filters. For schistosomiasis, control of the intermediate snail host population can be effective.

### 3-7 Algae of Concern in Drinking Water

---

Algae play an important role in the rivers, reservoirs, and lakes that serve as surface water supplies, playing a role in the cycling of nutrients, serving as part of the food chain, and influencing the water's flavor. A few algae are pathogenic to humans, producing endotoxins that can cause gastroenteritis. Still others interfere with treatment plant operations, specifically with filter operations.

Discussion of algal roles in nutrient cycling and as the basis of food chains is outside the framework of this text. Complete descriptions of these roles can be found in limnology texts such as Horne and Goldman (1994)

**Table 3-9**

Characteristics of helminths that infect humans

Agent	Hosts	Disease	Transmission	Occurrence
<i>Ascaris lumbricoides</i> (intestinal roundworm)	Humans.	Ascariasis: moderate infections cause digestive and nutritional problems, abdominal pain, and vomiting; live worms passed in stools or vomited; serious cases involving liver can cause death.	Ingestion of infected eggs from soil, salads, and vegetable contaminated with eggs from human feces.	Worldwide: especially in moist tropical areas, where prevalence can exceed 50%; in the United States disease is most common in the south.
<i>Schistosoma mansoni</i> , <i>S. haematobium</i> , <i>S. intercalatum</i> , <i>S. japonicum</i>	Humans, domestic animals, and rats serve as primary hosts; snails act as necessary intermediate hosts.	Schistosomiasis: a debilitating infection where worms inhabit veins of host, chronic infection affects liver or urinary system.	Water infected with larvae that develop in snails; penetration through human skin; eggs excreted via urine or feces and larvae develop in water and reinfect snails.	Africa, Arabian peninsula, South America, Middle East, the Orient, parts of India; in the United States immigrants from Middle East may carry disease.
Various schistosomes	Birds and rodents; humans are nonnormal hosts.	Schistosome dermatitis (swimmer's itch): local skin dermatitis caused by penetration of larvae; larvae die in skin.	Same as previous entry.	Widely distributed but only locally endemic.
<i>Necator americanus</i> or <i>Ancylostoma duodenale</i> (hookworm)	Humans.	Ancylostomiasis: hookworm disease; debilitating disease associated with anemia; heavy infestations can result in retardation; slight infections produce few effects.	Eggs from deposited feces develop into larvae that penetrate the skin; <i>Ancylostoma</i> can be acquired orally.	Widely endemic in moist tropical and subtropical areas where disposal of human feces not adequate.
<i>Strongyloides stercoralis</i>	Humans and possibly dogs.	Strongyloidiasis: intestinal infection causing cramps, nausea, weight loss, vomiting, and weakness; rarely results in death.	Larvae in moist soils with fecal contamination penetrate skin and reach digestive system via venous and respiratory system.	Similar distribution to hookworm.
<i>Trichuris trichiura</i> (whipworm)	Humans.	Trichuriasis: a nematode infection of the large intestine; often without symptoms. Heavy infestations result in abdominal pain, weight loss, and diarrhea.	Ingestion of eggs in soil and/or vegetables contaminated with fecal material.	Worldwide: especially in warm, moist environments.

and Wetzel (2001). The following sections provide an introduction to algal ecology and nomenclature and discuss algae impacts on lake trophic status, taste, and odor and summarize what is currently known about algal endotoxins and indicate some of the problems algae may cause in treatment plant filter operations.

Algae have limited ability to move themselves. Some use flagella or buoyancy mechanisms to achieve limited mobility, a few filamentous forms inhabit shorelines, and some others attach to bottom substrates. However, most are free floating but tend to sink because they are slightly denser than water.

Certain groups of algae, so identified in the past, have been reclassified, based on modern methods of taxonomic analysis. For example, blue-green algae are now classified as cyanobacteria (see Fig. 3-1). Some of the flagellated algae are grouped with the protozoa. All algae, however, are photoautotrophic, using photosynthesis as their primary mode of nutrition and as the basis for synthesis of new organic matter.

The most common algal groups and various members of interest to the water quality engineer are summarized in Table 3-10.

The *trophic level*, or fertility, of a body of water refers to the amounts of nutrients and organic matter being cycled through it. An *oligotrophic* lake is one with a low level of nutrients and organic matter. Often the water in such lakes appears clear and free of plant life. *Mesotrophic* refers to a moderate amount of nutrient input with correspondingly moderate amounts of plant and animal life. A *eutrophic* lake is one through which large amounts of nutrients and organic matter are being cycled and that supports substantial plant life.

Progression of a lake from oligotrophic to eutrophic is a natural occurrence. In principle, every lake eventually becomes filled with organic sediments and plants and becomes dry land. With little external input, such a progression occurs over a long time frame. When nutrient inputs are higher, eutrophication will occur more rapidly.

Algae speciation at these differing trophic levels is largely dictated by each strain's nutrient uptake capabilities and requirements. Some of the major algae groups that might be expected to occur under a given trophic level and set of water characteristics are described in Table 3-11. Seasonal variation in populations, micronutrient levels, and predator-grazing intensity will create shifts in these general trends, but they are useful as a baseline.

It is important to recognize that algae are not responsible for a lake's trophic status. They are merely an indication of the degree of fertilization that has been occurring. Thus, applying copper sulfate to reservoirs to control algae blooms, while it may work in the near term, does not arrest the long-term trend. However, controlling inputs of nutrients such as nitrogen and phosphorus can act to slow the eutrophication process.

## Algae Ecology and Nomenclature

## Algal and Lake Trophic Status

**Table 3-10**

Common algal groups and cyanobacteria and representative members

Group Name	Common Designation	Representative Members
Bacillariophyta	Diatoms	<i>Asterionella</i> , <i>Diatoma cyclotella</i> , <i>Fragilaria navicula</i> , <i>Melosira</i> , <i>Synedra</i> , <i>Tabellaria</i>
Chlorophyta	Green algae	<i>Chlamydomonas</i> , <i>Oocystis</i> , <i>Scenedesmus</i> , <i>Selenastrum</i> , <i>Sphaerocystis</i> , <i>Ulothrix</i> , <i>Volvox</i>
Chrysophyta	Golden algae	<i>Chryso-sphaerella</i> , <i>Dinobryon</i>
Cyanobacteria	Blue-green algae <sup>a</sup>	<i>Anabaena</i> , <i>Anacystis (Microcystis)</i> , <i>Aphanitomenon</i> , <i>Oscillatoria</i> , <i>Spirulina</i>
Dinophyta	Dinoflagellates	<i>Ceratium</i> , <i>Gonyaulax</i> , <i>Noctiluca</i> , <i>Peridinium</i> , <i>Pfisteria</i>
Euglenophyta	Euglenas	<i>Euglena</i> , <i>Trachelomonas</i>
Phaeophyta <sup>b</sup>	Brown algae	<i>Macrocystis pyrifera</i> , <i>Sargassum</i> , <i>Turbinaria</i>
Rhodophyta <sup>b</sup>	Red algae	<i>Chondrus</i> , <i>Corallina</i> , <i>Polysiphonia</i> , <i>Porphyra</i>

<sup>a</sup>Commonly known and identified as blue-green algae, these organisms are now classified as cyanobacteria, based on their taxonomic characteristics. They are included in the above listing because of common usage.

<sup>b</sup>Primarily marine algae.

Source: Adapted in part from Wetzel (2001), Hutchinson (1957), and Internet sources.

Various measures, including analyses of nitrogen and phosphorus, algae activity or productivity, organic carbon, and so on, are used to gauge lake or reservoir trophic status. The ranges of values likely to be cited in identifying such status are summarized in Table 3-12. The first four measures presented in Table 3-12 provide an overall indication of algal activity. Identifying the dominant phytoplankton groups may provide an indication of trophic status. The total phosphorous and total nitrogen measures provide a fairly direct indication of lake productivity, while the remaining three measures, light extinction, TOC, and inorganic solids, are measures that correlate with lake productivity as well as other factors.

### Harmful Algal Blooms

Algal blooms are localized proliferations of algae that occur during periods of optimal growth and reduced grazing pressure. When certain microalgae (especially cyanobacteria) reach high abundance in these blooms, the bloom can take on a harmful character. These microalgal species are a small proportion of nature's repertoire, but they are capable of producing

**Table 3-11**

Characteristics of common major algal associations of phytoplankton in relation to increasing lake fertility

General Lake Trophy	Water Characteristics	Dominant Algae	Other Commonly Occurring Algae
Oligotrophic	Slightly acidic; very low salinity	Desmids, <i>Staurodesmus</i> , <i>Straurastrum</i>	<i>Sphaerocystis</i> , <i>Gloeocystis</i> , <i>Rhizosolenia</i> , <i>Tabellaria</i>
	Neutral to slightly alkaline; nutrient-poor lakes	Diatoms, especially <i>Cyclotella</i> and <i>Tabellaria</i>	Some <i>Asterionella</i> spp., some <i>Melosira</i> spp., <i>Dinobryon</i>
	Neutral to slightly alkaline; nutrient-poor lakes or more productive lakes at seasons of nutrient reduction	Chrysophycean algae, especially <i>Dinobryon</i> , some <i>Mallomonas</i>	Other chrysophyceans, e.g., <i>Synura</i> , <i>Uroglena</i> ; diatom <i>Tabellaria</i>
	Neutral to slightly alkaline, nutrient-poor lakes	Chlorococcal <i>Oocystis</i> or chrysophycean <i>Botryococcus</i>	Oligotrophic diatoms
	Neutral to slightly alkaline, generally nutrient poor, common in shallow Arctic lakes	Dinoflagellates, some <i>Peridinium</i> , and <i>Ceratium</i> spp.	Small chrysophytes, cryptophytes, and diatoms
Mesotrophic or entrophic	Neutral to slightly alkaline, annual dominants or in eutrophic lakes at certain seasons	Dinoflagellates, some <i>Peridinium</i> , and <i>Ceratium</i> spp.	<i>Glenodinium</i> and many other algae
Eutrophic	Usually alkaline lakes with nutrient enrichment	Diatoms much of the year, especially <i>Asterionella</i> spp., <i>Fragilaria crotonensis</i> , <i>Synedra</i> , <i>Stephanodiscus</i> , and <i>Melosira granulata</i>	Many other algae, especially greens and blue-greens during warmer periods of year; desmids if dissolved organic matter is fairly high
	Usually alkaline, nutrient enriched, common in warmer periods of temperate lakes or perennially in enriched tropical lakes	Blue-green algae, especially <i>Anacystis (Microcystis)</i> , <i>Aphanizomenon</i> , <i>Anabaena</i> <sup>a</sup>	Other blue-green algae <sup>a</sup> ; euglenophytes if organically enriched or polluted

<sup>a</sup>Blue-green algae are now classified as cyanobacteria.

noxious or toxic substances that can cause a variety of adverse effects, including food web disruption, animal mortality, and significant human health risk through the consumption of contaminated food and, in at least one case, direct exposure to water or aerosols containing them (Caron et al., 2010). Additionally, in the ocean, the algal biomass itself can be a significant desalination issue, impacting the pretreatment systems and forcing treatment plants to be taken off-line. Blooms of this kind are referred to as harmful algal blooms (HABs). An example of the significance of HABs was the poisoning of cattle and wildlife or contamination of drinking water supplies by blue-green algal toxins from *Nodularia spumigena* (brackish water) and *Anabaena circinalis* and *Microcystis aeruginosa* (freshwater) (Hallegraeff, 1992).

For marine waters, the level of concern regarding HABs has reached a point in the United States where legislation was passed to support research into the problem (HABHRCA, 1998), research that contributed to the development of policies to protect from the adverse effects of coastal HABs (HABHRCA, 2004). No similar strategy exists for freshwater HABs (Hudnell, 2010), but a special White House paper was developed examining the problems of freshwater HABs (Lopez et al., 2008). A comprehensive understanding of the role harmful algal blooms may play in drinking water supplies is not yet available. Information on their health significance can be obtained from the CDC.

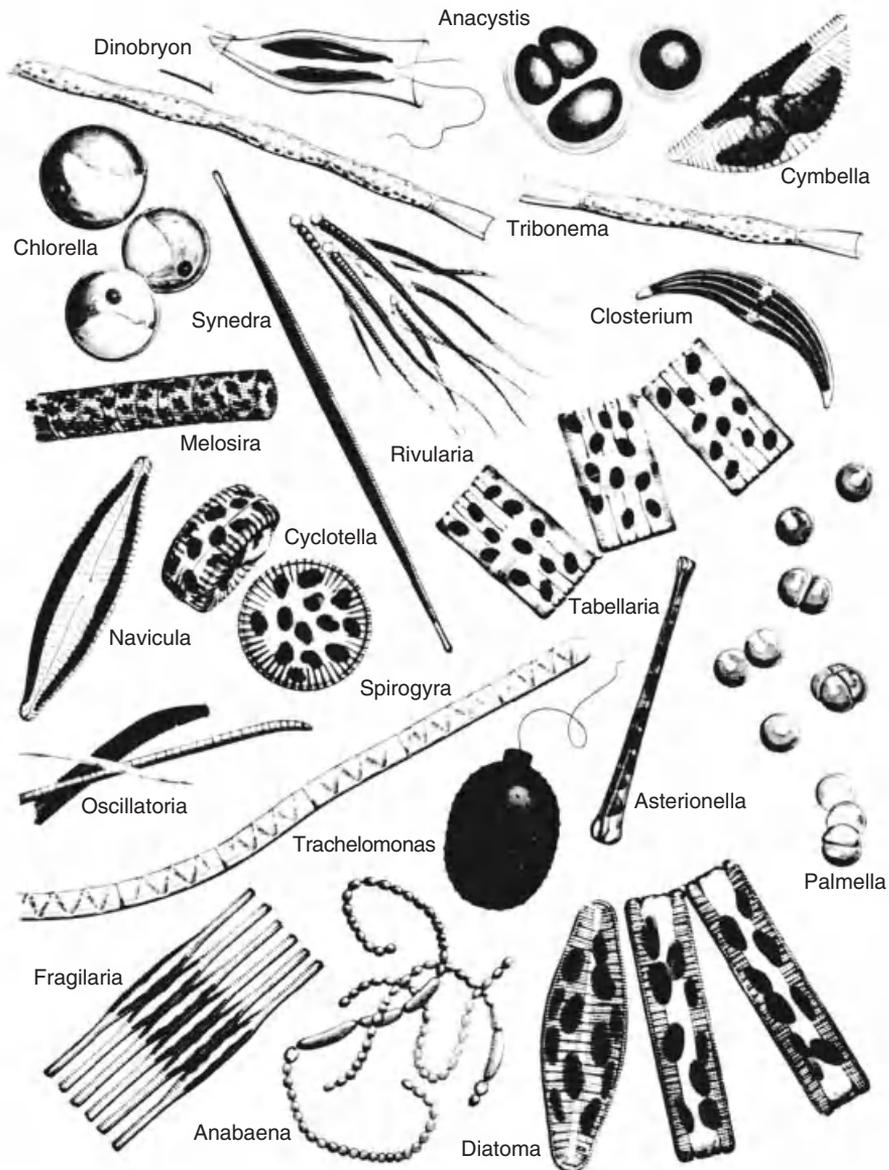

Algae that pass through preliminary treatment processes and become trapped among the spaces in a filter bed can cause gradual or rapid loss of head. Although effective coagulation and sedimentation can remove up to 90 or 95 percent of the incoming algae, the remainder may be sufficient to significantly shorten filter runs, even to the extent that the amount of water required to backwash the filter is greater than the amount of filtered water produced.

Nuisance filter-clogging algae include diatoms whose rigid cell walls prevent easy passage through filter media. Common problem diatoms include *Asterionella*, *Fragillaria*, *Tabellaria*, and *Synedra*. Various members of the blue-green algae, the green algae, and the golden browns also cause problems. *Palmella*, one of the green algae, forms copious mucilaginous material around its cells and literally gums up the filter bed. Some of the more common filter-clogging algae are illustrated on Fig. 3-14.

Enumeration of algae within a water supply can be useful in a variety of contexts. Maintaining regular records of numbers of taste and odor algae can aid a water supply manager in determining when potential problems are likely to occur. The total area, or volume, of algae, especially of diatoms, can aid in establishing a relationship between phytoplankton and length of filter runs. For recreational reservoirs, keeping track of the trophic status via measurement of indicator algae or other parameters (see Table 3-12)

### Algae and Filter Clogging

### Enumeration of Algae in Water Supplies

**Figure 3-14**

Filter-clogging algae (linear magnification in parentheses) (Palmer, 1959): *Anabaena flos-aquae* (500); *Anacystis dimidiata* (1000); *Asterionella formosa* (1500); *Chlorella pyrenoidosa* (5000); *Closterium moniliferum* (250); *Cyclotella meneghiniana* (1500); *Cymbella ventricosa* (1500); *Diatoma vulgare* (1500); *Dinobryon sertularia* (1500); *Fragilaria crotonensis* (1000); *Melosira granulata* (1000); *Navicula graciloides* (1500); *Oscillatoria princeps* (top) (250), *O. chalybea* (middle) (250), *O. splendida* (bottom) (500); *Palmella crebea* (1500); *Tribonema bombycinum* (500).

can help determine appropriate levels of usage for the reservoir. Finally, scanning for wastewater organisms can identify problems of contamination. Over the years, methods for measuring algal concentrations have changed. Before 1970, the standard areal unit was the dominant method for presenting algae concentrations. Since that time, total count and measurements of chlorophyll a have become the dominant methods used. Of these, chlorophyll a is probably the most widely supported. Unfortunately, the methods for measuring chlorophyll a are not well standardized. While it is important to use standard methods so that results can be compared with other utilities to benchmark experience, where algae are concerned, it is perhaps even more important to use consistent methods from season to season or from year to year so that useful comparisons can be made with past experience. Utilities considering changing their methods for algae enumeration should run both the old and new methods in parallel for several seasons or until there is an adequate tie with past experience.

As summarized by Palmer (1959), an adequate routine procedure for treatment plants using surface water supplies would include regular inspection of the raw-water supply, treatment plant, and distribution system for attached growths, floating mats, and blooms. In visible growths, identification and enumeration of dominant organisms should be made. Regular plankton analyses of water samples from these areas should also be made. When supplemented with physical and chemical water quality data, a useful record of algal activity and/or problems can be established.

### 3-8 Assessing the Presence of Pathogens in Source Water

---

One of the most important elements of assessing the viability of a potential water source is collecting and analyzing water samples to gain an understanding of the potential presence or absence of pathogens. Over the past 150 years, our understanding of waterborne pathogens has grown and so has our ability to monitor for indicators of their presence. While progress has been made and new techniques continue to become available, our ability to discern the presence or absence of pathogens still fall short of what we would like to achieve, hence conservative treatment measures are often applied. Coliform bacteria are one of the most widely used indicators of microbiological contamination of source waters, but have a number of limitations. More recently, efforts have been made to include monitoring for *Cryptosporidium* into the framework of assessing the treatment requirements for a particular source water. These topics, as well as the impact of viable but not culturable bacteria, are discussed in this section.

For the first hundred years following Snow's discovery, the public health community placed particular emphasis on controlling the transmission of waterborne bacterial enteric diseases through the drinking water supply, especially cholera and typhoid fever. As high as the infectious dose is for

**Use of Coliform  
as an Indicator  
of the Presence  
of Wastewater**

these organisms (see Fig. 3-6), it is still low enough that directly monitoring for their presence or absence in drinking water was unlikely to achieve a satisfactory outcome. As a result, efforts were made to develop an index of contamination. The index developed was based on *E. coli*, a small bacillus discovered by Escherich (1885) of Germany. *Escherichia coli* is plentiful in the feces of warm-blooded animals, approximately 1 billion per gram. Not long thereafter, Theobald Smith, with the Department of Health for the State of New York, used fermentation culture tubes to develop a presumptive test for the coliform group, of which *E. coli* is an important member (Smith, 1893). Shortly thereafter, the State of New York employed the technique to demonstrate that fecal contamination of the Mohawk River, a tributary of the Hudson River, had caused typhoid fever in persons drinking water from the Hudson downstream of the confluence of the two rivers (Mason, 1891).

In 1914, the U.S. PHS used Smith's fermentation tube test to set a standard requiring that drinking waters show evidence that members of the coliform group were not present. Technically speaking, the U.S. PHS standard was only applied to waters transported across state boundaries, but before long the test became a standard across the United States [American Public Health Association (APHA), 1965]. In the early 1940s, researchers at the U.S. PHS published two landmark articles demonstrating that *E. coli* densities in wastewater were correlated with those of waterborne pathogens (Kerr, 1943) and that *E. coli* is more resistant to disinfection and environmental exposure than several other pathogens (Wattie and Butterfield, 1944). This work greatly solidified the role of the coliform index as a means of confirming that a raw-water supply was not impacted by wastewater and also for determining if treatment had been successful.

As soon as the germ theory of disease became widely accepted and scientists began to use light microscopes to identify the bacteria causing disease, it became evident that certain diseases were caused by organisms that were not visible, even to the light microscope. For example, it had long been recognized that poliomyelitis was transmitted via the fecal–oral route. In the 1940s, several investigators confirmed that the virus responsible for this disease could be found in wastewater (Kling et al., 1942; Melnick, 1947; Paul et al., 1940; Trask and Paul, 1942). As early as 1945, an epidemic of infectious hepatitis was attributed to contaminated drinking water (Neeffe and Strokes, 1945). Though the proposition that viruses are a cause of waterborne disease was not widely accepted at the time, it gradually became so, and by the mid-1960s a review of waterborne outbreaks of disease cited 50 outbreaks of infectious hepatitis and 8 outbreaks of polio during the period of 1946 through 1960 (Weibel et al., 1964). About that same time it also became clear that, outside of the host, viruses are not living organisms and do not have metabolic activity. This supported earlier observations that, under certain conditions, viruses can survive in the environment much longer than members of the coliform group (Neeffe and Strokes, 1945). This observation raised serious questions about the suitability of

coliform as an indicator. The presence of coliforms could still be taken as an indicator of contamination, but the absence of coliforms could not be taken as assurance that the water was uncontaminated.

During the last two decades of the twentieth century, the protozoa *G. lamblia* and *C. parvum* were also identified as waterborne pathogens. These organisms form cysts (*Giardia*) or oocysts (*Cryptosporidium*) that survive much longer in the environment and show much greater resistance to virtually all chemical disinfectants, particularly free and combined chlorine. Some strains of these organisms are also zoonotic; that is, they are pathogenic to humans and can proliferate in other animals as well. Because *G. lamblia*, *C. parvum*, and other zoonotic pathogens can be present in source waters that have no exposure to wastewater, these organisms further undermine the utility of the coliform index. Today, the measurement of coliforms is still valuable, but it must be supplemented by other measures of microbiological safety.

From the beginning it was recognized that the coliform group included organisms that are not of fecal origin. As a result, methods continuously evolved to be more specific for the original target organism. A couple of the most significant developments were the fecal coliform test (Geldreich, 1966) and the MUG (a growth medium, 4-methylumbelliferyl- $\beta$ -D-glucuronide) test (Shadix and Rice, 1991). The fecal coliform test uses higher temperatures to select for thermotolerant members of the coliform group, eliminating those that cannot survive in the warm conditions of the mammalian gut. The MUG test specifically identifies *E. coli* itself, based on the action of the enzyme  $\beta$ -glucuronidase.

Finally, even the suitability of *E. coli* has been questioned in certain tropical climates where natural environmental conditions are occasionally adequate to support the organism's growth in the natural environment (Bermudez and Hazen, 1988; Fujioka et al., 1999; Hardina and Fujioka, 1991; Hazen et al., 1987).

The U.S. National Academy of Sciences (NAS) recently reviewed the indicator issue (NAS, 2004), and it concluded that no one indicator organism could be found that is suitable for all the purposes for which the coliform organism has been employed in the past. Rather the NAS recommended that a phased approach of flexible design be employed where a separate indicator or indicator system would be used for each circumstance. For example, *E. coli* might still be used in temperate climates as an indicator of contamination with fecal bacteria, but in tropical climates the results should be corroborated with another indicator such as *C. perfringens* (Fujioka, 2001; Fujioka et al., 1999). Moreover, the absence of *E. coli* cannot be taken as proof that source water is safe. Other indicators must be used to confirm the absence of more long-lived contaminants such as the viruses, cysts, and spores. In a similar fashion, whereas the presence of *E. coli* can be taken as an indication of fecal contamination in groundwaters, coliphage (a virus that infects *E. coli*) should also be sampled so that viruses, which are known to

have longer survival in groundwater, can be detected. Whereas the absence of *E. coli* can be taken as confirmation of the performance of advanced wastewater treatment in removing bacteria, the absence of coliphage could also be a useful component of an indicator system designed to evaluate the removal of viruses by processes such as membrane filtration or reverse osmosis (Adham et al., 1999). The NAS also discussed the application of biomolecular methods and raised the possibility that, with further development, these could lead to direct monitoring of the pathogens themselves. These monitoring systems show the promise of significantly reducing the response time required for obtaining an answer, but at the present time most are only suitable for analyzing a very small sample size. A great deal of research remains to be done on the question of concentrating samples so that pathogens can be detected at low concentrations.

### **Viable But Not Culturable Bacteria**

When van Leeuwenhoek first observed microorganisms in the seventeenth century, those that were in motion were obviously alive. For those that did not move, more information was required. Since the work of Pasteur and Koch in the late nineteenth century, growth-in-culture techniques have been the gold standard for evaluating the presence of viable organisms. In recent years, however, there has been increasing discussion of the concept of viable but nonculturable bacteria. The term, “viable but nonculturable” (VBNC) was first introduced by Oliver (Oliver, 1993; Oliver et al., 1991) to describe organisms that are alive but cannot be cultured in a laboratory using current techniques. A long-standing need in microbiology is a technique for a broad-spectrum measure of the total microbiological burden in the water (i.e., a total count of viable organisms).

When faced with the challenge of finding the total count of viable organisms, traditional culture-based methods have a serious, long-recognized shortcoming. The media used to support growth are inherently selective, that is, only a subset of the population of “viable” organisms will grow on any one media, at any one temperature. In fact, some culture-based methods are specifically designed to be highly selective, targeting one particular organism or group of organisms (e.g., the MUG method for *E. coli*) while others are designed to target a broad group of organisms (e.g. the methods for heterotrophic plate count). But no single culture method is suitable for a total viable count and some viable organisms have never been successfully grown in culture.

Others also argue that some bacteria can be present in the environment in a dormant or vegetative state and, though they may be sufficiently viable to reproduce over adequate time under the right conditions (e.g., in a host), they may not respond in culture, even when the culture techniques are those that are commonly used to detect their presence.

There is little controversy on the first point, that culture-based techniques are inherently selective and, as a result, they are not a suitable approach for determining the total count of viable bacteria in a water sample. Thus

research aimed at finding a means to obtain a “total viable count” will continue.

The second point, that organisms for which culture methods are available may be present in the environment in a vegetative state from which they can recover (in a host, but not in a culture), is more controversial. Some researchers argue that organisms that do not respond in culture can be viable, while others argue that they are dead. Nevertheless credible work has been done to support the viable-but-not-culturable idea (Oliver, 1993).

Most research directed toward developing a technique for a total viable count has explored direct methods using microscopic observations. These techniques have been labeled “direct viable count” (Rozak and Colwell, 1987; Yokomaku et al., 2000). However, there has also been criticism of these methods (NAS, 2004; Yokomaku et al., 2000). The fundamental problem is the one faced by van Leeuwenhoek so many years ago, that it is difficult to distinguish between viable and nonviable organisms through a microscope. Thus, direct count techniques often count debris (Zweifel and Hagstrom, 1995). Nevertheless, increasingly sophisticated techniques for direct viable count are becoming available, using new methods such as polymerase chain reaction (PCR), reverse transcriptase PCR (RT-PCR), and nucleic acid sequence-based amplification (NASBA) to label organisms so that the observer (often with a flow cytometer or an automated size analyzer) can better distinguish between viable and nonviable organisms. A recently developed direct bacterial count (DBC) technique using epifluorescence and a new nucleic acid stain SYBR Green I (Noble and Fuhrman, 1998) has been widely used to examine VBNC in marine samples.

Small VBNC bacteria may be particularly relevant in seawater because few nutrients are present, particularly in the Pacific (MacDonell and Hood, 1982), and some evidence suggests that many organisms, particularly marine organisms, enter into a viable but nonculturable state as a defense to starvation conditions—similar to other organisms forming spores or mammals hibernating. *Vibrio vulnificus* and *V. cholerae* are often cited for this behavior (Oliver et al., 1991). Some evidence indicates that, when they are in a starvation state, these organisms can also be extremely small, 0.2  $\mu\text{m}$  and smaller (MacDonell and Hood, 1982). At this size, they may be difficult to remove by filtration, even membrane filtration (Ghayeni et al., 1999). Once exposed to a suitable environment, they may recover and form a biofilm (Winters, 2006).

## Problems and Discussion Topics

---

- 3-1 Based on your reading of this chapter provide brief answers to the following questions: (a) For what contribution is Carl Woese known? (b) What are the distinguishing features of the three domains in the phylogenetic tree of life? (c) What sequence of events led to the first observation of a bacteria through the microscope?

## 3 Microbiological Quality of Water

- 3-2 What is the unique property of a pathogen?
- 3-3 Estimate the mass-based infectious dose for *B. anthracis* and adenovirus 4. Use Fig. 3-6 to estimate the median infectious dose and Tables 3-6 and 3-7 to estimate the size of the organism. Assume the specific gravity of both organisms is 1.1.
- 3-4 Construct a diagram similar to Fig. 3-7b for pathogenic *E. coli*. For purposes of constructing the diagram, assume that 50 percent of the persons infected are asymptomatic, 6 percent of those who get ill develop a prolonged illness, and 10 percent of those with a prolonged illness do not survive. Suppose that a town of 10,000 persons is exposed to a dose of this pathogen through the water supply and half the population is infected as a result. How many persons are likely to die as a result?
- 3-5 A town of 10,000 persons has an incident where *S. typhi* is present in its water supply at a level that results in infection of 70 percent of the population. Estimate the number of persons that will die from the disease. Assume that 60 percent of the infected persons are symptomatic (i.e., 40 percent get ill). Estimate the mortality ratio using Fig. 3-8. Repeat the estimate assuming that the incident occurred before antibiotics were available.
- 3-6 A new pathogen evolves in an adult human being that has unusual invasive properties as well as the ability to produce high levels of a serious toxicant. After a week in bed with serious gastroenteritis the patient dies. Using Fig. 3-5, trace the transmission of the pathogen throughout the rest of the population. Consider two cases: (1) No removal occurs at either the wastewater treatment plant or the water treatment plant, and (2) the water treatment plant completely removes the pathogen.
- 3-7 A new pathogen that evolves in a toddler who attends a childcare center generally results in mild or asymptomatic illness—occasional diarrhea. The disease is mild enough that it escapes the notice of the child's caregivers. Using Fig. 3-5, trace the transmission of the pathogen throughout the rest of the population. Consider two cases: (1) No removal occurs at either the wastewater treatment plant or the water treatment plant, and (2) the water treatment plant completely removes the pathogen.
- 3-8 Explain the role of plasmids in the evolution of bacterial pathogens.
- 3-9 What was Dr. John Snow's contribution to our understanding of waterborne disease?
- 3-10 Name and describe the three different forms of gastroenteritis and at least two pathogens associated with each type.
- 3-11 What is the significance of zoonotic disease to water treatment?

- 3-12 Name the three classic waterborne pathogens and describe their effects.
- 3-13 Discuss the different forms of pathogenic *E. coli*. What sort of diseases do they cause?
- 3-14 Besides pathogenic *E. coli*, what was the principal pathogen active in the Walkerton outbreak?
- 3-15 Discuss the emerging pathogens listed in Table 3-5 and the role water treatment can play in preventing the diseases they cause.
- 3-16 Why are *F. tularensis* A and *B. anthracis* considered important candidates for waterborne terrorism?
- 3-17 Draw a diagram similar to Fig. 3-7b for poliomyelitis.
- 3-18 How many types of hepatitis have been identified. Which types are of concern in water treatment and why?
- 3-19 Which viruses are most likely responsible for viral gastroenteritis?
- 3-20 Which species of *Entamoeba* is more invasive?
- 3-21 Which protozoan waterborne diseases have the most serious consequences?
- 3-22 What is the stage in the life cycle when protozoan pathogens are in the environment?
- 3-23 In developed countries highly active antiviral therapy (HAART) is widely available to patients with HIV. What effect has this had on the significance of *Cryptosporidium* as a pathogen for these patients?
- 3-24 Which species of algae are associated with eutrophic water bodies and with oligotrophic water bodies?
- 3-25 What methods are normally used for algae enumeration?
- 3-26 Why was the coliform organism chosen as an index of fecal contamination?
- 3-27 What are the shortcomings of *E. coli* as an index of the presence or absence of pathogens?

# 4 Water Quality Management Strategies

## 4-1 Objectives of Water Treatment

## 4-2 Regulatory Process for Water Quality

- Beneficial-Use Designation
- Criteria Development
- Standards
- Goal Selection

## 4-3 Water Quality Standards and Regulations

- Historical Development
- Development of U.S. EPA Federal Standards and Regulations
- State Standards and Regulations
- International Standards and Regulations
- Focus of Future Standards and Regulations

## 4-4 Overview of Methods Used to Treat Water

- Classification of Treatment Methods
- Application of Unit Processes

## 4-5 Development of Systems for Water Treatment

- General Considerations Involved in Selection of Water Treatment Processes
- Synthesis of Water Treatment Trains
- Treatment Processes for Residuals Management
- Hydraulic Sizing of Treatment Facilities and Processes
- Pilot Plant Studies
- Removal Efficiency and the Log Removal Value

## 4-6 Multiple-Barrier Concept

## Problems and Discussion Topics

## References

## Terminology for Water Quality Management Strategies

---

<b>Term</b>	<b>Definition</b>
Beneficial use	Uses of water that are beneficial to society and the environment. Typically, the identification of beneficial uses is the first step in the regulatory process.
Best available technology (BAT)	Technologies defined by regulation as being suitable to meet the maximum contaminant level.
Criteria, water quality	Water quality criteria, developed by various groups, to define constituent concentrations that should not be exceeded to protect given beneficial uses.
Endocrine disruptors	Substances that interfere with the normal function of natural hormones in the human body.
Maximum contaminant level (MCL)	Enforceable standard set as close as feasible to the MCL goal, taking cost and technology into consideration.
Maximum contaminant level goal (MCLG)	Nonenforceable concentration of a drinking water contaminant, set at the level at which no known or anticipated adverse effects on human health occur and that allows an adequate safety margin. The MCLG is usually the starting point for determining the MCL.
Multiple barrier concept	Inclusion of several barriers (both activities and processes) to limit the presence of contaminants in treated drinking water. Barriers might include source protection or treatment processes.
Nanoparticles	Extremely small particles that range in size from 1 to 100 nm, used in a number of manufacturing operations and products. The implications of these particles for human health and water treatment is not well understood.
Pharmaceuticals and personal care products	Substances used for medical or cosmetic reasons that enter the wastewater system during bathing or toilet use and are now detected at low levels in many water supply sources.
Physicochemical unit processes	Treatment processes used to remove or treat contaminants using a combination of physical and chemical principles.

<b>Term</b>	<b>Definition</b>
Standards	After specific beneficial uses have been established and water quality criteria developed for those beneficial uses, standards are set to protect the beneficial uses. Typically, standards are based on (1) determining the health-based maximum contaminant level goal (MCLG) and (2) setting the maximum contaminant level (MCL).
Treatment train	Sequence of unit processes designed to achieve overall water treatment goals.
Unit process	Individual process used to remove or treat constituents from water.

---

Other terms and definitions are available in the U.S. EPA Terms of Environment: Glossary, Abbreviations and Acronyms. (EPA, 2011).

The previous chapters have dealt with the chemical, physical, and biological characteristics and aesthetic quality of water. In this chapter, the treatment processes used for the removal of specific constituents found in water are introduced. For many constituents, there are a variety of processes or combinations of processes that can be used to effect treatment. The selection of which process or combination of processes to utilize is dependent on several factors, including (1) the concentration of the constituent to be removed or controlled, (2) the regulatory requirements, (3) the economics of the processes, and (4) the overall integration of a treatment process in the water supply system.

The topics considered in this chapter include (1) the objectives of water treatment, (2) a review of the regulatory process for water quality, (3) water quality standards and regulations, (4) an introduction to the methods used for the treatment of water, (5) an introduction to the development of systems for water treatment, and (6) an introduction to the concept of multiple barriers. Individual treatment unit processes, their expected performance, and some of the issues related to the design of the facilities to accomplish treatment of drinking water are examined in detail in the chapters that follow.

## 4-1 Objectives of Water Treatment

---

The principal objective of water treatment, the subject of this textbook, is the production of a safe and aesthetically appealing water that is protective of public health and in compliance with current water quality standards. The primary goal of a public or private water utility or purveyor is to provide

**Table 4-1**

Typical constituents found in various waters that may need to be removed to meet specific water quality objectives<sup>a</sup>

Class	Typical Constituents Found In	
	Groundwater	Surface Water
Colloidal constituents	Microorganisms, trace organic and inorganic constituents <sup>b</sup>	Clay, silt, organic materials, pathogenic organisms, algae, other microorganisms
Dissolved constituents	Iron and manganese, hardness ions, inorganic salts, trace organic compounds, radionuclides	Organic compounds, tannic acids, hardness ions, inorganic salts, radionuclides
Dissolved gases	Carbon dioxide, hydrogen sulfide	— <sup>c</sup>
Floating and suspended materials	None	Branches, leaves, algal mats, soil particles
Immiscible liquids	— <sup>d</sup>	Oils and greases

<sup>a</sup>Specific water quality objectives may be related to drinking water standards, industrial use requirements, and effluent.

<sup>b</sup>Typically of anthropogenic origin.

<sup>c</sup>Gas supersaturation may have to be reduced if surface water is to be used in fish hatcheries.

<sup>d</sup>Unusual in natural groundwater aquifers.

treated water without interruption and at a reasonable cost to the consumer. Meeting these goals involves a number of separate activities, including (1) the protection and management of the watershed and the conveyance system, (2) effective water treatment, and (3) effective management of the water distribution system to ensure water quality at the point of use.

Typical constituents found in groundwater and surface waters that may need to be removed, inactivated, or modified to meet water quality standards are identified in Table 4-1. The specific levels to which the various constituents must be removed or inactivated are defined by the applicable federal, state, and local regulations. However, as the ability to measure trace quantities of contaminants in water continues to improve and our knowledge of the health effects of these compounds expands, water quality regulations are becoming increasingly complex. As a consequence, engineers in the drinking water field must be familiar with how standards are developed, the standards that are currently applicable, and what changes can be expected in the future so that treatment facilities can be designed and operated in compliance with current and future regulations and so that consumers can be assured of an acceptable quality water.

## 4-2 Regulatory Process for Water Quality

Water quality criteria have become an important and sometimes controversial segment of the water supply field. Concern with water quality is based on findings that associate low levels of some constituents to higher incidence

of diseases such as cancer. Following the passage of the Safe Drinking Water Act (SDWA) in 1974 (Public Law 93-523), the principal responsibility for setting water quality standards shifted from state and local agencies to the federal government. Water quality standards and regulations are important to environmental engineers for a number of reasons. Standards affect (1) selection of raw-water sources, (2) choice of treatment processes and design criteria, (3) range of alternatives for modifying existing treatment plants to meet current or future standards, (4) treatment costs, and (5) residuals management.

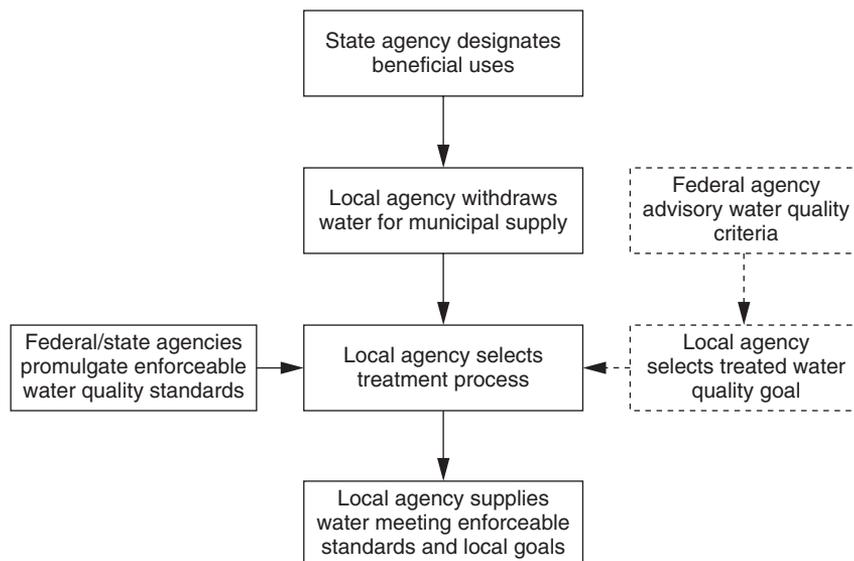

Water quality regulation typically proceeds in the following logical step-wise fashion:

1. Beneficial uses are designated.
2. Criteria are developed.
3. Standards are promulgated.
4. Goals are set.

Although often used interchangeably, there are significant differences in the terms *criteria*, *standards*, and *goals*. However, these items all fit under the general category of water quality regulation. The interrelationships of the various regulatory process steps in determining treatment for drinking water are illustrated on Fig. 4-1.

The first step in the regulatory process is designating beneficial uses for individual water sources. Surface waters and groundwaters are typically designated by a state water pollution control agency for beneficial uses such

### Beneficial-Use Designation

**Figure 4-1**  
Steps in the regulatory process for setting water quality standards.

as municipal water supply, industrial water supply, recreation, agricultural irrigation, aquaculture, power and navigation, and protection or enhancement of fish and wildlife habitat. These beneficial uses are based on the quality of the water, present and future pollution sources, availability of suitable alternative sources, historical practice, and availability of treatment processes to remove undesirable constituents for a given end use.

### Criteria Development

Water quality criteria have been developed by various groups to define constituent concentrations that should not be exceeded to protect given beneficial uses. Until criteria are translated into standards through rule making or adjudication, criteria are in the form of recommendations or suggestions only and do not have the force of regulation behind them. Criteria are developed for different beneficial uses solely on the basis of data and scientific judgment without consideration of technical or economic feasibility. For a single constituent, separate criteria could be set for drinking water (based on health effects or appearance), for waters used for fish and shellfish propagation (based on toxic effects), or for industry (based on curtailing interference with specific industrial processes). The primary data sources used for the development of water quality criteria are discussed below.

#### EARLY PUBLICATIONS DEALING WITH WATER QUALITY

Over the years, a number of publications and reports have been prepared that deal with water quality criteria for various beneficial uses, including drinking water. In 1952, the California State Water Pollution Control Board in conjunction with the California Institute of Technology published a report titled *Water Quality Criteria* in which the scientific and technical literature on water quality for various beneficial uses was summarized. The report was revised in 1963 (McKee and Wolf, 1963) and republished by the California State Water Resources Control Board (McKee and Wolf, 1971). Federal agencies have also developed water quality criteria documents in response to the federal Water Pollution Control Act and SDWA. These documents served as references for judgments concerning the suitability of water quality for designated uses, including drinking water. These references include the following:

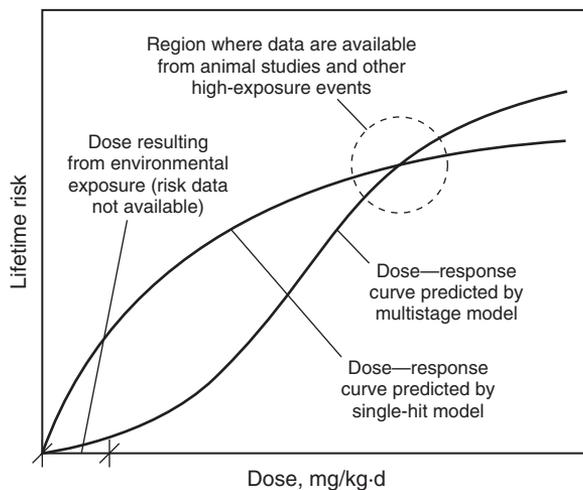

1. *Water Quality Criteria* (U.S. EPA, 1972), National Technical Advisory Committee to the Secretary of the Interior, 1968, reprinted by the U.S. EPA.
  2. *Water Quality Criteria* (NAS and NAE, 1972), prepared by the National Academy of Sciences and National Academy of Engineering for the U.S. EPA.
  3. *Quality Criteria for Water* (U.S. EPA, 1976a), published by the U.S. EPA.
- These three documents are often referred to as the *green book*, the *blue book*, and the *red book*, respectively.

**NATIONAL ACADEMY OF SCIENCES**

The NAS developed a systematic approach to establishing quantitative criteria and made a major contribution to the field of water treatment (NAS, 1977, 1980). The NAS iterated four principles for safety and risk assessment of chemical constituents in drinking water:

1. Effects in animals, properly qualified, are applicable to humans.
2. Methods do not now exist to establish a threshold for long-term effects of toxic agents.
3. The exposure of experimental animals to toxic agents in high doses is a necessary and valid method of discovering possible carcinogenic hazards in humans.
4. Material should be assessed in terms of human risk, rather than as “safe” or “unsafe.”

The NAS divided criteria development into two different methodological approaches, depending on whether the compound in question was believed to be a carcinogen or a noncarcinogen. For carcinogens, the NAS used a probabilistic multistage model to estimate risk from exposure to low doses. The multistage model is equivalent to a linear model at low dosages, as illustrated on Fig. 4-2. In selecting a risk estimation model, the NAS (1980) evaluated a number of quantitative models to describe carcinogenic response at varying dose, which are described in Table 4-2. The difficulty in using any of the models summarized in Table 4-2 is the inability to determine whether predictions of risk at low dosages are accurate. It is not possible to test the large number of animals needed to statistically validate an observed response at low dosage. The effect of model selection on predicted response at low dosages for two different models is also illustrated on Fig. 4-2. On extrapolation to low doses, predicted responses

**Figure 4-2**

Effect of model selection on predicted response at low dosage. (Adapted from NAS, 1980.)

**Table 4-2**

Types of quantitative models used to describe carcinogenic responses at varying doses of constituent of concern

Model Type	Description
Hitness	Based on radiation-induced carcinogenesis, in this model it is assumed that the site of action has some number of critical "targets" and that an event occurs if some number of them are "hit" by $k$ or more radiation particles. Single- and two-hit and two-target models are used most commonly. The single-hit model is similar to the linear, no-threshold model.
Linear, no threshold	Carcinogenic risk is assumed to be directly proportional to dose.
Logistic	A logistic distribution of the logarithms of the individual tolerance is assumed along with a theoretical description of certain chemical reactions.
Probabilistic multistage	Carcinogenesis is assumed to consist of one or more stages at the cellular level beginning with a single-cell mutation, at which point cancer is initiated. The model relates doses $d$ to the probability of response.
Time to tumor occurrence	Unlike the previous models, a latency period is assumed between exposure and carcinogenesis such that higher doses produce a shorter time to occurrence.
Tolerance distribution	Each member of the population at risk is assumed to have an individual tolerance for the toxic agent below which a dose will produce no response; higher doses will produce a response. Tolerances vary among the population according to some probability distribution $F$ . Toxicity tests have frequently shown an approximately sigmoid relationship with the logarithm of dose, leading to development of the lognormal or log probit model. The distribution of $F$ is normal against the logarithm of dose. Modified versions of this model have been developed.

will differ significantly, with values obtained using the single-hit model being the most conservative.

#### *Carcinogenic criteria*

The NAS selected the probabilistic multistage model to estimate carcinogenic risk at low doses because (1) it was based on a plausible biological mechanism of carcinogens, a single-cell mutation, and (2) other models were empirical. For the carcinogenic compounds, the safe level could not be estimated. However, estimates were made such that concentrations of a compound in water could be correlated with an incremental lifetime cancer risk, assuming a person consumed 2 L per day of water containing the compound for 70 years. For example, a chloroform concentration of 0.29  $\mu\text{g}/\text{L}$  corresponded to an incremental lifetime cancer risk of  $10^{-6}$ . Thus, an individual's risk of cancer would increase by 1 in 1,000,000 by drinking 2 L per day of water with 0.29  $\mu\text{g}/\text{L}$  chloroform for 70 years; alternatively, in a population of 1,000,000, one person would get cancer

who otherwise would not have. The NAS provided the criteria to allow correlations of contaminant levels and risks but made no judgment on an appropriate risk level. The latter decision properly falls in the sociopolitical realm of standards setting.

#### *Noncarcinogenic criteria*

For noncarcinogens, data from human or animal exposure to a toxic agent were reviewed and calculations made to determine the no-adverse-effect dosage in humans. Then, depending on the type and reliability of data, a safety factor was applied. This factor ranged from 10 (where good human chronic exposure data were available and supported by chronic oral toxicity data in other species) to 1000 (where limited chronic toxicity data were available). Based on these levels and estimates of the fraction of a substance ingested from water (compared to food, air, or other sources), the NAS method allowed calculations of acceptable daily intake and a suggested no-adverse-effect level in drinking water.

Once designation of water bodies for specific beneficial uses has been made and water quality criteria have been developed for those beneficial uses, the regulatory agency is ready to set standards. It is important to note that water quality standards, in contrast to criteria, have direct regulatory force. Quality standards in the past have been based on a number of considerations, including background levels in natural waters, analytical detection limits, technological feasibility, aesthetics, and health effects.

## **Standards**

### **STANDARD PROMULGATION**

The ideal method for establishing standards involves a scientific determination of health risks or benefits, a technical/engineering estimate of costs to meet various water quality levels, and a regulatory/political decision that weighs benefits and costs to set the standard.

The U.S. EPA is the governmental agency in the United States that is required to establish primary drinking water standards, which are protective of public health. Establishing standards occurs through (1) determining the health-based maximum contaminant level goal (MCLG) and (2) setting the minimum contaminant level (MCL). The MCL is the enforceable standard and is set as close as feasible to the MCLG taking costs and technology into consideration. To make the determination of where to set the MCL, the U.S. EPA gathers and assesses information on the occurrence of the contaminant, analytical methodologies and costs, and treatment technologies and costs in conjunction with the health effects information developed for the MCLG.

#### *Outside peer review*

The National Drinking Water Advisory Council (NDWAC) was created by the SDWA and consists of 15 members (appointed by the U.S. EPA administrator). The NDWA was established to provide the U.S. EPA with

peer review and comment on its activities. In addition, the SDWA requires that the U.S. EPA seek review and comment from the Science Advisory Board (SAB) prior to proposing or promulgating a National Primary Drinking Water Regulation (NPDWR).

*Best available technology*

The SDWA requires that whenever the U.S. EPA establishes an MCL, the technology, treatment technique, or other means feasible for purposes of meeting the MCL must be listed. This approach is referred to as the best available technology (BAT). A public water system is not required to install the BAT to comply with an MCL. However, for purposes of obtaining a variance, a public water system must first install the BAT.

**TREATMENT TECHNOLOGY**

The SDWA provides for establishing a treatment technique instead of specifying an MCL for a given contaminant for which it is not economically or technically feasible to monitor. Examples of treatment technique regulations are the Surface Water Treatment Rule (SWTR) and the Lead and Copper Rule (LCR).

**COMPLIANCE**

Several factors go into the determination of whether a water system is in compliance with a drinking water regulation. For contaminants regulated by an MCL, compliance means (1) using the correct analytical method, (2) following all sample collection and preservation requirements, (3) following the required frequency and schedule for sample collection, (4) reporting sample results to the state and maintaining records onsite, and (5) maintaining measured concentration of the contaminant below the MCL.

For contaminants regulated by an MCL, compliance can be based on a single sample (e.g., when a system is monitored on an annual basis) while in other situations compliance can be based on the average of four quarterly samples.

For treatment techniques, demonstrating compliance can involve meeting operating criteria for the treatment plant (e.g., the SWTR requires water systems to meet a specific turbidity level in the effluent of the treatment plant) or taking certain steps to reduce the corrosivity of drinking water by specific deadlines (as is required under the LCR).

*Reporting and record-keeping requirements*

Public water systems must report compliance information to the state agency with primary enforcement responsibilities (primacy) by specified deadlines. In general, these deadlines are either 10 days after the month in which the monitoring was conducted or 10 days after the monitoring period (e.g., if conducting quarterly monitoring) in which the monitoring was conducted.

In addition to reporting compliance information to the state within specific deadlines, public water systems must maintain records onsite of monitoring results for specified periods of time. For example, under current regulations, public water systems must maintain copies of all monthly coliform reports for 5 years.

#### *Violations, public notification, and fines*

The U.S. EPA issues a notice of violation to a public water system that violates a NPDWR. As described previously, compliance includes (1) meeting the MCL or treatment technique requirements, (2) conducting monitoring at the correct frequency and at the correct locations, (3) using approved analytical methodologies, and (4) meeting all reporting and record-keeping requirements.

When a public water system violates an NPDWR, the system must provide public notification. Such notification may involve notice in a newspaper or for more acute situations could involve radio or television notice. Public notification requirements have evolved since passage of the original SDWA to better take into consideration the seriousness of the violation.

The U.S. EPA may take civil action against a water system or may issue an administrative order for a system in violation of a drinking water regulation. A public water system that is not in compliance with a drinking water regulation faces potential penalties up to \$25,000 per day.

#### *Variances and exemptions*

The U.S. EPA or the state (if the state has primacy) can issue a variance or an exemption from an NPDWR, but only after the BAT has been installed in the water system and the drinking water regulation continues to be violated. The variance must include a schedule of steps to be taken by the water agency to eventually achieve compliance. A state can also grant an exemption from a drinking water regulation if, due to compelling factors, including economics, a system is unable to comply with an MCL or a treatment technique.

Water quality goals represent contaminant concentrations, which an agency or water supplier attempts to achieve. Goals are typically more stringent than standards and may include constituents not covered by regulations but of particular importance to the goal-setting entity. There are two main types of water quality goals in the United States. The first type of goals is the MCLGs that are set by the U.S. EPA and the second type is set by an individual water supplier.

## **Goal Selection**

### **MAXIMUM CONTAMINANT LEVEL GOALS**

The MCLG is a health-based goal for a given contaminant. These goals are nonenforceable and are set at a level at which no known or anticipated adverse effects on human health occur and that provides an adequate

margin of safety. The U.S. EPA has developed different approaches for establishing MCLGs based upon whether a contaminant is considered to be a carcinogen. Typically, short- and long-term animal-feeding studies as well as available epidemiological studies are evaluated in making this determination.

#### **INDIVIDUAL WATER SUPPLIER GOALS**

Water suppliers may set operational goals that are lower than the treatment standards to ensure that the standards are always met. For example, if the turbidity standard is 0.3 NTU, a utility might choose an operating goal of 0.1 NTU to ensure meeting the standard.

Alternatively, an individual water supplier may elect to provide water quality that is better than required by the applicable standards or for constituents that are either not regulated by standards or are secondary standards. Examples include goals for turbidity or THMs in treated water lower than required by regulation or goals for unregulated parameters such as standard plate counts or secondary standards such as odor. Decisions on setting goals involve determinations of costs, benefits, and the overall philosophy or posture of a supplier.

### 4-3 Water Quality Standards and Regulations

---

The specific levels to which the various constituents must be removed are, as noted in the introduction to this chapter, defined by the applicable federal, state, and local regulations. The purpose of this section is to introduce and discuss the evolution of the current federal, state, and international drinking water standards and regulations that govern the design of water treatment plants.

#### **Historical Development**

The development of water quality criteria and standards, at least in a quantifiable sense, is a relatively recent phenomenon in the course of human history. The first standards in the United States were promulgated in 1914, but there have been numerous developments since then, particularly in the last 30 years. Key developments prior to 1900 and the actions of the U.S. PHS in establishing limits that were widely followed voluntarily are reviewed in this section along with the entry of the federal government into a standards-setting role for community water supplies.

#### **EVENTS PRIOR TO 1900**

Based on historical records, water quality standards, except for infrequent references to aesthetics, were notably absent from the time of ancient civilization through most of the nineteenth century. Typically, the sensory perceptions of taste, odor, and visual clarity were used to judge the quality of the supply. The deficiency of this system was clearly pointed out during the London Asiatic cholera epidemic of 1853 when John Snow did

epidemiological investigations tracing cholera to wastewater contamination in the Broad Street Well (Snow, 1855). Even though the well was contaminated, some consumers traveled there specifically because they preferred its water, presumably on the basis of taste, appearance, or smell. From this example, it is clear that standards need to be quantifiable and related directly to measurable water quality contaminants that could have health effects and not just the appearance or aesthetics of a supply.

After the germ theory of disease, developed by Pasteur in the 1860s, was recognized, the issue of drinking water contaminated from wastewater was explored. The earliest quantitative measurements were chemical tests because bacteriological tests were not available until the end of the nineteenth century. Because it was recognized that ammonia and albumoid nitrogen from fresh wastewater were gradually oxidized in receiving water to nitrites and nitrates, these forms of nitrogen were measured in drinking water in an attempt to ensure that contamination, if present, was not recent. However, this method was an indirect measure of bacterial contamination and did not serve to curtail outbreaks of waterborne disease, particularly typhoid, in the United States. The development of a bacterial test for water supplies by Theobald Smith in 1891 (Smith, 1893) made it possible to directly analyze bacterial water quality. In 1892, the New York State Board of Health first applied the technique developed by Smith to study pollution in the Mohawk and Hudson Rivers (Clendening, 1942).

#### **ROLE OF U.S. PUBLIC HEALTH SERVICE**

The U.S. PHS, a part of the Treasury Department, has had an indirect, but nevertheless key role in setting water quality standards in the United States. In 1893 the U.S. Congress enacted the Interstate Quarantine Act authorizing the U.S. PHS to set regulations necessary to stop the spread of communicable diseases. The ability to detect bacteria, coupled with the introduction of chlorine as a disinfectant in 1902, led to the first quantitative water quality standards. In 1914, the U.S. PHS adopted the first standards for drinking water supplied to the public by any common carrier engaged in interstate commerce such as commercial trains, airplanes, and buses. Maximum permissible limits were specified for bacterial plate count and *B. coli* (a coliform bacteria).

Following the entry of the U.S. PHS into the regulatory field, standards development proceeded rapidly. Over the next 50 years, the U.S. PHS developed additional standards for minerals, metals, and radionuclides and standards for the indication of organics with revised standards issued in 1925, 1942, 1946, and 1962 (U.S. PHS, 1962). In 1969 the U.S. PHS conducted the Community Water Supply Survey (CWSS) to assess drinking water quality, water supply facilities, and bacteriological surveillance programs in the United States. The goal of the survey was to determine if drinking water in the United States met the U.S. PHS drinking water standards and to determine what kinds of surveillance programs were in

place. Among other things, the results of the CWSS would play a role in the eventual enactment of the SDWA.

After the initial emphasis on controlling waterborne bacteria, new parameters were added to limit exposure to other contaminants that cause acute effects, such as arsenic, or adversely affect the aesthetic quality of the water. In 1925, a number of aesthetic parameters (color, odor, and taste) were added, along with certain minerals (chloride, copper, iron, lead, magnesium, sulfate, and zinc). Except for lead, these minerals are related to taste or aesthetics. In 1942, a number of constituents were added, including selenium, residue (dissolved solids), turbidity, fluoride, manganese, alkyl benzene sulfonate, and phenols. The latter two compounds marked the first time that specific organic constituents were covered by regulations. In 1946, standards were reissued that were similar to the 1942 standards except that a limit was set for another toxic constituent, chromium.

Following the dawning of the atomic age, the U.S. PHS standards in 1962 included  $^{226}\text{Ra}$ ,  $^{90}\text{Sr}$ , and gross beta activity. Addition of an indicator of organics (carbon chloroform extract) plus additional toxic constituents (cadmium, cyanide, nitrate) reflected an awareness of the rapid postwar development of the chemical industry plus new data on toxicological effects. The last action of the U.S. PHS, before its standards-setting function was transferred to the newly formed U.S. EPA in 1970, was to recommend additional parameters such as pesticides, boron, and the uranyl ion be regulated.

#### **TWO-TIERED SYSTEM**

Another significant feature of the U.S. PHS standards was the development of a two-tiered system, which began in 1925. Water quality contaminants were controlled by either tolerance limits or recommended limits depending on how the effect of the contaminant was viewed. Tolerance limits were set for substances that, if present in excess of specified concentrations, constituted grounds for rejecting the supply; examples included arsenic, chromium, and lead. Alternately, recommended limits were developed for constituent concentrations that should not be exceeded if other more suitable supplies were or could be made available; examples included chloride, iron, and sulfate. This type of differentiation was the forerunner of present regulations, wherein the tolerance limits correspond to primary regulations intended for public health protection and recommended limits are analogous to secondary standards for public welfare or aesthetics.

#### **APPLICATION OF U.S. PHS STANDARDS**

The U.S. PHS standards applied only to suppliers of water engaged in interstate commerce, as the original intent was to protect the health of the traveling public. Thus, standards applied to water used on commercial trains, airplanes, buses, and similar vehicles. However, the U.S. PHS standards became recognized informally as water quality criteria and were

adopted or adapted by many regulatory agencies at the state or local level as standards. Thus, prior to the entry of the U.S. EPA into the role of regulating community water supplies, many water suppliers were producing water in accordance with the levels listed in the U.S. PHS standards (U.S. PHS, 1970). A similar response occurred internationally, with agencies such as the WHO using the U.S. PHS standards as a guideline in developing their own standards (WHO, 1993, 2006). It is clear from reviewing the history of regulations, at least in the United States, that the number of regulated contaminants has continued to increase as (1) toxicological evidence has been gathered and (2) new and improved (e.g., more sensitive) analytical techniques have been developed.

The U.S. EPA was created through an executive reorganization plan where the goal was to consolidate federal environmental regulatory activities into one agency. On July 9, 1970, the plan to create the U.S. EPA was sent by the president to Congress and came into being on December 2, 1970.

The mandate for the U.S. EPA was to protect public health and the environment. As originally created, the U.S. EPA was headed by an administrator supported by a deputy administrator and five assistant administrators responsible for planning and management, legal enforcement, water and hazardous materials, air and waste management, and research and development. By 1974, the U.S. EPA had over 9000 employees with an operating budget of approximately \$500 million and has continued to grow in size and responsibilities since then.

#### **SAFE DRINKING WATER ACT**

The activities of the U.S. PHS related to water quality, as discussed above, were transferred to the newly formed U.S. EPA in 1970. The first major event following the transfer was the passage of the Safe Drinking Water Act (SDWA) on December 16, 1974 (Public Law 93-523). With the passage of the SDWA, the federal government, through the U.S. EPA, was given the authority to set standards for drinking water quality delivered by community (public) water suppliers. Thus, direct federal influence on water quality was authorized, as opposed to the indirect influence exerted by the U.S. PHS.

A series of steps and timetables for developing the drinking water quality regulations were outlined in the SDWA. Procedures were established for setting (1) National Interim Primary Drinking Water Regulations (NIPDWR), (2) revised National Primary Drinking Water Regulations (NPDWR), National Secondary Drinking Water Regulations (NSDWR), and (3) periodic review and update of the regulations. With each step, proposed regulations were to be developed by the U.S. EPA, published in the *Federal Register*, discussed at public hearings, commented upon by interested parties, and revised as necessary before final promulgation. A summary of major U.S. legislation and executive orders related to drinking water treatment is given in Table 4-3.

#### **Development of U.S. EPA Federal Standards and Regulations**

**Table 4-3**

Summary of major legislation and executive orders related to drinking water treatment

Law	Description
Interstate Quarantine Act, 1893	U.S. Congress authorizes the U.S. PHS to set regulations necessary to stop the spread of communicable diseases.
U.S. Environmental Protection Agency, 1970	U.S. EPA is created through an executive reorganization plan whose goal is to consolidate federal environmental regulatory activities into one agency. On July 9, 1970, the plan to create U.S. EPA is sent by the president to Congress, and the agency comes into being on December 2, 1970.
SDWA; Public Law 93-523, 1974	The SDWA requires U.S. EPA to establish drinking water regulations in two phases. (1) Establish National Interim Drinking Water Regulations (NIPDWR) within 90 days of enactment of the SDWA that specify maximum levels of drinking water contaminants and monitoring requirements that would apply to public water systems. (2) Review and revise the NIPDWRs and establish National Primary Drinking Water Regulations (NPDWR).
SDWA amendments; Public Law 99-339, 1986	Requires U.S. EPA to set standards for 83 compounds within 3 years and to establish 25 new standards every 3 years, establish criteria for filtration of surface water supplies, and establish requirements for all public water systems to provide disinfection. Requires that the MCLG and the MCL be proposed and finalized on the same schedule. Bans the use of lead pipes and solder and requires water utilities to go through a one-time public education program notifying consumers of the health effects and sources of lead in drinking water and steps that individuals can take to reduce exposure.
Lead Contamination Control Act; Public Law 100-572, SDWA amendment of 1988	Establishes a program to eliminate lead-containing drinking water coolers in schools.
SDWA amendments; Public Law 104-182, 1996	Requires the U.S. EPA to publish and seek public comment on health risk reduction and cost analyses when proposing an NPDWR that includes an MCL or a treatment technique and take into consideration the effects of contaminants upon sensitive subpopulations (i.e., infants, children, pregnant women, the elderly, and individuals with a history of serious illness) and other relevant factors. Within 5 years evaluate five contaminants from a drinking water contaminant candidate list. Establishes specific deadlines for standards for arsenic (a revised standard from the existing standard), a new standard for radon, a source water assessment and protection program, a requirement for public water systems to distribute Consumer Confidence Reports to their customers, a State Drinking Water Revolving Fund, and a program to develop operator certification requirements.

The SDWA has been amended periodically, as reported in Table 4-3. While the SDWA was amended slightly in 1977 (Public Law 95-190), 1979 (Public Law 96-63), and 1980 (Public Law 96-502), significant changes were made when the SDWA was reauthorized on June 16, 1986 (Public Law 99-339), and amended in 1996 (Public Law 104-182). The amendments of 1986 were driven by public and congressional concern over the slow process of establishing the NPDWR. The 1986 amendments also finalized the original NIPDWR and renamed the interim standards the NPDWR. The amendments enacted in 1996 emphasized the use of sound science and risk-based standard setting, increased flexibility and technical assistance for small water systems, source water assessment and protection programs, and public right to know and established a program to provide water system assistance through a multi-billion-dollar state revolving loan fund.

#### **EVOLUTION OF NATIONAL PRIMARY DRINKING WATER REGULATIONS**

A brief overview of the evolution of the key U.S. federal regulations that affect drinking water is presented in Table 4-4. As reported in Table 4-4, the current regulations for drinking water evolved from the U.S. PHS standards. As required by the SWDA, The National Interim Primary Drinking Water Regulations (NIPDWR), published on December 24, 1975, became effective June 24, 1977. The regulations contained MCLs for a number of inorganic chemicals, organic chemicals, physical parameters, radioactivity, and bacteriological factors. Maximum contaminant levels are set as concentrations that are never to be exceeded (with some minor exceptions). Perhaps the most substantial change of the NIPDWR compared to the U.S. PHS standards was the designation of turbidity as a health-related, rather than an aesthetic, parameter. The original NIPDWRs were amended several times. As noted above, on June 19, 1986 the interim standards established under the NIPDWRs were finalized and renamed the NPDWR.

#### **NATIONAL SECONDARY DRINKING WATER REGULATIONS**

The U.S. EPA has also promulgated secondary drinking water regulations (U.S. EPA, 1979a). The NSDWR pertain to those contaminants, such as taste, odor, and color, that may adversely affect the aesthetic quality of drinking water. These secondary levels represent reasonable goals for drinking water quality but are not federally enforceable; rather, they are intended as guidelines. States may establish levels as appropriate to their particular circumstances.

#### **REGULATIONS RELATED TO CHEMICAL AND MICROBIAL AND CONTAMINANTS AND DISINFECTION BY-PRODUCTS**

The regulations related to: (1) chemical contaminants and (2) microbial and disinfection by products can be found in a number of different rules and regulations. The principal rules and regulations where information can be found on microbial contaminants and disinfection by-products are

**Table 4-4**

Summary of key U.S. federal regulations that affect drinking water

Regulation and date <sup>a</sup>	Description
U.S. PHS standards, 1914 (U.S. Treasury Department, 1914)	The first drinking water standard is established in the United States. The standard establishes a maximum permissible limit for bacterial plate count and <i>B. coli</i> (a coliform bacteria) of 2 coliforms per 100 mL for water supplied to the public by any common carrier engaged in interstate commerce such as commercial trains, airplanes, and buses. These bacteriological quality standards are commonly known as the Treasury Standards.
U.S. PHS standards, revised in 1925, 1942, 1946, and 1962 (U.S. PHS, 1925, 1942, 1946, and 1962)	Bacteriological quality standards are made more restrictive, physical and chemical standards are established, and the principle of attainability is established (1925). Regulates 28 contaminants commonly found in drinking water by setting mandatory limits for health-related chemical and biological impurities and recommends limits for constituents that affect appearance, taste, and odor (1962).
National Interim Primary Drinking Water Regulations (NIPDWR); Pub. <i>FR</i> December 24, 1975; effective June 24, 1977 (U.S. EPA, 1975)	Published in December 1975, these regulations set 18 interim standards for 6 synthetic organic chemicals, 10 inorganic chemicals, turbidity, total coliform bacteria, and radionuclides.
NIPDWR; Promulgation of Regulations on Radionuclides; Pub. <i>FR</i> July 9, 1976; effective June 24, 1977 (U.S. EPA 1976b)	Sets interim standards for radionuclides, gross alpha emitters, <sup>226</sup> Ra and <sup>228</sup> Ra combined, and two other classes of radionuclides. Final standard adopted December 7, 2000 (see below).
National Secondary Drinking Water Regulations (NSDWR); Pub. <i>FR</i> July, 19, 1979 (U.S. EPA 1979a)	Sets nonenforceable guidelines for contaminants that may cause aesthetic problems in drinking water, including aluminum, chlorides, color, copper, corrosivity, foaming agents, iron, manganese, odor, pH, silver, sulfate, total dissolved solids, and zinc.
NIPDWR; Control of Trihalomethanes in Drinking Water; Final Rule; Pub. <i>FR</i> November 29, 1979, effective date varied depending on size of system (U.S. EPA 1979b)	Sets 0.1 mg/L as the MCL for total trihalomethanes (TTHMs).
National Primary Drinking Water Regulations (NPDWR); Pub. <i>FR</i> June 19, 1986, effective June 19, 1986 (U.S. EPA 1986)	Each national interim or revised primary drinking water regulation promulgated before June 19, 1986, shall be deemed to be a national primary drinking water regulation.
NPDWR; Volatile Organic Chemicals (VOCs) Rule—Chemical Phase Rules—Phase I; July 7, 1987, effective 1989 (U.S. EPA 1987)	The chemical contaminants regulated under these rules generally pose long-term (i.e., chronic) health risks if ingested over a lifetime at levels consistently above the MCL.

**Table 4-4** (Continued)

Regulation and date <sup>a</sup>	Description
NPDWR; Filtration and Disinfection; Turbidity, <i>Giardia lamblia</i> , Viruses, <i>Legionella</i> , and Heterotrophic Bacteria; Final Rule; also known as Surface Water Treatment Rule; Pub. <i>FR</i> June 29, 1989 (U.S. EPA 1989a)	Seeks to reduce the occurrence of unsafe levels of disease-causing microbes, including viruses, <i>Legionella</i> heterotrophic bacteria, and <i>G. lamblia</i> . Filtration of surface waters required. Criteria for avoiding filtration, criteria for disinfection based on <i>Giardia</i> and viruses, filtered water turbidity <0.3 NTU for 95% of time.
NPDWR; Total Coliforms, Final Rule; Pub. <i>FR</i> June 29, 1989 (U.S. EPA 1989b)	Sets an MCL with an MCLG of zero for total coliforms and changes the previous coliform MCL from a density-based standard to a presence/absence basis.
NPDWR; Synthetic Organic Chemicals (SOCs) and Inorganic Chemicals (IOCs)—Phase II; Final Rule; January 30, 1991 (U.S. EPA 1991a)	The chemical contaminants regulated under these rules generally pose long-term (i.e., chronic) health risks if ingested over a lifetime at levels consistently above the MCL.
NPDWR; Lead and Copper; Final Rule; Pub. <i>FR</i> June 7, 1991 (U.S. EPA 1991b)	Sets health goals and action levels (trigger for requiring additional prevention of removal steps) for lead and copper (Pb ≤ 15 μg/L, Cu ≤ 1.3 mg/L in 90% of samples at consumer's tap).
NPDWR; Synthetic Organic Chemical and Inorganic Chemicals—Phase V; Final Rule; Pub. <i>FR</i> July 17, 1992 (U.S. EPA 1992)	The chemical contaminants regulated under these rules generally pose long-term (i.e., chronic) health risks if ingested over a lifetime at levels consistently above the MCL.
NPDWR; Monitoring Requirements for Public Drinking Water Supplies or Information Collection Rule; Final Rule; <i>FR</i> May 14, 1996 (U.S. EPA 1996)	Establishes requirements for monitoring microbial contaminants and disinfection by-products by large public water systems and requires these systems to provide operating data and descriptions of their treatment plant design, plus conducting either bench- or pilot-scale testing of advanced treatment techniques. The Information Collection Rule (ICR) is a one-time monitoring effort to gather information for future microbial and disinfection by-product regulations.
NPDWR; Stage 1 Disinfectants and Disinfection Byproducts; Final Rule; Pub. <i>FR</i> December 16, 1998 (U.S. EPA 1998a)	Lowers the MCLs for disinfection by-products (DBPs) to 0.08 mg/L for THMs, 0.06 mg/L for five haloacetic acids (HAA5), 0.10 mg/L for bromate, and 1.0 mg/L for chlorite. Sets requirements for reducing total organic carbon (TOC) in surface water treatment systems based on a 3 × 3 matrix of source water TOC concentration and source water alkalinity.
NPDWR; Interim Enhanced Surface Water Treatment Rule (IESWTR); Pub. <i>FR</i> December 16, 1998 (U.S. EPA 1998b)	Lowers turbidity performance standards, requires 2 log <i>Cryptosporidium</i> removal for filtering and individual filter monitoring for turbidity, and requires disinfection profiling/benchmarking, covering of new finished water reservoirs, and sanitary surveys by the states.

(continues)

Table 4-4 (Continued)

Regulation and date <sup>a</sup>	Description
NPDWR; Final Standards for Radionuclides; Final Rule; Pub. <i>FR</i> December 7, 2000 (U.S. EPA 2000)	This regulation became effective on December 8, 2003, and covers combined $^{226}\text{Ra}/^{228}\text{Ra}$ (adjusted), gross alpha, beta particle, and photon radioactivity, and uranium. This promulgation consists of revisions to the 1976 rule, as proposed in 1991.
NPDWR; Filter Backwash Recycling Rule; Final Rule; Pub. <i>FR</i> June 8, 2001 (U.S. EPA 2001a)	Any system that recycles (spent-filter backwash water, thickener supernatant, or liquids from dewatering processes) must return flows through all processes of the systems exiting conventional or direct filtration plant (or an alternate location approved by the state) by June 8, 2004, plus additional record-keeping requirements.
NPDWR; Arsenic and Clarifications to Compliance and New Source Contaminants Monitoring; Final Rule; Pub. <i>FR</i> January 22, 2001, effective February 22, 2002 (U.S. EPA 2001b)	Arsenic MCL is lowered from 50 to 10 ppb. Systems must comply by January 23, 2006.
NPDWR; Long Term 1 Enhanced Surface Water Treatment Rule (LT1ESWTR); Pub. <i>FR</i> January 14, 2002, effective February 13, 2002 (U.S. EPA 2002a)	The purposes of the LT1ESWTR are to improve control of microbial pathogens, specifically the protozoan <i>Cryptosporidium</i> , in drinking water and address risk trade-offs with disinfection by-products. The rule will require systems to meet strengthened filtration requirements as well as to calculate levels of microbial inactivation to ensure that microbial protection is not jeopardized if systems make changes to comply with disinfection requirements of the Stage 1 D/DBP Rule. The LT1ESWTR builds upon the framework established for systems serving a population of 10,000 or more in the IESWTR. Regulated entities must comply with this rule starting March 15, 2002.
NPDWR; Stage 2 Disinfectant and Disinfection Byproduct; Final Rule; proposed in 2002, Pub. <i>FR</i> January 4, 2006 (U.S. EPA 2006a)	DBP compliance method to change to be specific to each sampling location rather than systemwide and to select compliance points through an initial distribution system evaluation.
NPDWR; Long Term 2 Enhanced Surface Water Treatment Rule (LT2ESWTR); proposed in 2002 Pub. <i>FR</i> January 5, 2006 (U.S. EPA 2006b)	Sets <i>Cryptosporidium</i> removal levels based on source water concentration ranges that are established through a 24-month monitoring program and provides a toolbox of available control methods for meeting treatment requirements. Inactivation of <i>Cryptosporidium</i> is required for all unfiltered systems, disinfection profiling, and benchmarking to assure continued levels of microbial protection while systems comply with the Stage 2 D/DBP Rule and covering, treating, or implementing a risk management plan for all uncovered finished water reservoirs. The LT2ESWTR builds upon the framework established in the LT1ESWTR and the IESWTR.

**Table 4-4** (Continued)

Regulation and date <sup>a</sup>	Description
NPDWR; Ground Water Rule (GWR); October 11, 2006; Pub. <i>FR</i> November 8, 2006 (U.S. EPA 2006c)	The rule establishes a risk-based approach to target ground water systems that are vulnerable to fecal contamination. The rule applies to all systems that use groundwater as a source of drinking water.

<sup>a</sup>The date reported is typically the date the rule or regulation was published in the *Federal Register* (*FR*). In some cases, the date the rule was proposed and or became effective is also given.

Source: Information in this table is taken in part from the U.S. EPA (1999), the EPA website, *Federal Register*, and Pontius and Clark (1999).

**Table 4-5**

Summary of U.S. EPA drinking water regulations for microbial contaminants and disinfection by-products arranged in chronological order by date enacted or most current version

Date	Regulation and/or Rule
1989	Total Coliform Rule
1989	Surface Water Treatment Rule (SWTR)
1998	Interim Enhanced Surface Water Treatment Rule (IESWTR)
1998	Stage 1 Disinfectants and Disinfection Byproducts Rule (Stage 1 DBP)
2001	Filter Backwash Recycling Rule (FBR)
2002	Long Term 1 Enhanced Surface Water Treatment Rule (LT1ESWTR)
2006	Long Term 2 Enhanced Surface Water Treatment Rule (LT2ESWTR)
2006	Stage 2 Disinfectants and Disinfection Byproducts Rule (Stage 2 DBP)
2006	Ground Water Rule (GWR)

summarized in Table 4-5. Additional specific information may be found at the following U.S. EPA website: [www.epa.gov/safewater/contaminants/index.html#listsec](http://www.epa.gov/safewater/contaminants/index.html#listsec).

#### UNREGULATED CONTAMINANTS

As part of its ongoing drinking water program, the U.S. EPA maintains a list of unregulated compounds. Compounds are continually added to the list as they are identified from a variety of sources. Listed unregulated compounds are (1) not scheduled for any proposed or promulgated national primary drinking water regulation (NPDWR), (2) have either been identified or are anticipated to be identified in public water systems, and (3) may ultimately need to be regulated under SDWA. Unregulated contaminants are typically grouped into the following general categories.

- Pharmaceuticals and personal care products (PPCPs)
- Endocrine disrupting chemicals (EDCs)
- Organic wastewater contaminants (OWCs)
- Persistent organic pollutants (POPs)

## 4 Water Quality Management Strategies

- Contaminants of emerging concern (CECs)
- Microconstituents
- Nanomaterials

To be current, the Drinking Water Contaminant Candidate List (CCL) website maintained by the U.S. EPA should be consulted on a periodic basis. For example, the U.S. EPA is currently examining a number of contaminants and others on the CCL list may be regulated within the next few years, including perchlorate and *N*-nitrosodimethylamine; selected endocrine disruptors, pharmaceuticals, and personal care products; and nanoparticles.

*Perchlorate*

Perchlorate ( $\text{ClO}_4^-$ ) is a contaminant from the solid salts of ammonium, potassium, or sodium perchlorate. Ammonium perchlorate has been used as an oxygen-adding component in solid fuel propellant for rockets, missiles, and fireworks. Perchlorate is mobile in aqueous systems, and it can persist under typical groundwater and surface water conditions for decades. Beginning around 1997 (with development of a low-level detection methodology), perchlorate has been detected in various drinking water supplies throughout the United States. In January 2009, the U.S. EPA issued an Interim Health Advisory for perchlorate to assist state and local officials in addressing local contamination of perchlorate in drinking water, while the opportunity to reduce risks through a national primary drinking water standard is being evaluated.

*N-Nitrosodimethylamine*

*N*-Nitrosodimethylamine (NDMA) is a semivolatile organic chemical that is soluble in water. From the mid-1950s until 1976, it was manufactured and used as an intermediate in the production of 1,1-dimethylhydrazine, a storable liquid rocket fuel that contained approximately 0.1 percent NDMA as an impurity. NDMA has also been used as an inhibitor of nitrification in soil, a plasticizer for rubber and polymers, a solvent in the fiber and plastics industry, an antioxidant, a softener of copolymers, and an additive to lubricants. A potential link between the quaternary amines present in many consumer products including shampoos, detergents, and fabric softeners and the formation of nitrosamine in wastewater has been identified.

It has been found that NDMA, along with other nitrosamines, can cause cancer in laboratory animals. In its Integrated Risk Information System (IRIS) database, the U.S. EPA has classified a number of the nitrosamines as probable human carcinogens. Because of the presence of NDMA and other nitrosamines in drinking water, it appears likely that NDMA will be a candidate for future regulation. However, because the development of an MCL for NDMA will not be available for several years, a 10-mg/L notification level has been established by a number of states to provide

information to local government agencies that may ultimately be used in the developing regulations.

*Endocrine Disruptors, Pharmaceuticals, and Personal Care Products*

The presence of pharmaceuticals, personal care products, and hormonally active agents in the environment is also another area of concern. One of the concerns with these products is they release chemical substances that may have possible endocrine disrupting effects in humans in the environment (Trussell, 2001). Domestic wastes are the primary sources of these personal care products and hormonally active agents in the environment. There are a broad variety of pharmaceuticals and personal care products that can be released into the environment, as listed in Table 4-6. In addition, other types of compounds are being examined as potentially being hormonally active agents. These include such compounds as pesticides, plastic additives, polychlorinated biphenyls, brominated flame retardants, dioxins, and hormones and their metabolites.

The public health impacts of exposure to low levels of these contaminants are not well defined. Potential health impacts include disruption of the male and female reproductive systems, the hypothalamus and pituitary, and the thyroid. The 1996 amendments to the SDWA required the U.S. EPA to develop a screening and testing program to determine which chemical substances have possible endocrine-disrupting effects in humans. For the development of this program the Endocrine Disruptor Screening and Testing Advisory Committee (EDSTAC) was formed. Several compounds that may turn out to be identified as hormonally active agents are already regulated in drinking water and include such contaminants as cadmium, lead, mercury, atrazine, chlordane, dichlorodiphenyl trichloroethane (DDT), endrin, lindane, methoxychlor, simazine, toxaphene, benzo[*a*]pyrene, di-(2-ethylhexyl) phthalate, dioxin, and polychlorinated biphenyls.

*Nanoparticles and Nanotechnology*

The manufacture and use of nanoparticles, which range from 1 to 100 nm, is a relatively new and rapidly growing field. Nanotechnology involves the

**Table 4-6**

Representative examples of pharmaceuticals and personal care products

Analgesics	Fragrances
Antibiotics	Hormones
Antiepileptic medicines	Hair care products
Anti-inflammatory medicines	Oral hygiene products
Bath additives	Skin care products
Blood lipid regulators	Stimulants
Cough syrups	Sunscreens
Detergents	

design, production, and application of nanoparticles in various configurations (e.g., singly, clusters, clumps, etc.) in a variety of commercial and scientific applications such as consumer products, food technology, medical products, electronics, pharmaceuticals, and drug delivery systems (SCENIHR, 2006).

Because the field of nanotechnology is so new, few research programs have been initiated that are aimed at understanding the toxicity and potential risk of nanoparticles in the environment. The potential for discharge of nanoparticles to the environment will increase as production increases, so it is important to obtain a better understanding of the health risk and environmental impact of these materials. The U.S. EPA is currently leading scientific efforts to understand the potential risks to humans, wildlife, and ecosystems from exposure to nanoparticles and nanomaterials. One nanoparticle that will likely be regulated in the near future is nanosilver because of its potential toxicity.

### **State Standards and Regulations**

Although the U.S. EPA sets national regulations, the SDWA gives states the opportunity to obtain primary enforcement responsibility (primacy). States with primacy must develop their own drinking water standards, which must be at least as stringent as the U.S. EPA standards. Almost all states have applied for and have been granted primacy. In many instances, the state water quality standards are identical to the U.S. EPA NPDWR and amendments thereto.

### **International Standards and Regulations**

A number of agencies outside the United States have developed drinking water regulations. These include standards for individual countries or groups of countries. The WHO has been at the forefront of developing standards. The WHO standards, known as the Guidelines for Drinking Water Quality (WHO, 1993, 2006), are meant for guidance only and are recommendations, not mandatory requirements. However, the WHO standards have been adopted in whole or in part by a number of countries as a basis of formulation for national standards. The WHO guidelines contain recommendations, health-based standards, monitoring, measurement, and removal for microbial quality and waterborne pathogens, chemical constituents, radionuclides, and aesthetic aspects.

### **Focus of Future Standards and Regulations**

The continued process of water quality regulation is expected to produce additional standards in the future, especially as new compounds are being developed and identified continually. As the U.S. EPA continues to work toward protection of public health, it is expected that standards will be set or revised for more constituents as well as the individual processes and the distribution systems. Improved methods for risk assessment, analysis, and removal of drinking water constituents will also contribute to regulatory activity in the future. In addition, the U.S. EPA released nine white papers

on potential public health risks associated with various distribution system issues in 2002 covering the following topics: (1) intrusion, (2) cross-connection control, (3) aging infrastructure and corrosion, (4) permeation and leaching, (5) nitrification, (6) biofilms/microbial growth, (7) covered storage, (8) decay in water quality over time, and (9) new and repaired water mains.

## 4-4 Overview of Methods Used to Treat Water

---

A variety of methods have been developed and new methods are being developed for the treatment of water. In most situations, a combination or sequence of methods is needed depending on the quality of the untreated water and the desired quality of the treated water. Although treating water is relatively inexpensive on a volumetric basis, there is little opportunity to modify water quality directly in most natural systems such as streams, lakes, and groundwaters because of the large volumes involved. It is common to treat the water used for public water supplies before distribution and to treat wastewater in engineered systems before it is returned to the environment. It is the purpose of this section to present an overview of the various methods and means used for the treatment of water. Topics to be considered include (1) the classification of treatment methods and (2) the application of the various methods used for the treatment of specific constituents.

The constituents in water and wastewater are removed by physical, chemical, and biological means. An individual process is known throughout environmental engineering and chemical engineering literature as a *unit process*, although the phrase *unit operation* is sometimes used and the two phrases can be used interchangeably. The most common unit processes in water treatment remove constituents through a combination of physical and chemical means and are known as *physicochemical unit processes*. The unit processes used for the treatment of water are reported in Table 4-7.

Water treatment plants rarely contain a single unit process; instead, they typically have a series of processes. Multiple processes may be needed when different processes are needed for different contaminants. In addition, sometimes processes are effective only when used in concert with another; that is, two processes individually may be useless for removing a compound but together may be effective if the first process preconditions the compound so that the second process can remove it. A series of unit processes is called a *treatment train*. Although unit processes are combined into treatment trains in water treatment plants, they are usually considered separately. By considering each unit process separately, it is possible to examine the fundamental principles involved apart from their application in the treatment of water.

### Classification of Treatment Methods

**Table 4-7**

Typical unit processes used for the treatment of water

<b>Unit Process</b>	<b>Description</b>	<b>Typical Application in Water Treatment</b>
Adsorption	The accumulation of a material at the interface between two phases	Removal of dissolved organics from water using granular activated carbon (GAC) or powdered activated carbon (PAC)
Advanced oxidation	Use of chemical reactions that generate highly reactive short-lived hydroxyl radicals (OH•) for purpose of oxidizing chemical compounds; typical reactions that produce these free radicals, listed from most common to least common: O <sub>3</sub> , Peroxone (H <sub>2</sub> O <sub>2</sub> and O <sub>3</sub> ), O <sub>3</sub> and UV radiation, and H <sub>2</sub> O <sub>2</sub> and UV radiation	Oxidation of certain humic compounds, pesticides, and chlorinated organics and some taste and odor compounds such as methylisoborneol (MIB) and geosmin found in surface waters and contaminated groundwaters
Aeration	The process of contacting a liquid with air by which a gas is transferred from one phase to another: either the gas phase to the liquid phase (gas absorption) or the liquid phase to the gas phase (gas stripping)	Removal of gases from groundwater (e.g., H <sub>2</sub> S, VOCs, CO <sub>2</sub> , and radon); oxygenation of the water to promote oxidation of iron and manganese
Biofiltration	Rapid granular media (often activated carbon) filter operated for dual purpose of particle removal and removal of biodegradable organic matter by biological oxidation	Removal of biodegradable organic matter (BOM) following ozonation
Chemical disinfection	Addition of oxidizing chemical agents to inactivate pathogenic organisms in water	Disinfection of water with chlorine, chlorine compounds, or ozone
Chemical neutralization	Neutralization of solution through addition of chemical agents	Control of pH; optimizing operating range for other treatment processes
Chemical oxidation	Addition of oxidizing agent to bring about change in chemical composition of compound or group of compounds	Oxidation of iron and manganese for subsequent removal with other processes; control of odors; removal of ammonia
Chemical precipitation	Addition of chemicals to bring about removal of specific constituents through solid-phase precipitation	Removal of heavy metals, phosphorus
Coagulation	Process of destabilizing colloids so that particle growth can occur during flocculation	Addition of chemicals such as ferric chloride, alum, and polymers to destabilize particles found in water

**Table 4-7** (Continued)

Unit Process	Description	Typical Application in Water Treatment
Denitrification	Biological conversion of nitrate ( $\text{NO}_3^-$ ) to nitrogen gas ( $\text{N}_2$ )	Conversion of nitrate found in some surface wastes to nitrogen gas
Disinfection	Addition of chlorine, chloramines, chlorine dioxide, ozone, or UV light followed by a specified amount of contact time	Inactivation of pathogenic organisms such as viruses, bacteria, and protozoa
Distillation	Separation of components of liquid from liquid by vaporization and condensation	Used for desalination of seawater
Filtration (granular)	The removal of particles by passing water through a bed of granular material, particles are removed by transport and attachment to the filter media	Removal of solids following coagulation, flocculation, gravity sedimentation, or flotation
Filtration (membrane)	The removal of particles by passing water through a porous membrane material; particles are removed by straining (size exclusion) because they are larger than the pores	Used to remove turbidity, viruses, bacteria, and protozoa such as <i>Giardia</i> and <i>Cryptosporidium</i>
Flocculation	Aggregation of particles that have been chemically destabilized through coagulation	Used to create larger particles that can be more readily removed by other processes such as gravity settling or filtration
Flotation, dissolved air	Removal of fine particles and flocculent particles with specific gravity less than water or very low settling velocities	Removal of particles following coagulation and flocculation for high-quality raw waters that are low in turbidity, color, and/or TOC or experience heavy algal blooms
Flow equalization	Storage basin in a process train, which can store water to equalize flow and minimize variation in water quality	Large storage tanks used to store waste washwater to permit constant return flow to head of treatment plant; clearwells used to store treated water to allow treatment plant to operate at constant rate regardless of short-term changes in system demand
Gravity separation, accelerated	Solids contact clarifiers and floc-blanket clarifiers where coagulation, flocculation, and sedimentation occur in a single basin and gravity settling occurs in an accelerated flow field	Where land area is limited, surface loading rates are typically 2.4 m/h (1 gal/ft <sup>2</sup> • min) and higher; lime-soda softening

(continues)

**Table 4-7** (Continued)

Unit Process	Description	Typical Application in Water Treatment
Ion exchange	Process in which ions of given species are displaced (exchanged) from insoluble exchange material by ions of different species in solution	Removal of hardness, nitrate, NOM, and bromide; also complete demineralization
Mixing	Mixing and blending of two or more solutions through input of energy	Used to mix and blend chemicals
Nitrification	Biological conversion of ammonia (NH <sub>3</sub> ) to nitrate (NO <sub>3</sub> <sup>-</sup> )	Conversion of ammonia found in some surface wastes to nitrate for subsequent removal by denitrification
Reverse osmosis	A membrane process that separates dissolved solutes from water by differences in solubility or diffusivity through the membrane material; uses reverse osmosis or nanofiltration membranes	To produce potable water from ocean, sea, or brackish water; water softening; removal of specific dissolved contaminants such as pesticides and removal of NOM to control DBP formation
Screening, coarse	Passing untreated water through coarse screen to remove large particles from 20 to 150 mm and larger	Used at the intake structure to remove sticks, rags, and other large debris from untreated water by straining (i.e., interception) on screen
Screening, micro	Passing water through stainless steel or polyester media for removal of small particles from 0.025 to 1.5 mm from untreated water by straining (i.e., interception) on a screen	Used for removal of filamentous algae
Sedimentation	Separation of settleable solids by gravity	Used to remove particles greater than 0.5 mm generally following coagulation and flocculation
Stabilization	Addition of chemical to render treated water neutral with respect to formation of calcium carbonate scale	Stabilization of treated water before entry into distribution system
Ultraviolet light oxidation	Use of UV light to oxidize complex organic molecules and compounds	Used for the oxidation of <i>N</i> -nitrosodimethylamine (NDMA)

### Application of Unit Processes

As discussed in Chaps. 2 and 3, a wide variety of constituents may be found in water. Representative specific physical, inorganic chemical, organic chemical, radionuclides biological, and aesthetic constituents that may have to be removed from surface and groundwater to meet specific water quality objectives are identified in Table 4-8, along with the treatment processes that can be used for their removal. For many constituents, a number of

**Table 4-8**

Application of unit processes for the removal of specific constituents

Constituent	Process	Applicability
<i>Physical Constituents</i>		
Hardness	Lime–soda softening	Applicable for moderate to extremely hard waters. Historically the most common method for removal of hardness.
	Ion exchange	Most common in small installations. Disposal of regenerate solutions can be a problem.
	Nanofiltration	Often referred to as low-pressure reverse osmosis (RO) membranes. Applicable for moderate to extremely hard waters. Disposal of concentrate may be the limiting factor in using nanofiltration.
Total dissolved solids (TDS)	Reverse osmosis, ion exchange, distillation	Used for desalination with ocean, sea, and brackish water. Reverse osmosis concentrate and ion exchange regenerate solution disposal may be the limiting factor in selecting these treatment processes.
Turbidity/ particles	In-line filtration <sup>a</sup>	Works well in low-turbidity, low-color waters. Pilot studies should be performed to establish performance and design criteria.
	Direct filtration <sup>b</sup>	Applicable for low to moderate turbidity and colored waters. Pilot studies should be performed to establish performance and design criteria. Shorter filter runs than conventional treatment.
	Conventional treatment <sup>c</sup>	Works well in moderate- to high-turbidity waters. More operational flexibility than direct or in-line filtration options. Sedimentation basin detention time allows for NOM, taste and odor, and color removal in combination with sedimentation. Sometimes can be designed without piloting if local regulatory agency guidelines are followed.
	Membrane filtration	Effective at removing turbidity, bacteria, and protozoa-sized particles. Viruses may be removed by some types of ultrafiltration membranes. Works well on low-turbidity waters or with pretreatment for particle removal. Natural organics can foul membranes. Pilot testing required to demonstrate particle removal and potential for organic fouling. Easily automated and space requirements are much smaller than conventional plants.
	Slow sand filtration	Primary removal mechanisms are biological and physical. Works well in low-turbidity waters. When used in conjunction with granular activated carbon (GAC), effective at taste and odor removal. Surface loading rates are 50 to 100 times lower than rapid filtration so filters are very large. Most applicable to small communities, but there are very large plants in operation throughout the world.

(continues)

Table 4-8 (Continued)

Constituent	Process	Applicability
<i>Inorganic Chemical Constituents</i>		
Arsenic	Coagulation/ precipitation, activated alumina, ion exchange, reverse osmosis	Conventional coagulation with iron or aluminum salts is effective for removing greater than 90% of As(V) (with initial concentrations of roughly 0.1 mg/L) at pH values of 7 or below. As with fluoride, is strongly adsorbed/exchanged by activated alumina. Arsenic(III) is difficult to remove but is rapidly converted to As(V) with chlorine (Cl <sub>2</sub> ).
Fluoride	Lime softening, coagulation/ precipitation, activated alumina	Lime softening will remove fluoride from water both by forming an insoluble precipitate and by co-precipitation with magnesium hydroxide [Mg(OH) <sub>2</sub> ]. Alum coagulation will reduce fluoride levels to acceptable drinking water standards but requires very large amounts of alum to do so. Contact of fluoride-containing water with activated alumina will remove fluoride.
Iron/ manganese	Oxidation, polyphosphates, ion exchange	Typically found in groundwaters or lake waters with low dissolved oxygen. Removal is most commonly through precipitation by oxidation using aeration or chemical addition (e.g., potassium permanganate or chlorine) for removal by sedimentation or filtration. Greensand filtration in which oxidation and filtration take place simultaneously is also common. The use of polyphosphate precipitation is another method that can be used for the removal of iron and manganese. Iron oxidizes much more readily than does manganese.
Nitrate	Biological denitrification, reverse osmosis, ion exchange	Biological denitrification requires the use of special organisms to reduce nitrate to nitrogen gas. Reverse osmosis will reduce nitrate levels in drinking water, but this process is used primarily for treating high TDS and salt water. Ion exchange with anionic resins is attractive when brine disposal is available.
Selenium	Coagulation/ precipitation, activated alumina, ion exchange, reverse osmosis	Conventional treatment techniques using alum or ferric sulfate coagulation and lime softening have been investigated for selenium removal. Activated alumina has also been investigated for its potential to remove Se(IV) and Se(VI). Although strong-base anion exchange resins have not been thoroughly investigated for selenium removal, it appears that they could be successful, but they are not selective for selenium.
Sulfate	Reverse osmosis	Reverse osmosis is most common for removal of sulfate from seawater.
Sulfide	Oxidation	Typically found in groundwaters as H <sub>2</sub> S and is responsible for taste and odors similar to rotten eggs. Removal is most common through aeration and chlorination.

**Table 4-8** (Continued)

Constituent	Process	Applicability
<i>Organic Chemical Constituents</i>		
Disinfection by-products	Enhanced coagulation, adsorption, alternative disinfectants low-pressure reverse osmosis	Strategies for the control of disinfection by-products (DBPs) include alternative disinfectants (ozone, chlorine dioxide, chloramines, and ultraviolet light) or removal of DBP precursor material (NOM) through enhanced coagulation or adsorption on activated carbon [either GAC or powdered activated carbon (PAC)]. GAC can be used to remove bromate, a DBP formed from ozone and bromide. Reverse osmosis is very effective but expensive.
Natural organic matter	Enhanced coagulation, adsorption, ion exchange, reverse osmosis	Enhanced coagulation (low-pH coagulation) can be used to remove significant amounts of NOM as measured by TOC and is the most widely used process for NOM removal. GAC adsorption, postfiltration is also very effective in removing NOM. Ion exchange use is limited by disposal of the high-TDS regeneration brine. The high cost of RO and concentrate disposal issues limit the use of this process for NOM removal.
Volatile organics, pesticides/herbicides	Air stripping, coagulation, adsorption, advanced oxidation	For volatiles, air-stripping process is recommended. Usually, volatile organic compound (VOC) removal from the gas phase is required posttreatment. For nonvolatile components, coagulation or adsorption process can be used. Low-pH coagulation (enhanced coagulation) can be used to remove significant amounts of TOCs and some nonvolatile organic compounds.
<i>Radionuclides</i>		
Radium	Coagulation	The selected process depends on the level of contamination. Residuals may represent a low-level radioactive waste disposal problem.
Radon	Aeration, detention time	Simple aeration is effective. Packed tower aeration can be used for removal of very high levels. Mixing and detention time may control low-level radon contamination.
	Adsorption	Carbon used for adsorption may be a low-level radioactive disposal problem.
Uranium	Lime softening, ion exchange, reverse osmosis	The selected process depends on the level of contamination. Residuals may represent a low-level radioactive waste disposal problem.

(continues)

**Table 4-8** (Continued)

Constituent	Process	Applicability
<i>Microbial Constituents</i>		
Algae	Copper sulfate, conventional treatment, dissolved air flotation, microscreening	Copper sulfate application in raw-water storage areas (e.g., reservoirs, ponds, and lakes) has been used to control algal blooms. Moderate to severe seasonal algae bloom situations can be handled through careful control of conventional processes: sedimentation and filtration. Direct filtration and in-line filtration can experience extremely shortened filter runs during algae episodes. For persistent algae problems, dissolved air flotation processes or contact clarification devices should be considered. Microscreening may be used at the headworks of a treatment plant for filamentous algae removal.
Bacteria	Conventional treatment, membrane filtration, reverse osmosis, disinfection	Bacteria can be removed through conventional processes, including sedimentation and filtration. Membrane processes provide a positive barrier to most bacteria. Given sufficient dose and contact time, all common disinfectants (chlorine, chlorine dioxide, chloramines, UV, ozone) are effective at inactivation of bacteria.
Protozoan cysts	Conventional treatment, granular media filtration, reverse osmosis, high-pressure membranes, disinfection	Pathogenic cysts and oocysts ( <i>Giardia</i> and <i>Cryptosporidium</i> ) require high levels of disinfectants to inactivate. Effectiveness in decreasing order is ozone > chlorine dioxide > chlorine >> chloramines. Conventional treatment as well as granular media filtration is effective at removing cysts and oocysts. Membrane processes provide a positive barrier for cysts. UV irradiation is also very effective.
Viruses	Conventional treatment, <sup>c</sup> membrane filtration, reverse osmosis, disinfection	Viruses can be removed through conventional processes, including sedimentation and filtration. Membrane process with low-molecular-weight cutoff such as some ultrafiltration membranes can be used for virus removal. Pilot studies are required with membranes to demonstrate effective control. All common disinfectants, with the exception of chloramines, are effective at inactivation of most viruses. Chloramines require a long contact time at high doses for effective virus disinfection.

Table 4-8 (Continued)

Constituent	Process	Applicability
		<i>Aesthetic Constituents</i>
Color	Coagulation/precipitation	High coagulation doses and low pH can be effective even for very high color levels. Bench or pilot testing is recommended.
	Adsorption with GAC or PAC	Granular activated carbon as a filter medium can be very effective for low to moderate taste and odor levels. Replacement is usually on a 3–5-year cycle. In slurry form, PAC can be added to the coagulation process for taste and odor control. PAC is especially effective in contact clarification devices.
	Oxidation with chlorine, ozone, potassium permanganate, and chlorine dioxide	Effectiveness is generally ozone > chlorine > chlorine dioxide > KMnO <sub>4</sub> . pH can affect the efficiency and some colors may return after oxidation. Pilot or bench studies are recommended.
	Ozone/BAC (biologically active carbon)	Preoxidation followed by biologically active carbon treatment has proven effective for a number of colored waters.
Taste and odors <sup>d</sup>	Source control with copper sulfate and reservoir destratification (in situ aeration)	Many taste and odor problems are associated with algae growths and reservoir turnover. Copper sulfate applied in the source water is effective at controlling algae growth. Aeration is appropriate for use in relatively shallow raw-water storage areas where seasonal turnover of stratified water releases taste and odor compounds.
	Oxidation with chlorine, ozone, potassium permanganate, and chlorine dioxide	Chlorine may be used to control taste and odors from H <sub>2</sub> S but is not effective at algal taste and odors and may even make these types of taste and odors worse. Chlorination of industrial chemicals such as phenols intensifies objectionable tastes. Ozone is viewed as one of the most effective oxidants for reducing taste and odors and has the additional benefit in that it can also be used for disinfection. Permanganate is effective for removal of some algae taste and odors at alkaline pH but not the most common taste and odor compounds MIB and geosmin. Additionally, overdosing results in pink water and the formation of black deposits in the distribution systems and household and industrial appurtenances. Chlorine dioxide is effective at controlling many tastes and odors but is not effective in reducing geosmin and MIB. Pilot or bench testing should be performed to determine the best oxidation approach.
	Adsorption with GAC	Granular activated carbon bed life can be short depending on the levels and empty bed contact time (EBCT).

<sup>a</sup>In-line filtration is comprised of coagulation followed by filtration. Also known as contact filtration in countries outside the United States.

<sup>b</sup>Direct filtration is comprised of coagulation followed by flocculation and filtration.

<sup>c</sup>Conventional treatment is comprised of coagulation, flocculation, sedimentation, and filtration.

<sup>d</sup>Total dissolved solids, which can also cause taste and odor problems, are considered under the heading physical parameters.

processes can be used. Final process selection will depend, in part, on what additional constituents must be removed and how complimentary are the processes being considered.

## 4-5 Development of Systems for Water Treatment

---

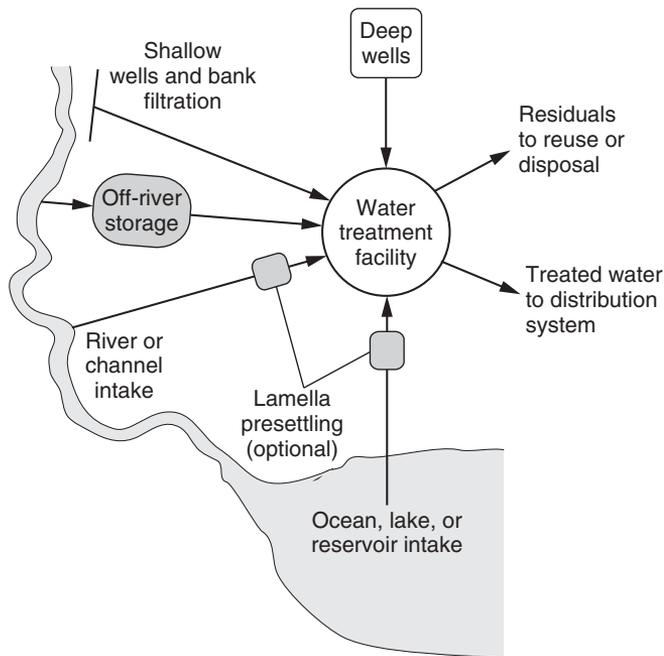

The design, construction, and operation of water treatment facilities follow a process that starts with the desire or need for clean potable water. The initial design is based on water quality data, regulatory requirements, water quality issues, consumer concerns, construction challenges, operational constraints, water treatment technology, and economic feasibility, all of which are combined with human creativity to develop a water treatment plant design. The design is then transformed into a permanent facility through the construction process and becomes an operational water treatment facility with the addition of raw materials and operator know-how. The general considerations involved in the development of systems for water treatment include (1) process selection, (2) the synthesis of surface water and groundwater treatment processes, (3) treatment processes for residuals management, (4) the sizing of treatment train processes and ancillary equipment, and (5) conducting pilot studies. The multibarrier concept as applied to the design of water treatment systems is considered in Sec. 4-6. Detailed analysis of the unit processes are considered in the following chapters.

### **General Considerations Involved in Selection of Water Treatment Processes**

The water treatment process selection starts with at least three key pieces of information: source water quality and variability, required and/or desired quality of the treated water, and required plant production and operational goals. Other factors that affect treatment process selection, including the impact of BAT and the various treatment rules, are also considered (Patania Brown, 2002).

#### **SOURCE WATER QUALITY**

The first step is gathering key information about the source water quality and variability, be it surface water or groundwater (see Fig. 4-3). For surface waters, this information should include typical and event water as well as source stability. Event water quality (i.e., variability) is the water quality that coincides with specific occurrences such as spring runoff, summer algae growth, fall reservoir turnover, and minimum winter water temperatures. Impounded water sources tend to be more stable than flowing river sources, meaning the water quality in impounded sources changes much less rapidly than the water quality in flowing river sources. In general, groundwaters tend to be more stable but, depending on the pumping rate, may contain variable amounts of gases and synthetic organic compounds (SOCs).

**Figure 4-3**

Definition sketch for water supply sources. Depending on water quality and characteristics of surface water sources, presedimentation facilities may be employed.

Many source water quality characteristics can affect treatability. Physical characteristics include turbidity and particulates. Organic characteristics include natural organic matter (NOM), disinfection by-product precursors, color, and chlorine demand. Microbial constituents include protozoa such as *Cryptosporidium* and *Giardia*, viruses, bacteria, and helminths. Chemical parameters that affect treatability include pH, alkalinity, hardness, and corrosivity. Inorganic constituents may include iron, manganese, arsenic, and bromide. Aesthetic concerns include color, taste, and odor. Constituents of regulatory concern include SOCs, VOCs, some inorganic constituents, and radionuclides plus other water quality characteristics such as algae and biological stability.

#### REQUIRED TREATED WATER QUALITY

The required and/or desired treated water quality also imposes constraints on the treatment process. Treated water quality is directly impacted by current and future regulatory compliance, the quality objectives of the utility, consumer expectations, and political constraints. For example, regulatory compliance with disinfection by-products may become more stringent or a water may have periodic taste and odor episodes. Achieving treated water quality goals frequently means more than one process is necessary to address a quality issue. This multiple-barrier approach is described in Sec. 4-6.

**PLANT PRODUCTION AND OPERATIONAL GOALS**

Plant production and operational goals can vary and sometimes can be at odds with each other. Typical productivity operational goals for a water filtration plant can include:

- Filtration efficiency, generally defined by unit filter run volume (UFRV)
- Filter run length, which may be based on operator convenience
- Terminal head loss, which is typically dictated by the hydraulic profile
- Filter maturation volume, which is the volume of water filtered to waste
- Disinfection  $Ct$  value [the residual disinfection concentration  $C$  (mg/L) multiplied by the contact time  $t$  (min)], which can be in the chlorine contact basin, the ozone contactors, or throughout the plant processes, depending upon where the disinfectant addition occurs

An example of specific operational goals for a new water treatment plant is given in Table 4-9.

If there are other plants that are treating the same or similar source water, it is important to take full advantage of this knowledge and experience. Operator knowledge is a huge source of information that is practical and useful in designing a new plant. Operational information that may be available could include what processes and types of chemicals are being used, how to treat changes in raw-water quality, what the operators like and do not like about their plant, and how the new plant may be more efficient, easier to operate, and more flexible for meeting future regulations.

**Table 4-9**

Example operational goals for new direct-filtration water treatment plant

Parameter	Unit	Goal
Ozone disinfection	log inactivation	1.0 log <i>Cryptosporidium</i> inactivation for direct-filtration process train 0.5 log <i>Cryptosporidium</i> inactivation for clarification process train
Filter run length	h	24 h
Terminal head loss	m	3.0
	ft	10.0
Turbidity at breakthrough	NTU	0.1 NTU
Unit filter run volume (UFRV)	m <sup>3</sup> /m <sup>2</sup> (gal/ft <sup>2</sup> )	200–400 5000–10,000
Unit backwash volume	m <sup>3</sup> /m <sup>2</sup> (gal/ft <sup>2</sup> )	4–8 100–200

**BEST AVAILABLE TECHNOLOGY AND TREATMENT RULES**

Along with the establishment of MCL values for a variety of constituents, the U.S. EPA has also developed a recommended list of BATs for treating each contaminant for which EPA sets an MCL. The BAT represents the minimum acceptable level of treatment. As noted in the previous section, a water purveyor is not required to install the recommended BAT but must comply with the appropriate MCLs. It is also interesting to note that if BAT is used and the MCL values cannot be met, the water purveyor is not held responsible.

The various U.S. EPA rules that apply to water supply systems also impact the selection of treatment processes. For example, rules that deal with the removal of microbial contaminants (e.g., viruses, heterotrophic bacteria, *G. lamblia*, *Cryptosporidium*, etc.) were identified previously in Table 4-5. Thus, the requirements set forth in the various rules will also affect the selection, design, and operation of water treatment facilities. The challenge for the designer of water treatment facilities is to meet current regulations while at the same time trying to anticipate what changes will occur in regulations and rules over the useful life of the facility and how they might impact the design and operation of the facility in the future.

**OTHER FACTORS AFFECTING PROCESS SELECTION**

Other factors such as steering committee guidance, phasing options, meeting known regulations, and balancing meeting versus planning for future regulations are all important in treatment process selection. Sometimes an important driver of process selection may be a political agenda, a community issue, or an unusual health issue, but whatever the driver is, it may be the deciding factor for why a particular process is selected over another process.

As described in the previous section, many different processes are available for drinking water treatment. Some processes may be easily ruled out, as they are obviously not appropriate for the raw water being treated. Other processes may seem reasonable and warrant further investigation. Important factors that must be considered in the selection of the treatment process scheme and facility designs are reported in Table 4-10.

Experience acquired through treatment of the same or similar source waters provides an excellent guide in selecting the treatment process scheme. However, where experience is lacking or where there is desire to provide for a different degree of treatment, special studies are required. The special studies include bench-scale study in the laboratory, pilot plant testing, and plant-scale simulation testing. Examples of prototype studies used in actual treatment plant design are presented in Chap. 23.

Reference materials that provide design guidelines and standards are valuable tools to the water treatment plant design engineer. The many books published by the American Water Works Association (AWWA) contain a

**Table 4-10**

Important factors that must be considered when evaluating and selecting unit processes

Factor	Comment
Adaptability	Can the process be modified to meet future treatment requirements?
Applicable flow range	The process should be matched to the expected range of flow rates. For example, slow sand filters are generally not suitable for extremely large flow rates in highly populated areas.
Applicable flow variation	Most unit processes have to be designed to operate over a wide range of flow rates. Most processes work best at a relatively constant flow rate.
Ancillary processes	What support processes are required? How do they affect the treated water quality, especially when they become inoperative? What backup provisions are necessary to ensure continued operation of vital ancillary processes, such as chemical feed?
Chemical requirements	What resources and what amounts must be committed for a long period of time for the successful operation of the unit process? What effects might the addition of chemicals have on the characteristics of the treatment residuals and the cost of treatment? Are there neighbor concerns that have to be considered both onsite and in transporting chemicals to the site?
Climatic constraints	Temperature affects the rate of reaction of most processes. Temperature may also affect the physical operation of the facilities.
Compatibility	Can the unit process be used successfully with existing facilities? Can plant expansion be accomplished easily?
Complexity	How complex is the process to operate under routine or emergency conditions? What levels of training must the operators have to operate the process?
Energy requirements	The energy requirements, as well as probable future energy cost, must be known if cost-effective treatment systems are to be designed.
Environmental constraints	Environmental factors, such as animal habitat and proximity to residential areas, may restrict or affect the use of certain processes and types of intakes. Noise and traffic may affect selection of a plant site and impact the plant deliveries.
Environmental protection	What specific steps need to be taken to protect the environment? Are chemical spills or discharges environmental threats and what ancillary processes are necessary to address these events?
Economic life-cycle analysis	Cost evaluation must consider initial capital cost and long-term operating and maintenance costs. The plant with the lowest initial capital cost may not be the most effective with respect to operating and maintenance costs. The nature of the available funding will also affect the choice of the process.
Inhibiting and unaffected constituents	What constituents are present and may be inhibitory to the treatment processes? What constituents are not affected during treatment?
Land availability	Is there sufficient space to accommodate not only the facilities currently being considered but also possible future expansion? How much of a buffer zone is available to provide landscaping to minimize visual and other impacts?

**Table 4-10** (Continued)

Factor	Comment
Operating and maintenance requirements	What special operating or maintenance requirements will need to be provided? What spare parts will be required and what will be their availability and cost?
Other resource requirements	What, if any, additional resources must be committed to the successful implementation of the proposed treatment system using the unit process being considered?
Performance	Performance is usually measured in terms of treated water quality, which must be consistent with the governing regulations and treatment goals.
Personnel requirements	How many people and what levels of skills are needed to operate the unit process? Are these skills readily available? How much training will be required?
Process applicability	The applicability of a process is evaluated on the basis of past experience, data from full-scale plants, published data, and pilot plant studies. If new or unusual conditions are encountered, pilot plant studies are essential.
Process sizing based on mass transfer rates or process criteria	Reactor sizing is based on mass transfer coefficients. If mass transfer rates are not available, process criteria are used. Data for mass transfer coefficients and process criteria usually are derived from experience, published literature, and the results of pilot plant studies.
Process sizing based on reaction kinetics or process loading criteria	Reactor sizing is based on the governing reaction kinetics and kinetic coefficients. If kinetic expressions are not available, more general process criteria are used. Data for kinetic expressions and process loading criteria usually are derived from experience, published literature, and the results of pilot plant studies.
Process sizing based on redundancy requirements and size availability	Size processes to accommodate regular operational and maintenance activities such as when a sedimentation basin is drained for maintenance or a filter is being backwashed. Additionally, some processes (typically proprietary processes) are available only in certain sizes, which may make them either too large for some applications or so small that numerous units are required, making the process impractical.
Raw-water characteristics	The characteristics of the raw water affect the types of processes to be used and the requirements for their proper operation.
Reliability	What is the long-term reliability of the unit process being considered? Is the process easily upset? Can it stand periodic excursions in raw-water quality? If so, how do such occurrences affect the treated-water quality?
Residuals processing	Are there any constraints that would make sludge, concentrate, or regeneration brine processing and disposal infeasible or expensive? The selection of the residuals-processing system should go hand in hand with the selection of the liquid treatment system.

(continues)

**Table 4-10** (Continued)

Factor	Comment
Security	Secure water treatment plants are vital to protect the public from attack. Can the process be readily protected from intentional upset? What steps or facilities are required to protect the overall plant?
Treatment residuals	The types and amounts of solid, liquid, and gaseous residuals produced must be known or estimated.

wealth of material gathered from a number of sources on specific topics. The AWWA handbook on *Water Quality and Treatment* (AWWA, 2011), is also useful. A popular reference for treatment plant design used primarily in the mid and eastern United States is the *Recommended Standards for Water Works*, which is also known as the *Ten State Standards* (Great Lakes Upper Mississippi River Board, 2003). The book *Integrated Design and Operation of Water Treatment Facilities* (Kawamura, 2000) is an excellent all-round reference on design and operation. The book *Pump Station Design* (Jones et al., 2008) is comprehensive with respect to the design of pumping facilities. Ancillary equipment such as chemical feed systems is generally not addressed in typical water treatment plant references but is covered in specialty references and brochures supplied by manufacturers. The U.S. EPA has published many manuals and reports, including documents for optimizing water treatment plants using the comprehensive performance evaluation/composite correction program (CPE/CCP).

#### **TYPICAL TREATMENT PROCESSES FOR SURFACE WATER**

Depending on the quality of the surface water, a number of alternative treatment trains (described on process flow diagrams) can be used. Four common treatment trains for treating surface water are identified below. Each of these treatment trains is illustrated and described in the following discussion:

- Conventional water treatment
- Direct- and in-line filtration treatment
- Membrane filtration treatment
- Reverse osmosis treatment

##### *Conventional water treatment*

Conventional treatment trains are typically used to treat surface waters with water quality issues such as high turbidity (typically >20 NTU), high color (>20 c.u.), or high TOC (>4 mg/L). A conventional process treatment train consists of coagulation, flocculation, sedimentation, granular media filtration, and disinfection, as shown on Fig. 4-4. In general, conventional

plants have more operational flexibility, are hydraulically stable, and require somewhat less operator attention than other types of water treatment plants. Another consideration when selecting a conventional process train is land availability as surface loading rates are typically low, resulting in large process surface area requirements.

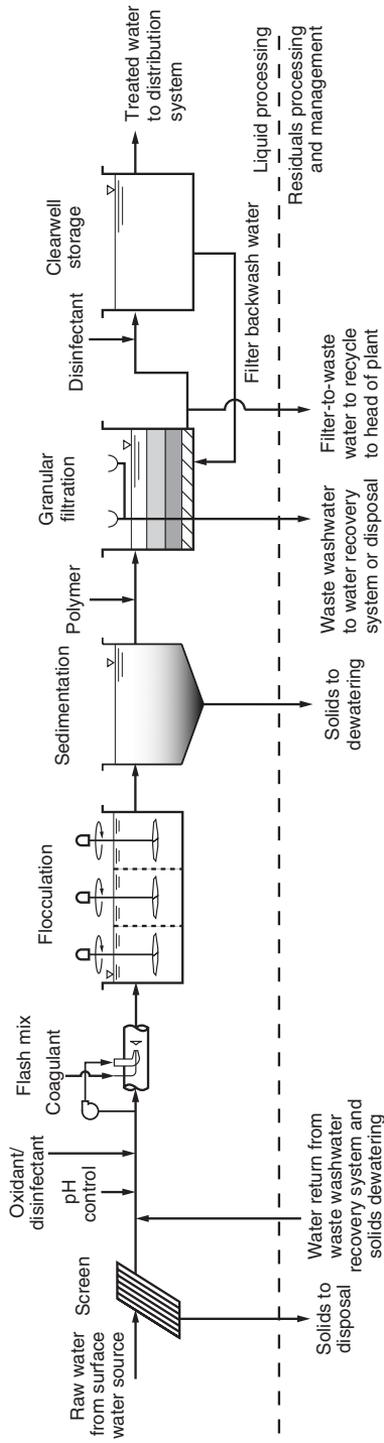

#### *Direct and in-line (contact) filtration*

Direct- and in-line filtration treatment trains are typically used to treat higher quality surface waters with low turbidity (typically  $\leq 15$  NTU), moderate to low color ( $\leq 20$  c.u.), and low TOC ( $< 4$  mg/L). As shown on Fig. 4-5, a direct-filtration process treatment train consists of flash mixing, flocculation, granular media filtration, and disinfection. Coarse deep-bed monomedia filters (or dual-media filters consisting of a deep layer of anthracite over a shallow lower layer of coarse sand) are commonly used in direct-filtration plants as a deep coarse filter can store more suspended solids than a conventional filter. The coagulation and flocculation processes are very important and must be able to form a small, tough floc, as a large floc will readily blind the filters, resulting in shortened filter run times.

An in-line filtration process treatment train is the same as a direct-filtration process treatment train, except flocculation is incidental, meaning flocculation occurs in conveyance structures between the coagulation process and the filters and above the filter media instead of in a flocculation basin. In-line filtration treatment trains are used to treat high to excellent quality surface waters, meaning very low turbidity (typically  $\leq 5$  NTU), low color ( $< 10$  c.u.), and low TOC ( $< 4$  mg/L). Coagulation and filter designs for in-line process trains are similar to that for direct-filtration process trains. Granular filtration is considered in detail in Chap. 11.

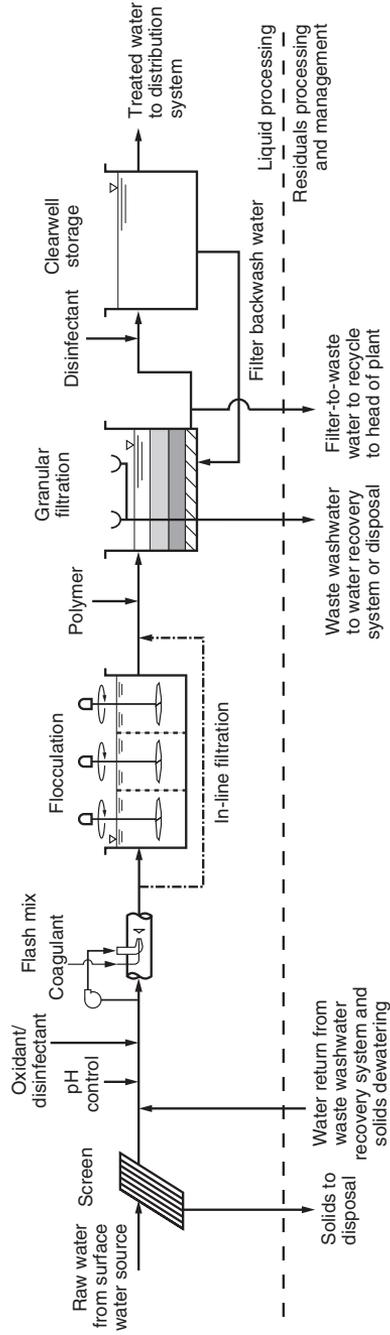

#### *Membrane filtration*

A membrane filtration process treatment train consists of a screening system, low-pressure membranes, and disinfection, as shown on Fig. 4-6. The screening system consists of cartridge filters or microscreens and may include coarse screens at the raw-water source if needed. Membrane filtration process trains as configured on Fig. 4-6 are typically used to treat good-quality surface waters with low turbidity (typically  $\leq 10$  NTU) and moderate to low color ( $< 10$  c.u.) and TOC ( $< 4$  mg/L). However, membrane filters can be used to treat water of any quality when combined with other processes by replacing the granular filters with membrane filters in the conventional water treatment process described earlier. Filtration membranes are configured in modules, which may be stacked, and membrane plants may be readily automated, making membrane plants ideal for small, remote plants on constrained sites. Membrane filtration is considered in detail in Chap. 12.

**Figure 4-4**

Typical process train for treatment of surface water by conventional treatment.

**Figure 4-5**

Typical process train for treatment of surface water by direct and in-line filtration.

*Reverse osmosis treatment*

A reverse osmosis (RO) process treatment train consists of a screening system, RO membranes, and disinfection, as shown on Fig. 4-7. The screening system typically consists of cartridge filters or microscreens and may include coarse screens at the raw-water source and other processes for pretreatment if needed. Reverse osmosis is mainly used for desalination of seawater or brackish water and may be used for specific contaminant removal such as arsenic. Reverse osmosis is considered in detail in Chap. 17.

**TYPICAL TREATMENT PROCESSES FOR GROUNDWATER**

As with surface water, a number of alternative treatment trains can be used depending on the quality of the groundwater. Four common treatment trains for treating groundwater are identified and described in the following discussion:

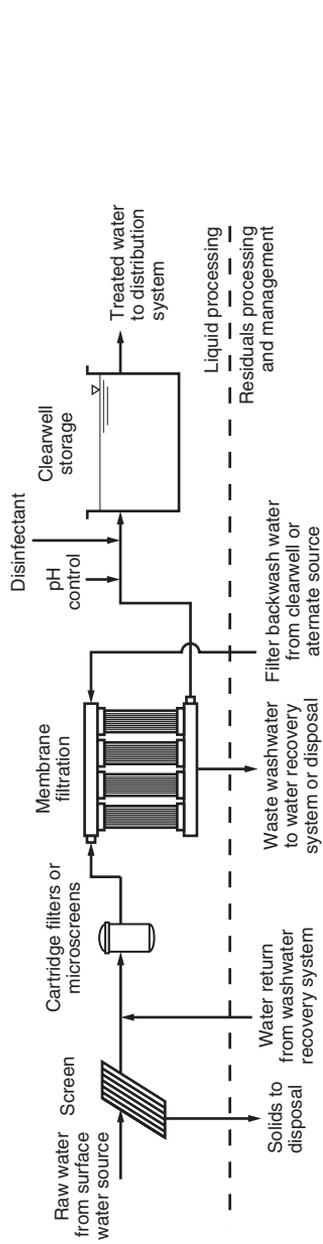

- Conventional lime-softening treatment
- Membrane water softening
- Gas removal treatment
- Iron and manganese treatment

*Conventional lime softening*

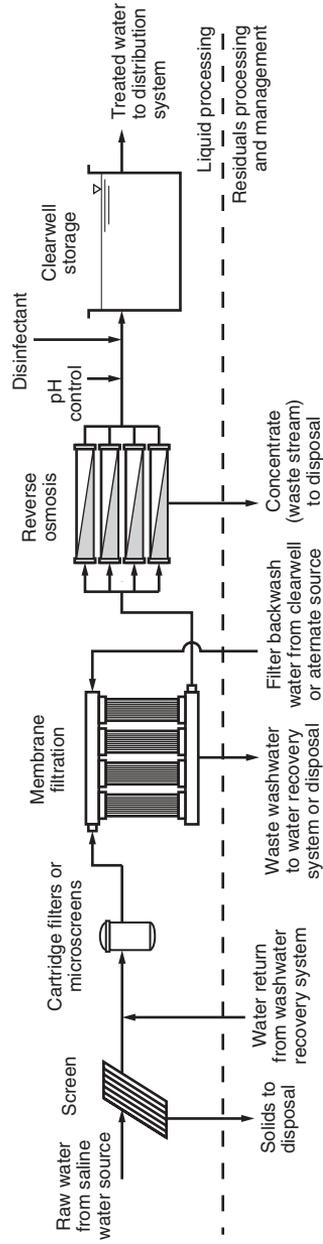

Conventional lime softening is used to remove hardness from groundwater. Water is generally considered hard when total hardness (the sum of carbonate and noncarbonate hardness) is greater than 150 or 180 mg/L (see discussion in Chap. 2), but many utilities do not provide softening unless the hardness is much higher or there is public and political support for water softening. When hardness is mainly from calcium and magnesium hardness is low (<40 mg/L), lime is added in a single-stage softening process, as shown on Fig. 4-8. Adding soda ash increases alkalinity, which removes noncarbonate hardness. Frequently the coagulation, flocculation, and sedimentation steps occur in one basin, called a reactor-clarifier with sludge recirculation, as shown on Fig. 4-8. A more complete discussion of the softening process may be found in Sec. 20-4.

*Membrane softening*

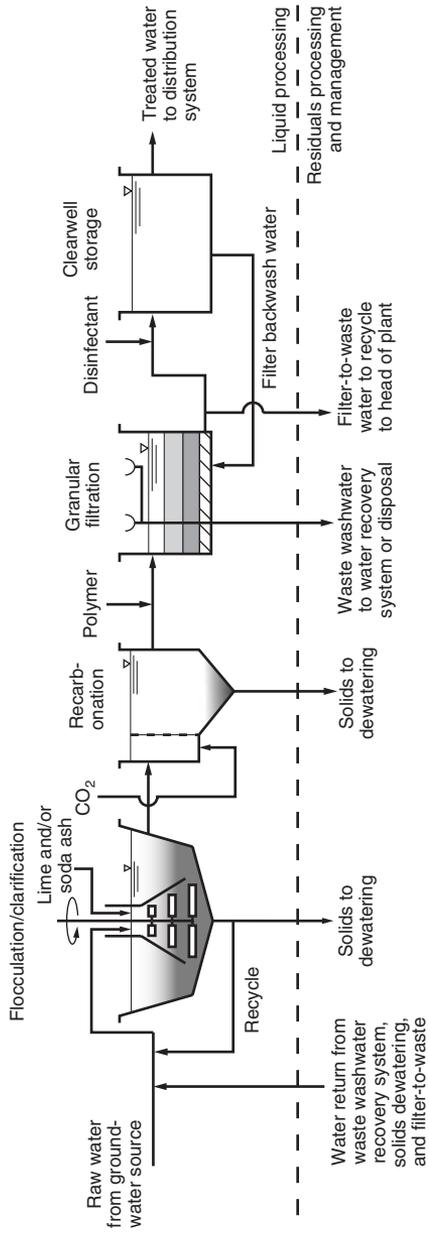

An alternative to lime softening for the removal of hardness from groundwater involves the use of membranes, as shown on Fig. 4-9. Membrane products that have been used for the softening and removal of other constituents such as color, TOC, and DBP precursors include nanofiltration (NF) and RO membranes. The difference between NF and RO is the size of ion removed, with NF removing divalent ions and RO removing monovalent ions (see Fig. 12-2). A major consideration when siting a membrane softening plant is concentrate disposal, which may be a regulatory stumbling block. Reverse osmosis membranes are configured in modules, which may be stacked, and membrane plants may be readily automated, making RO membrane plants ideal for small, remote plants on constrained sites.

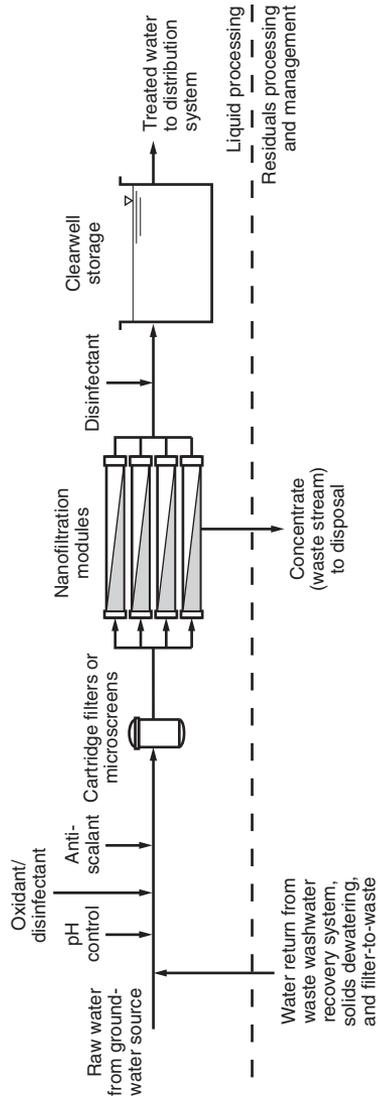

**Figure 4-7**  
Typical process train for treatment of saline water by reverse osmosis.

**Figure 4-8**

Typical process train for removal of hardness (calcium and magnesium) from groundwater with lime-soda softening process.

**Figure 4-9**

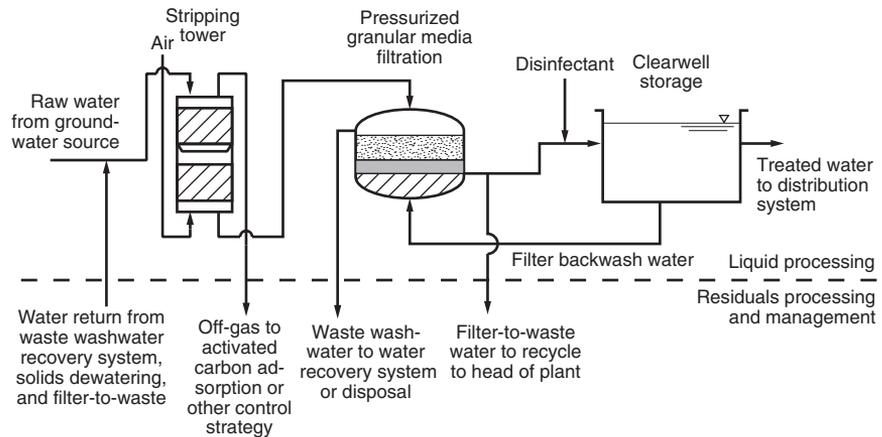

Typical process train for treatment of groundwater with nanofiltration softening process.

*Air stripping*

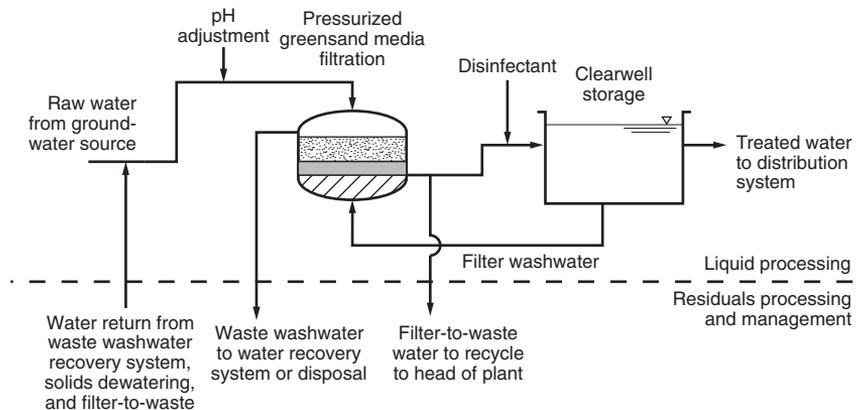

Air stripping is used to treat groundwater containing undesirable gases such as hydrogen sulfide or VOCs at levels above the MCL. An air-stripping process treatment train consists of a stripping tower followed by pressurized granular media filtration and disinfection, as shown on Fig. 4-10. In some cases the use of conditioning chemicals and/or acid addition may be necessary to prevent the formation of precipitates. A consideration when using air stripping is treating the off-gas from the stripping tower. One method for treatment of the off-gas is carbon adsorption, as shown on Fig. 4-10.

*Iron and manganese treatment*

Oxidation and precipitation on pressure filters is the process used most commonly for the removal of inorganic iron and manganese typically found in groundwaters with low dissolved oxygen, as shown on Fig. 4-11. Oxidants that are used include chlorine, potassium permanganate ( $\text{KMnO}_4$ ), oxygen,

**Figure 4-10**  
Typical process train for removal of dissolved gases and/or volatile constituents from groundwater.

**Figure 4-11**  
Typical process train for removal of iron and manganese from groundwater.

and ozone. Chlorine is used when the concentration of iron is less than 2 mg/L and little or no manganese is present. In many cases chlorine is not effective for the removal of iron because iron can be complexed with NOM. Consequently, the use of chlorine must be assessed with bench and pilot tests. In addition, the impact of chlorine on DBP formation must be considered before choosing chlorine as an oxidant. Potassium permanganate and ozone are used when both iron and manganese are present. Oxygen can be effective for oxidizing iron but is not able to break the NOM–iron complex. Pressure filters may use manganese greensand media, which is the name commonly used for sand having a high percentage of glauconite, as shown on Fig. 4-11.

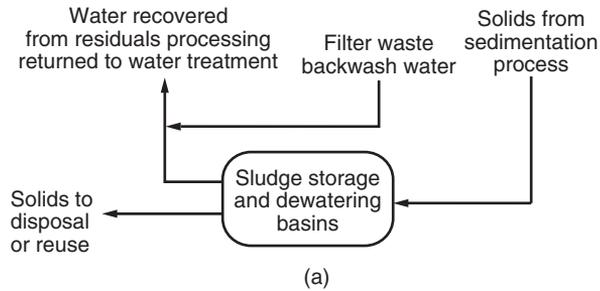

In the treatment processes presented on Figs. 4-4 through 4-11, the primary objective is to remove certain impurities from the water. Impurities removed during treatment, along with the added materials and transport water, are referred to as *residuals* and consist of liquid-, semisolid-, solid-, and gaseous-phase products. Typically, these residuals are comprised of the turbidity-causing materials in raw water, organic and inorganic solids, algae, bacteria, viruses, protozoa, colloids, precipitates from the raw water and those added in treatment, and dissolved salts. *Sludge* is the term used to refer to the solid, or liquid–solid, portion of some types of water treatment plant residuals, such as the underflow from sedimentation basins.

The planning, design, and operation of facilities to reuse or dispose of water treatment residuals is known as *residuals management*. The principal objective in residuals management is usually to minimize the amount of material that must ultimately be disposed by recovering recyclable materials and reducing the water content of the residuals. Typical residual management options are illustrated on Fig. 4-12. Residuals management can have an important impact on the design and operation of many water treatment plants. For existing plants, residuals management systems may limit overall plant capacity if not designed and operated properly. Frequently, residuals are stored temporarily in the process train before removal for treatment, recycle, and/or disposal. Residual removal must be optimized for the process train and coordinated with the residuals management systems to maintain water quality in the process train. Common unit processes used for residuals management are given in Table 4-11. The subject of residuals management is considered in detail in Chap. 21.

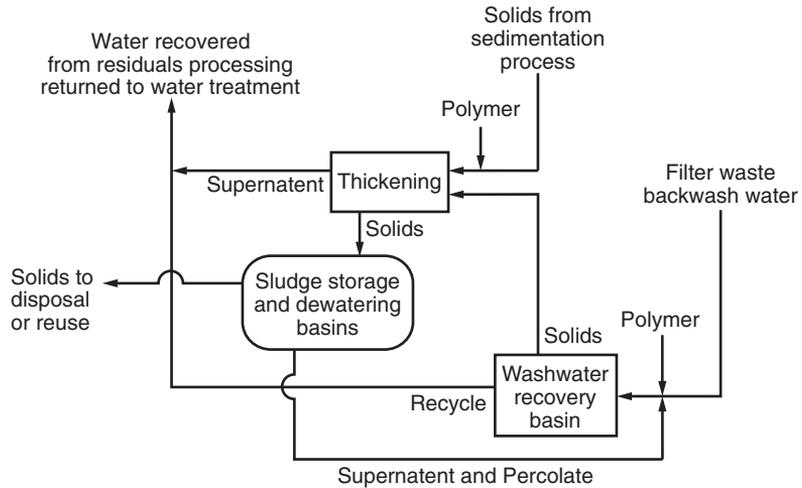

Along with selection of the treatment processes to achieve a specific treatment goal or goals, it is equally important to understand how large or of what capacity the individual treatment processes must be to meet the treated water requirements. General guidance on the hydraulic sizing of treatment processes is presented in Table 4-12. As reported in Table 4-12, the sizing of most treatment units in a water treatment facility is based on the peak-day demand at the end of the design period, with the hydraulic

### **Treatment Processes for Residuals Management**

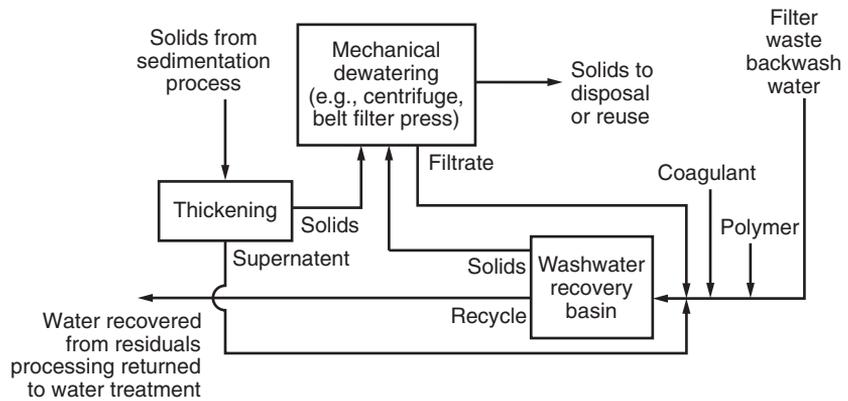

### **Hydraulic Sizing of Treatment Facilities and Processes**

(a)

(b)

(c)

**Figure 4-12**  
 Typical residual processing options: (a) least mechanically intensive employing sludge storage and dewatering basins, typically used at small and remote treatment plants where adequate land is available; (b) more mechanically intensive employing sludge thickening, sludge storage and dewatering basins, and filter waste washwater recovery basins, typically used at intermediate size plants where adequate land is available; and (c) mechanically intensive employing sludge thickening, filter waste washwater recovery basins, and mechanical dewatering, typically used at larger water treatment plants.

**Table 4-11**

Typical unit processes used for residual management

Unit Process	Description	Typical Application in Water Treatment
Concentration	Reducing the volume of reject streams from reverse osmosis and ion exchange processes.	The reject stream from membrane processes is passed through additional membranes to further concentrate the reject stream and reduce the volume required for ultimate disposal.
Conditioning	Conditioning is used to improve the physical properties of the sludge so that it can be dewatered easily.	The addition of polymers or lime to alum or ferric thickened sludge from sedimentation basins and filter waste washwater clarifiers prior to mechanical dewatering.
Dewatering, mechanical	The objective is to reduce the sludge volume and produce a sludge that can be easily handled for further processing.	Thickened, conditioned sludge from sedimentation basins, waste washwater clarifiers, and lagoons is compressed using vacuum filters, filter presses, or belt filter presses.
Lime sludge pelletization	Lime sludge is formed into pellets.	Primarily used in the southeastern United States on high-calcium, warm-temperature groundwaters during the suspended-bed cold-softening water treatment process.
Thickening (sludge)	Thickening to increase the solids content of sludge involves the removal of excess water by decanting and the concentration of the solids by settling.	Sludge from sedimentation basins and clarifiers in the waste washwater recovery system is thickened using centrifuges, thickeners, lagoons, or sand drying beds.

capacity higher than the peak day to account for recycle and treated waste streams. Thus, it is very important to secure the best possible estimate of projected future population growth in the service area.

Information on the acceptable velocities in conveyance piping between unit processes is presented in Table 4-13. The information given in Table 4-13 along with the information given in Table 4-12 can be used to size the piping used to interconnect the various unit processes that comprise the treatment train. Special attention must be devoted to the piping that is used to connect flocculation facilities to downstream filters if floc breakup is to be avoided.

At the other end of the spectrum, a plant also needs to function at the low end of the anticipated flow range. Frequently, multiple basins and conveyance pipes are designed so that one or more units may be turned off when flows are low to maintain appropriate basin loading and pipe velocities to ensure treated water quality. Chemical feed pumps and storage

**Table 4-12**

Guidance for hydraulic sizing of treatment facilities and unit processes

Design Flow	Facility and Unit Processes	Value
Maximum hour	High-service pump station, depending on local conditions	$Q_{\max h}$
	Water distribution reservoir in distribution system	$Q_{\max h}$
Average day	Storage volume for one sludge lagoon	$365 \times Q_{\text{avg d}}$
	Unit processes with one unit out of service	$Q_{\text{avg d}}$ for $Q_{\max \text{ month}/30 \text{ d}}$
	Bulk chemical storage	$\text{Dose}_{\text{avg}} \times 30 \text{ d} \times Q_{\text{avg d}}$ for $Q_{\max \text{ yr}}$
	Day tank for chemical feed	$\text{Dose}_{\text{avg}} \times 12 \text{ h} \times Q_{\text{avg d}}$ for $Q_{\max \text{ yr}}$
	Average capacity of chemical feeders	$\text{Dose}_{\text{avg}} \times Q_{\text{avg d}}$ for $Q_{\max \text{ yr}}$
Maximum day <sup>a</sup>	All treatment processes, including intake facilities <sup>b</sup>	$Q_{\max d}$
	Plant hydraulic capacity (e.g., piping)	$1.25\text{--}1.50 \times Q_{\max d}$
	Maximum capacity of chemical feeders	$\text{Dose}_{\max} \times Q_{\max d}$
	Sludge collection, pumping, and treatment facilities	$Q_{\max d}$
	Clearwell capacity	$0.15\text{--}0.20 \times Q_{\max d}$
	Low- and high-lift internal plant process pumps with largest pump out of service	$Q_{\max d}$
	High-service pump station with largest pump out of service	$Q_{\max d}$
Minimum day	Maximum capacity of flowmeters <sup>b</sup>	$Q_{\max d}$
	Minimum capacity of chemical feeders	$\text{Dose}_{\min} \times Q_{\min d}$
	Lower capacity of flowmeters	$Q_{\min d}$
	Minimum flow for recycle pumps	$Q_{\min d}$

<sup>a</sup>The maximum day demand,  $Q_{\max d}$ , is at the end of the design period.

<sup>b</sup>Rating the unit processes high is an alternative method for building in future plant capacity (e.g., design the flocculation basins for 15 min detention time, with the intent of operating at 20 min detention time for the foreseeable future). The ancillary equipment, such as flowmeters, should be designed to match the rating for the unit processes.

Source: Adapted, in part, from Kawamura (2000).

facilities also need to be designed to cover the entire anticipated flow range and the dose range. The same approach of multiple facilities as well as pump turndown may be considered when sizing ancillary facilities such as chemical feed systems.

### Pilot Plant Studies

Where the applicability of a process for a given situation is unknown but the potential benefits of using the process are significant, bench- or pilot-scale tests must be conducted (see Fig. 1-3). The purpose of conducting pilot plant studies is to establish the suitability of the process in the treatment of a specific water under specific environmental conditions and to obtain the necessary data on which to base a full-scale design. Factors that should be considered in planning pilot plant studies for water treatment are presented

**Table 4-13**

Guidance for acceptable velocities in water treatment facility piping

Piping Component	U.S. Customary Units		SI Units	
	Unit	Value	Unit	Value
Distribution system	ft/s	4.0–10.0	m/s	1.25–3.0
Filter backwash main line	ft/s	6.0–9.0	m/s	1.8–2.75
Filter effluent line	ft/s	5.0–6.0	m/s	0.4–1.8
Line from floc basin (conventional rapid sand filter with alum floc)	ft/s	1.0–4.0	m/s	0.3–1.25
Line from floc basin (direct filtration with polymer)	ft/s	2.5–4.5	m/s	0.75–1.4
Pump discharge line	ft/s	6.0–9.0	m/s	1.8–2.75
Pump suction line	ft/s	4.0–6.0	m/s	1.2–1.8
Raw-water main	ft/s	6–8	m/s	1.8–2.5
Waste washwater line	ft/s	6.0–8.0	m/s	1.8–2.5

Source: Adapted, in part, from Kawamura (2000).

in Table 4-14. The relative importance of the factors presented in Table 4-14 will depend on the specific application and the reasons for conducting the testing program. For example, testing of UV disinfection systems is typically done to (1) verify manufacturers' performance claims, (2) quantify effects of water quality on UV performance, (3) assess the effect(s) of system and reactor hydraulics on UV performance, and (4) investigate photo reactivation and impacts.

In addition to the criteria in Table 4-14, certain general considerations are required in the design of pilot plant facilities that make these facilities useful in process evaluation and selection:

1. The equipment design is dictated by the anticipated use and objective of the pilot equipment. Permanently mounted trailer installations do offer some advantages; however, they tend to be somewhat bulky and inflexible. A modular approach provides the engineer with a reusable, flexible, and easily transportable configuration. In the module approach, each process module is self-contained; thus the experimental designer is free to vary the process train without concern for the interdependence of the various unit processes on each other.
2. At least two process trains are required to enable side-by-side comparison of various design parameters; otherwise no control is available for data evaluation comparison.
3. There should be adequate raw-water supply that mimics the supply for the full-scale application.

**Table 4-14**

Considerations in setting up pilot plant testing programs

Item	Consideration
Design of pilot testing program	Dependent variables including ranges Independent variables including ranges Time required Test facilities Test protocols Statistical design of data acquisition program
Nonphysical design factors	Available time, money, and labor Degree of innovation and motivation involved Quality of water or waste washwater Location of facilities Complexity of process Similar testing experience Dependent and independent variables
Pilot plant size	Bench- or laboratory-scale model Pilot-scale tests Full- (prototype) scale tests
Physical design factors	Scale-up factors Size of prototype Facilities and equipment required and setup Materials of construction
Reasons for conducting pilot testing	Test new process Simulation of another process Predict process performance Document process performance Optimize system design Satisfy regulatory agency requirements Satisfy legal requirements Verify performance claims made by manufacturer

Source: Adapted from Tchobanoglous et al. (2003).

4. Adequate bypass capabilities need to be provided around and within unit processes.
5. The effect of scale-up on system process performance should be considered (e.g., the “sidewall” effects in granular media filtration, hydrodynamics of gravity settling and mixing).
6. Flexibility in the operation should be maximized, especially with respect to multiple chemical addition points. In addition, provisions to add various types of chemicals are desirable.
7. All pumps and motors should be equipped with a variable-speed adjustment and rate control. For example, the speed of the flocculators should be adjustable to test the effect of flocculation energy input for various treatment schemes.

8. Positive flow splitting is best achieved by use of weirs or variable-speed rate-controlled pumps.
9. Accurate flowmeters are necessary.
10. If positive displacement (peristaltic) pumps are used, a pulsation dampener is needed to eliminate high and low surges created by the action of the pump.
11. Unlike full-scale facilities, the hydraulics of pilot plants should be designed to accommodate a wide range of flow conditions. For example, normal filtration rates in water treatment plants are on the order of 12 to 19 m/h (5 to 8 gpm/ft<sup>2</sup>); however, higher filtration rate (e.g., 29 to 36 m/h or 12 to 15 gpm/ft<sup>2</sup>) should be utilized in sizing the inlet and outlet piping of pilot equipment.
12. Provisions for the artificial injection of turbidity (or other water quality constituents) may be desirable to simulate periodic extreme raw-water quality conditions.
13. When more than one process train is utilized, an influent or transition structure may be required. Such a structure should include (1) a means of providing an even flow split to each process train, (2) a common location for the introduction of pretreatment chemicals and monitoring of influent water quality parameters, and (3) provisions for a strainer to remove gross debris such as leaves and twigs that could clog tubing.

The objective of treatment processes is to remove contaminants. Removal can be determined for bulk water quality measures (e.g., turbidity, total dissolved solids) or for individual constituents of interest (e.g., perchlorate, *Cryptosporidium* oocysts). The fraction of a constituent removed by a process can be calculated with the equation

$$R = 1 - \frac{C_e}{C_i} \quad (4-1)$$

where  $R$  = removal expressed as a fraction, dimensionless  
 $C_e$  = effluent concentration, mg/L  
 $C_i$  = influent concentration, mg/L

In general, Eq. 4-1 is used where the removal efficiency for a given constituent is three orders of magnitude or less (i.e., 99.9%). For some constituents, such as microorganisms and trace organics, and some processes, such as membrane filtration, the concentration in the effluent is typically three or more orders of magnitude less than the influent concentration. For these situations, the removal is expressed in terms of log removal value (LRV) as given by the equation

$$\text{LRV} = \log(C_i) - \log(C_e) = \log\left(\frac{C_i}{C_e}\right) \quad (4-2)$$

**Removal  
Efficiency and the  
Log Removal  
Value**

For example, if the influent and effluent concentrations of *E. coli* were  $10^7$  and  $10^2$  org/100 mL, respectively, the corresponding log removal value would be 5 [ $\log(10^7/10^2) = 5$ ]. The log removal notation is used routinely to express the removals achieved with membrane filtration (Chap. 12) and for disinfection (Chap. 13).

## 4-6 Multiple-Barrier Concept

---

Pathogens, one of the most important targets of drinking water treatment, place special demands on the performance of the water treatment process because acute effects can result from short-term exposure. As a result, where pathogens are concerned, the reliability of the treatment train is especially important. To address this issue, public health engineers require that the water supply systems include multiple barriers to limit the presence of pathogens in the treated drinking water. Barriers might include source protection or additional treatment (Haas and Trussell, 1998). Additional security in the design and operation of the water distribution system is also helpful in protecting the treated water from further contamination. The multiple-barrier approach is not just a concept of redundancy. It can be shown that multiple barriers will increase the reliability of the system, even if the overall removal capability is not significantly different. The multiple-barrier concept is illustrated in Example 4-1.

### Example 4-1 Effect of multiple barriers on reliability

A thought experiment can be used to illustrate the increased reliability associated with the use of multiple barriers. Consider two alternative treatment trains. Train 1 includes one unit process, which, when operating normally, reduces the target pathogen by six orders of magnitude (a 6 log reduction). Train 2 includes three independent unit processes in series, each of which, when operating normally, reduces the target pathogen by two orders of magnitude (a 2 log reduction in each step).

For the purpose of this analysis, assume that each of the four unit processes listed above fails to perform, at random, about 1 percent of the time and that when a unit process fails the removal it achieves is half of what it normally achieves. Use the following information estimate: (a) the overall removal for trains 1 and 2 when all the unit processes are operating normally and (b) for each train the frequency (in days per year) of various levels of removal assuming that process failures occur randomly. Present the results of the frequency in a summary table for various levels of removal.

**Solution**

1. Overall removal during normal operation:
  - a. Train 1. Normal operation = 6 log removal.
  - b. Train 2. Normal operation = 2 + 2 + 2 = 6 log removal.
2. Frequency of various levels of removal:
  - a. Train 1:
    - i. Provides 6 log removal 99 percent of time =  $0.99 \times 365 \text{ d} = 361.35 \text{ d}$ .
    - ii. Provides 3 log removal 1 percent of time =  $0.01 \times 365 \text{ d} = 3.65 \text{ d}$ .
  - b. Train 2:
    - i. Provides 6 log removal when all three processes are operating normally =  $0.99 \times 0.99 \times 0.99 \times 365 \text{ d} = 354 \text{ d}$ .
    - ii. Provides 5 log removal when two of the three processes are operating normally and one is in failure mode =  $0.99 \times 0.99 \times 0.01 \times 3 \text{ (failure mode combinations)} \times 365 \text{ d} = 10.73 \text{ d}$ .
    - iii. Provides 4 log removal when one of the three processes is operating normally and two are in failure mode =  $0.99 \times 0.01 \times 0.01 \times 3 \text{ (failure mode combinations)} \times 365 \text{ d} = 0.11 \text{ d} = 2.6 \text{ h}$ .
    - iv. Provides 3 log removal when all three processes are in failure mode =  $0.01 \times 0.01 \times 0.01 \times 365 \text{ d} = 0.00037 \text{ d} = 32 \text{ s}$ .
3. The results of this analysis are displayed in the following table:

Log Removal	Time of Operation During Typical Year, d	
	Train 1	Train 2
6	361.35	354.16
5		10.73
4		0.11
3	3.65	0.00037
Total	365.0	365.0

**Comment**

Referring to the data in the above table, it will be observed that the process train with multiple barriers (train 2) is much more robust, reducing the time in which the consumer is exposed to the poorest removal by 10,000-fold, from 3.65 d per year to 32 s per year (0.00037 d). The use of multiple barriers in treatment provides reduced exposure to the risks that are associated with process failure.

## Problems and Discussion Topics

---

- 4-1 The U.S. EPA sets water treatment goals and standards. Discuss the differences between goals and standards and the differences between primary and secondary standards.
- 4-2 A water treatment plant design engineer is establishing the treated water quality goals for a new treatment plant. Describe the steps the engineer should take to be sure the goals that are established are in compliance with all current regulations. Identify other groups or individuals who would be valuable to have participate in the goal-setting process.
- 4-3 Drinking water regulations are continually evolving. Discuss how an engineer might approach the design of a new water treatment plant so that the plant is readily able to meet future regulations.
- 4-4 A drinking water treatment plant is located in an area that is prone to intense summer rainstorms. The source water for the plant is a river that begins high in the mountains and flows through land that is used for growing crops and grazing for cows before it reaches a lake that is the source for the plant. What constituents would be of concern in drinking water that would be expected to be in the source water and what types of unit processes would be appropriate to treat them?
- 4-5 Develop a plan for a pilot plant to evaluate the treatment alternatives identified in the previous problem. In the plan, include a process flow diagram, constituents to be evaluated (testing requirements), and operational information such as study duration.
- 4-6 Discuss how the multiple barrier concept, as it applies to the removal of pathogens, is at work in one of the process trains, to be selected by instructor, that are presented on Figs. 4-4 through 4-11 and discussed in Sec. 4-5.
- 4-7 Consider two alternative treatment trains. Train 1 includes two treatment processes, each of which, when operating normally, reduces the target pathogen by three orders of magnitude (a 3 log reduction). Train 2 includes three independent unit processes in series, each of which, when operating normally, reduces the target pathogen by two orders of magnitude (a 2 log reduction in each step). If each of the five unit processes listed above fails to perform, at random, about one percent of the time and if, when a unit process fails, the removal it achieves is half of what it normally achieves, estimate: (a) the overall removal for trains 1 and 2 when all the unit processes are operating normally and (b) for each train the frequency (in days per year) of various levels of removal assuming that process failures occur randomly.
- 4-8 Two alternative treatment trains are being considered. Train 1 includes three treatment processes, each of which, when operating

normally, reduces the target pathogen by two orders of magnitude (a 2 log reduction). Train 2 includes four independent unit processes in series. Two of the processes reduce the target pathogen by two orders of magnitude (a 2 log reduction) Each of the other two processes reduce the target pathogen by one order of magnitude (a 1 log reduction in each step). If each of the seven unit processes listed above fails to perform, at random, about one percent of the time and if, when a unit process fails, the removal it achieves is half of what it normally achieves, estimate: (a) the overall removal for trains 1 and 2 when all the unit processes are operating normally and (b) for each train the frequency (in days per year) of various levels of removal assuming that process failures occur randomly.

## Terminology for Chemical Reactions

---

<b>Term</b>	<b>Definition</b>
Acid	A molecule that is capable of releasing a proton.
Acid–base reactions	Reactions that involve the loss or gain of a proton. The solution becomes more acidic if the reaction produces a proton or basic if it consumes a proton. Acid/base reactions are reversible.
Activation energy	Energy barrier that reactants must exceed in order for the reaction to proceed as written.
Activity	Ability of an ion or molecule to participate in a reaction. In dilute solution, the activity is equal to the molar concentration. For ions in solution, the activity decreases as ionic strength increases.
Activity coefficient	Parameter that relates the concentration of a species to its activity.
Conjugate base	A molecule that can accept a proton and is formed when an acid releases a proton.
Conversion	Amount of a reactant that can be lost or converted to products, normally given as a moles fraction.
Catalyst	A species that speeds up a chemical reaction, but is neither consumed nor produced by the reaction.
Complex	Species that is comprised of a metal ion and a ligand.
Elementary reaction	A chemical reaction in which products are formed directly from reactants without the formation of intermediate species.
Free energy	Thermodynamic energy in a system available to do chemical work. Associated with the potential energy of chemical reactions. Also known as the Gibbs energy.
Heterogeneous reaction	A chemical reaction in which the reactants are present in two or more phases (i.e., a liquid and a solid).
Homogeneous reaction	A chemical reaction in which all reactants are present in a single phase.

<b>Term</b>	<b>Definition</b>
Ionic strength	A measure of the total concentration of ions in solution. An increase in the ionic strength increases nonideal behavior of ions and causes activity to deviate from concentration.
Irreversible reaction	A chemical reaction that proceeds in the forward direction only, and proceeds until one of the reactants has been totally consumed.
Ligand	Anions that bind with a central metal ion to form soluble complexes. Common ligands include $\text{CN}^-$ , $\text{OH}^-$ , $\text{Cl}^-$ , $\text{F}^-$ , $\text{CO}_3^{2-}$ , $\text{NO}_3^-$ , $\text{SO}_4^{2-}$ , and $\text{PO}_4^{3-}$ .
Oxidant	A reactant that gains electrons in a oxidation/reduction reaction.
Oxidation/reduction reaction	A chemical reaction in which electrons are transferred from one molecule to another. Also known as a redox reaction. Redox reactions are irreversible.
Precipitation reaction	A chemical reaction in which dissolved species combine to form a solid. Precipitation reactions are reversible. The reverse is a dissolution reaction, in which a solid dissolved to form soluble species.
Parallel reactions	Reactions that involve the concurrent utilization of a reactant by multiple pathways.
Reaction order	The power to which concentration is raised in a reaction rate law.
Reaction rate law	Mathematical description of rate of reaction. It takes the form of a rate constant multiplied by the concentration of reactants raised to a power.
Reductant	A reactant that loses electrons in a oxidation/reduction reaction.
Reversible reaction	A chemical reaction that proceeds in either the forward or reverse direction, and reaches an equilibrium condition in which products and reactants are both present.
Selectivity	The preference of one reaction over another. Selectivity is equal to the moles of desired product divided by the moles of reactant that has reacted.
Series reactions	Individual reactions that proceed sequentially to generate products from reactants.
Stoichiometry	A quantitative relationship that defines the relative amount of each reactant consumed and each product generated during a chemical reaction.

---

Chemical reactions are used in water treatment to change the physical, chemical, and biological nature of water to accomplish water quality objectives. An understanding of chemical reaction pathways and stoichiometry is needed to develop mathematical expressions that can be used to describe the rate at which reactions proceed. Kinetic rate laws and reaction stoichiometry are valid regardless of the type of reactor under consideration and are used in the development of mass balances (see Chap. 6) to describe the spatial and temporal variation of reactants and products in chemical reactors. Understanding the equilibrium, kinetic, and mass transfer behavior of each unit process is necessary in developing effective treatment strategies. Equilibrium and kinetics are both introduced in this chapter, and mass transfer is discussed in Chap. 7.

Topics presented in this chapter include (1) chemical reactions and stoichiometry, (2) equilibrium reactions, (3) thermodynamics of chemical reactions, (4) reaction kinetics, (5) determination of reaction rate laws, and (6) chemical reactions used in water treatment. Water chemistry textbooks (Benefield et al., 1982; Benjamin, 2002; Pankow, 1991; Sawyer et al., 2003; Snoeyink and Jenkins, 1980; Stumm and Morgan, 1996) may be reviewed for more complete treatment of these concepts and other principles of water chemistry.

## 5-1 Chemical Reactions and Stoichiometry

---

Chemical operations used for water treatment are often described using chemical equations. These chemical equations may be used to develop the stoichiometry that expresses quantitative relationships between reactants and products participating in a given reaction. An introduction to the types of chemical reactions and reaction stoichiometry used in water treatment processes is presented below.

### Types of Reactions

Chemical reactions commonly used in water treatment processes can be described in various ways. For example, the reactions of acids and bases, precipitation of solids, complexation of metals, and oxidation–reduction of water constituents are all important reactions used in water treatment. In general, reactions can be thought of as reversible and irreversible. Irreversible reactions tend to proceed to a given endpoint as reactants are consumed and products are formed until one of the reactants is totally consumed. Irreversible reactions are signified with an arrow in the chemical equation, pointing from the reactants to the products. Symbols commonly used in chemical equations are described in Table 5-1. In the following reaction, reactants A and B react to form products C and D:

Reversible reactions tend to proceed, depending on the specific conditions, until equilibrium is attained at which point the formation of products from

**Table 5-1**

Symbols used in chemical equations

Symbol	Description	Comments
→	Irreversible reaction	Single arrow points from the reactants to the products, e.g., $A + B \rightarrow C$
⇌	Reversible reaction	Double arrows used to show that the reaction proceeds in the forward or reverse direction, depending on the solution characteristics
[ ]	Brackets	Concentration of a chemical constituent or compound in mol/L
{ }	Braces	Activity of a chemical constituent or compound
(s)	Solid phase	Used to designate chemical component present in solid phase, e.g., precipitated calcium carbonate, $\text{CaCO}_3(\text{s})$
(l)	Liquid phase	Used to designate chemical component present in liquid phase, e.g., liquid water, $\text{H}_2\text{O}(\text{l})$
(aq)	Aqueous (dissolved)	Used to designate chemical component dissolved in water, e.g., ammonia in water, $\text{NH}_3(\text{aq})$
(g)	Gas	Used to designate chemical component present in gas phase, e.g., chlorine gas, $\text{Cl}_2(\text{g})$
$\xrightarrow{x}$	Catalysis	Chemical species, represented by x, catalyzes reaction, e.g., cobalt (Co) is the catalyst in the reaction $\text{SO}_3^{2-} + \frac{1}{2}\text{O}_2 \xrightarrow{\text{Co}} \text{SO}_4^{2-}$
↑	Volatilization	Arrow directed up following a component is used to show volatilization of given component, e.g., $\text{CO}_3^{2-} + 2\text{H}^+ \rightleftharpoons \text{CO}_2(\text{g}) \uparrow + \text{H}_2\text{O}$
↓	Precipitation	Arrow directed down following a component is used to show precipitation of given component, e.g., $\text{Ca}^{2+} + \text{CO}_3^{2-} \rightleftharpoons \text{CaCO}_3(\text{s}) \downarrow$

Source: Adapted from Benefield et al., 1982.

the forward reaction is equal to the loss of products for the reverse reaction. For example, in Eq. 5-1 the reactants A and B react to form products C and D, whereas in Eq. 5-2 the reactants C and D react to form products A and B:

The reactions presented in Eqs. 5-1 and 5-2 can be combined as follows:

Theoretically, all reactions are reversible given the appropriate conditions; however, under the limited range of conditions typically experienced in water treatment processes, some reactions may be classified as irreversible for practical purposes.

#### HOMOGENEOUS REACTIONS

When all the reactants and products are present in the same phase, the reactions are termed *homogeneous*. For homogeneous reactions occurring in water, the reactants and products are dissolved. For example, the reactions of chlorine (liquid phase) with ammonia (liquid phase) and dissolved organic matter (liquid phase) are common homogeneous reactions.

#### HETEROGENEOUS REACTIONS

When reacting materials composed of two or more phases are involved, the reactions are termed *heterogeneous*. The use of ion exchange media (solid phase) for the removal of dissolved constituents (liquid phase) from water is an example of a heterogeneous reaction used in water treatment. Reactions that require the use of a solid-phase catalyst may also be considered heterogeneous.

### Reaction Sequence

An understanding of the sequence of reaction steps is needed for engineering and control of reactions in water treatment reactors. Chemical reactions in water treatment can occur via a single reaction step or multiple steps in a sequential manner. In addition, reactions may occur in series or parallel or in a combination of series and parallel reactions. Due to the diverse chemistry of water originating from surface and subsurface sources, many reactions occur during water treatment processes.

#### SERIES REACTIONS

The conversion of a reactant to a product through a stepwise process of individual reactions is known as a series reaction. For example, reactant A forms product B, which in turn reacts to form product C:

For example, the two-step conversion of carbonic acid ( $\text{H}_2\text{CO}_3$ ) to carbonate ( $\text{CO}_3^{2-}$ ) takes place in water according to the following series reaction:

The extent and rate of the reactions shown in Eqs. 5-5 and 5-6 are determined by the water pH, temperature, and other properties, as discussed later in this chapter.

**PARALLEL REACTIONS**

Reactions that involve the concurrent utilization of a reactant by multiple pathways are known as parallel reactions. Parallel reactions may be thought of as competing reactions. In the reactions shown in Eqs. 5-7 and 5-8, reactant A is simultaneously converted to products B and C:

When there are competing parallel reactions such as those shown in Eqs. 5-7 and 5-8, there is often a preferred reaction. The preference of one reaction over another is known as reaction selectivity. For example, if Eq. 5-7 were the preferred reaction over Eq. 5-8 due to the undesirable nature of product C, product B would be the desired product, and the selectivity would be defined as

$$S = \frac{\text{moles of desired product formed, [B]}}{\text{moles of all products formed, [B] + [C]}} \quad (5-9)$$

where  $S$  = selectivity, dimensionless

**MULTIPLE REACTIONS**

Many reactions in water treatment involve complex combinations of series and parallel reactions, as shown in the following reactions:

For example, the reaction of ozone ( $O_3$ ) with bromide ions ( $Br^-$ ) in groundwater occurs by the following three-step process:

In this series of reactions, ozone converts bromide to bromate ( $BrO_3^-$ ), which can be a health concern. Reactions involving ozone are discussed in more detail in Chaps. 8, 13, and 18.

Many reactions proceed as a series of simple reactions between atoms, molecules, and radical species. A radical species is an atom or molecule containing an unpaired electron, giving it unusually fast reactivity. A radical species is always expressed with a dot in the formula (e.g.,  $HO\cdot$ ). Intermediate products are formed during each step of a reaction leading up to the final products. An understanding of the mechanisms of a reaction may be used to improve the design and operation of water treatment processes.

**Reaction Mechanisms**

**ELEMENTARY REACTIONS**

Reaction mechanisms involving an individual reaction step are known as elementary reactions. Elementary reactions are used to describe what is happening on a molecular scale, such as the collision of two reactants. For example, the decomposition of ozone (in organic-free, distilled water) has been described by the following four-step process (McCarthy and Smith, 1974):

In this series of elementary reactions, ozone reacts with water to form, among other compounds,  $\text{HO}\cdot$  (hydroxyl radical) and  $\text{HO}_2$  (superoxide), which are very reactive and sometimes used for the destruction of organic compounds.

**OVERALL REACTIONS**

A series of elementary reactions may be combined to yield an overall reaction. The overall reaction is determined by summing the elementary reactions and canceling out the compounds that occur on both sides of the reaction. For the elementary reactions shown in Eqs. 5-15 to 5-18, the overall reaction may be written as

The specific reaction mechanism and intermediate products that are formed cannot be determined from the overall reaction sequence. In many cases the elementary reaction mechanisms are not known and empirical expressions must be developed to describe the reaction kinetics.

**Reaction  
Catalysis**

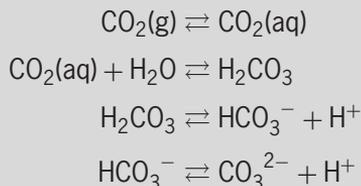

A catalyst speeds up a chemical reaction, but it is neither consumed nor produced by the reaction. For a reaction between two molecules to occur, the molecules must collide with the proper orientation. However, molecules have a tendency to move in ways that make the proper orientation less likely. For example, molecules move about their axis in two directions (called a rotation and a translation) and they vibrate. Adsorption and reaction on a catalyst surface reduce this motion and increase the local concentration of reactant.

Catalysts may be homogeneous or heterogeneous in nature. Homogeneous catalysts are dissolved in solution and speed up homogeneous reactions. For example, cobalt, a homogeneous catalyst, is known to speed up the following reaction, which is used to deoxygenate water for oxygen transfer studies (Pye, 1947):

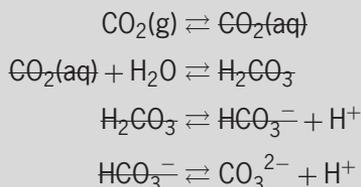

### Example 5-1 Reactions for dissolution of carbon dioxide in water

The dissolution of carbon dioxide in water leads to the formation of several different components. Combine the following elementary reactions to determine the overall reaction with the initial product  $\text{CO}_2$  and the final product of  $\text{CO}_3^{2-}$ :

#### Solution

1. Eliminate species that occur on both sides of the elementary reaction equations:

2. Determine the overall reaction by combining the remaining species from step 1:

Heterogeneous catalysts speed up reactions at the interface of a liquid or gas with a solid phase, even if all reactants and products are in a single phase. If the products and reactant are not adsorbed too strongly, reactions at a surface can increase the rate of reaction, which demonstrates the utility of heterogeneous catalysis. Another purpose of catalysis is to improve reaction selectivity and minimize the formation of harmful by-products.

The amount of a substance entering into a reaction and the amount of a substance produced are defined by the stoichiometry of a reaction. In the general equation for a chemical reaction, as shown in Eq. 5-21, reactants A and B combine to yield products C and D:

where  $a, b, c, d$  = stoichiometric coefficients, unitless

Using the stoichiometry of a reaction and the molecular weight of the chemical species, it is possible to predict the theoretical mass of reactants and products participating in a reaction. For example, calcium hydroxide [ $\text{Ca}(\text{OH})_2$ ] may be added to water to remove calcium bicarbonate:

As shown in Eq. 5-22, 1 mole of  $\text{Ca}(\text{HCO}_3)_2$  and 1 mole of  $\text{Ca}(\text{OH})_2$  react to form 2 moles of  $\text{CaCO}_3(\text{s})$  and 2 moles of  $\text{H}_2\text{O}$ . The molecular weights can be used to determine the theoretical mass of calcium hydroxide needed to react with a specified mass of calcium bicarbonate and the amount of calcium carbonate formed, as shown in Example 5-2.

### Example 5-2 Determination of product mass using stoichiometry

For the reaction shown in Eq. 5-22, estimate the amount of  $\text{CaCO}_3(\text{s})$  that will be produced from the addition of calcium hydroxide to water containing 50 mg/L  $\text{Ca}(\text{HCO}_3)_2$ . Use a flow rate of 1000  $\text{m}^3/\text{d}$  and determine the quantity of  $\text{CaCO}_3(\text{s})$  in kilograms per day. Assume that the reaction proceeds in the forward direction to completion.

#### Solution

1. Write the chemical equation and note the molecular weight of the reactants and products involved in the reaction. The molecular weights are written below each species in the reaction.

2. Determine the molar relationship for the disappearance of  $\text{Ca}(\text{HCO}_3)_2$  and formation of  $\text{CaCO}_3(\text{s})$ :

$$\begin{aligned} & \left[ \frac{2 \text{ mol CaCO}_3(\text{s})}{1 \text{ mol Ca}(\text{HCO}_3)_2} \right] \left[ \frac{100 \text{ g CaCO}_3(\text{s})}{\text{mol CaCO}_3(\text{s})} \right] \left[ \frac{1 \text{ mol Ca}(\text{HCO}_3)_2}{162 \text{ g Ca}(\text{HCO}_3)_2} \right] \\ & = 1.23 \frac{\text{g CaCO}_3(\text{s})}{\text{g Ca}(\text{HCO}_3)_2} \end{aligned}$$

Therefore, for each gram of  $\text{Ca}(\text{HCO}_3)_2$  removed, 1.23 g of  $\text{CaCO}_3(\text{s})$  will be produced.

3. Compute the mass of  $\text{CaCO}_3(\text{s})$  that will be produced each day.
  - a. Determine the mass of  $\text{Ca}(\text{HCO}_3)_2$  removed each day:

$$\begin{aligned} \text{Ca}(\text{HCO}_3)_2 \text{ removed} &= (0.050 \text{ g/L})(1000 \text{ m}^3/\text{d})(1000 \text{ L/m}^3) \\ &= 50,000 \text{ g/d} \end{aligned}$$

b. Estimate the amount of  $\text{CaCO}_3(\text{s})$  produced each day:

$$\begin{aligned}\text{CaCO}_3(\text{s}) \text{ produced} &= [50,000 \text{ g Ca(HCO}_3)_2/\text{d}] \\ &\times [1.23 \text{ g CaCO}_3(\text{s})/[\text{g Ca(HCO}_3)_2](1 \text{ kg}/10^3 \text{ g}) \\ &= 61.5 \text{ kg CaCO}_3 (\text{s})/\text{d}\end{aligned}$$

### Comment

In addition to estimating the amount of  $\text{CaCO}_3(\text{s})$  produced, it is also possible to estimate the amount of calcium hydroxide that must be added to water to bring about this reaction. However, due to the nonideal nature of water treatment processing, the amount of calcium hydroxide that is required will exceed the stoichiometric amount, which is the minimum amount needed.

As a reaction proceeds, reactants are converted into products. At any intermediate point during the reaction or when the reaction has reached equilibrium, it is possible to determine the amount (in moles) of reactants and products remaining if the stoichiometry and the amount of one of the reactants present is known. For example, consider the reaction shown in Eq. 5-21, in which  $a$ ,  $b$ ,  $c$ , and  $d$  are stoichiometric coefficients. For this reaction, the conversion may be determined for a reference reactant A and written per mole of A by dividing by the stoichiometric coefficient  $a$ :

For the general reaction shown in Eq. 5-23, all the reactants and products can be related to the conversion of reactant A,  $X_A$ , and the initial concentration of A, assuming there is no volume change upon reaction (which is valid for most water treatment problems):

$$X_A = \frac{\text{moles of A reacted}}{\text{moles of A present initially}} = \frac{N_{A0} - N_A}{N_{A0}} \quad (5-24)$$

where  $X_A$  = conversion of reactant A  
 $N_{A0}$  = initial amount of reactant A, mol  
 $N_A$  = final amount of reactant A, mol

Equation 5-24 can be written in molar concentration units by dividing each term by the volume in which the reaction is occurring. Thus, Eq. 5-24 written in concentration units is

$$X_A = \frac{C_{A0} - C_A}{C_{A0}} \quad (5-25)$$

### Reactant Conversion

where  $C_{A0}$  = initial concentration of reactant A, mol/L  
 $C_A$  = final concentration of reactant A, mol/L

If the final amount and concentration of A,  $N_A$ , and  $C_A$  are written in terms of the conversion, the following expressions are obtained:

$$N_A = N_{A0} (1 - X_A) \quad (5-26)$$

$$C_A = C_{A0} (1 - X_A) \quad (5-27)$$

For the reaction given in Eq. 5-23, the final concentrations of B, C, and D can be computed in terms of A. The final amount of B, C, and D are determined by subtracting the product of moles of A reacted and the stoichiometric ratio of B, C, and D to A from the initial moles of B, C, and D, as shown by the following expressions. The final amount of B written in terms of moles is shown below.

$$N_B = N_{B0} - \frac{b}{a} X_A N_{A0} \quad (5-28)$$

where  $N_B$  = final amount of reactant B, mol  
 $N_{B0}$  = initial amount of reactant B, mol

The final amount of B in terms of concentration is

$$\begin{aligned} C_B &= \frac{N_B}{V} = C_{B0} - \frac{b}{a} X_A C_{A0} \\ &= C_{B0} - \frac{b}{a} \frac{C_{A0} - C_A}{C_{A0}} C_{A0} = C_{B0} - \frac{b}{a} (C_{A0} - C_A) \end{aligned} \quad (5-29)$$

where  $C_B$  = final concentration of reactant B, mol/L  
 $V$  = solution volume, L  
 $C_{B0}$  = initial concentration of reactant B, mol/L

Similarly, for reactants C and D,

$$C_C = C_{C0} + \frac{c}{a} (C_{A0} - C_A) \quad (5-30)$$

$$C_D = C_{D0} + \frac{d}{a} (C_{A0} - C_A) \quad (5-31)$$

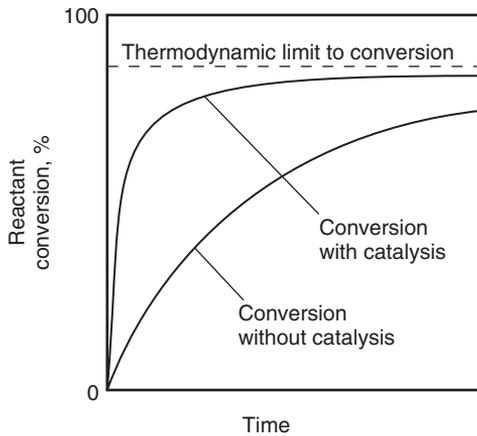

where  $C_C, C_D$  = final concentration of reactants C and D, mol/L  
 $C_{C0}, C_{D0}$  = initial concentration of reactants C and D, mol/L

The final concentration of the various species are related to one another and to the conversion, as summarized in Table 5-2. As illustrated on Fig. 5-1, the addition of a catalyst (or other change in the reaction conditions) may improve the selectivity and the reaction conversion for a given time. The conversion from reactant to product can eventually reach the thermodynamic limit of the reaction, as discussed in the following section.

**Table 5-2**

Final concentration of various species related to one another and to conversion

Initial Amount Present, mol	Change in Initial Amount, mol	Final Amount Present, mol	Final Concentration, mol/L
$N_{A0}$	$-N_{A0}X_A$	$N_A = N_{A0}(1 - X_A)$	$C_A = C_{A0}(1 - X_A)$
$N_{B0}$	$-\frac{b}{a}X_A N_{A0}$	$N_B = N_{B0} - \frac{b}{a}X_A N_{A0}$	$C_B = C_{B0} - \frac{b}{a}(C_{A0} - C_A)$
$N_{C0}$	$\frac{c}{a}X_A N_{A0}$	$N_C = N_{C0} + \frac{c}{a}X_A N_{A0}$	$C_C = C_{C0} + \frac{c}{a}(C_{A0} - C_A)$
$N_{D0}$	$\frac{d}{a}X_A N_{A0}$	$N_D = N_{D0} + \frac{d}{a}X_A N_{A0}$	$C_D = C_{D0} + \frac{d}{a}(C_{A0} - C_A)$

**Figure 5-1**

Improved reactant conversion with addition of catalyst.

## 5-2 Equilibrium Reactions

As discussed previously in this chapter, many of the reactions of significance in water treatment processes are reversible reactions. In other words, reactions such as that shown in Eq. 5-3 will not usually achieve complete conversion of reactants to products but instead will reach a state of dynamic equilibrium. Dynamic equilibrium is characterized by a balance between the continuous formation of products from reactants and reactants from products. If there is a change or stress to the system that affects the balance, the amount of reactants and products present will change to accommodate the stress. This concept is known as Le Chatelier's principle, which states that a reaction at equilibrium shifts in the direction that reduces a stress to the reaction. For example, in Eq. 5-21 if constituent A is removed from the

system, the equilibrium will shift to form more A. In a chemical system, the difference between the actual state and the equilibrium state is the driving force used to accomplish treatment objectives.

### Equilibrium Constants

When chemical reactions come to a state of equilibrium, the numerical value of the ratio of the concentration of the products over the concentration of the reactants all raised to the power of the corresponding stoichiometric coefficients is known as the equilibrium constant ( $K_c$ ) and, for the reaction shown in Eq. 5-21, is written as

$$\frac{[C]^c[D]^d}{[A]^a[B]^b} = K_c \quad (5-32)$$

where  $K_c$  = equilibrium constant (subscript  $c$  used to signify equilibrium constant based on species concentration)  
 $[ ]$  = concentration of species, mol/L  
 $a, b, c, d$  = stoichiometric coefficients of species A, B, C, D, respectively

For example, the ionization of carbonic acid, given previously as Eq. 5-5, is shown as

The equilibrium constant at 25°C (neglecting nonidealities) for the reaction shown above may be written as

$$\frac{[\text{H}^+][\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]} = K_c = 5.0 \times 10^{-7} \quad (5-33)$$

The value of equilibrium constants and reactant and product concentrations are typically small and, therefore, are often reported in the literature using the operand “p,” which is defined as

$$\text{p}[i] = -\log_{10}[i] \quad (5-34)$$

where  $[i]$  = concentration of species  $i$ , mol/L

The reporting of the hydrogen ion activity as pH is a familiar example of the p notation. Similarly, an equilibrium constant  $K$  may be reported as  $\text{p}K$ , which is defined as

$$\text{p}K = -\log_{10} K \quad (5-35)$$

Therefore, the  $K_c$  reported in Eq. 5-33 may be written as

$$\text{p}K_c = -\log_{10} K_c = -\log_{10}(5.0 \times 10^{-7}) = 6.3 \quad (5-36)$$

### Ionic Strength

In dilute solutions, the ions present behave independently of each other. However, as the concentration of ions in solution increases, the activity of the ions decreases because of ionic interaction. The ionic strength may be

### Example 5-3 Dependence of chemical species on pH

A drinking water contains hypochlorous acid (HOCl). Using the following relationship, determine the ratio of the hypochlorite ion ( $\text{OCl}^-$ ) to HOCl at (a) pH 7.0 and (b) pH 8.0 (neglecting nonidealities):

The equilibrium constant  $K_c$  for the dissociation of HOCl into  $\text{OCl}^-$  and  $\text{H}^+$  (also known as an acid dissociation constant and typically reported as  $K_a$ ) is  $10^{-7.5}$  ( $\text{p}K_a = 7.5$ ).

#### Solution

- Write the equilibrium relationship for the equation provided in the problem statement

$$\frac{[\text{H}^+][\text{OCl}^-]}{[\text{HOCl}]} = K_a = 10^{-7.5}$$

- Determine the ratio of  $[\text{OCl}^-]$  to  $[\text{HOCl}]$  at the given pH values.
  - At pH 7.0, the hydrogen concentration  $[\text{H}^+]$  is equal to  $10^{-7}$  and the equilibrium relationship is written as

$$\frac{(10^{-7})[\text{OCl}^-]}{[\text{HOCl}]} = 10^{-7.5} \quad \frac{[\text{OCl}^-]}{[\text{HOCl}]} = 10^{-0.5} = 0.32$$

- At pH 8.0, the hydrogen concentration  $[\text{H}^+]$  is equal to  $10^{-8}$  and the equilibrium relationship is written as

$$\frac{(10^{-8})[\text{OCl}^-]}{[\text{HOCl}]} = 10^{-7.5} \quad \frac{[\text{OCl}^-]}{[\text{HOCl}]} = 10^{0.5} = 3.2$$

#### Comment

As shown in the calculations above, the solution pH can have a significant impact on the chemical species present. As shown in Chapter 13, HOCl is a more effective disinfectant than  $\text{OCl}^-$  and is formed when chlorine is added to water. Consequently, it will be important to keep the pH 7 or less to achieve the greatest level of disinfection for a given dose of chlorine.

For a given reaction, the value of the equilibrium constant, expressed in terms of concentration, will depend on the temperature and ionic strength of the solution. It should be noted that the equilibrium condition shown in Eq. 5-32 is based on the concentration of the chemical species involved in the reaction and may need to be adjusted for ionic activity, as discussed below.

determined using the equation (Lewis and Randall, 1921)

$$I = \frac{1}{2} \sum_i C_i Z_i^2 \quad (5-37)$$

where  $I$  = ionic strength of solution, mol/L(M)  
 $C_i$  = concentration of species  $i$ , mol/L(M)  
 $Z_i$  = number of replaceable hydrogen atoms or their equivalent  
 (for oxidation–reduction reactions,  $Z$  is equal to the change  
 in valence)

If the concentration of individual species is not known, the ionic strength may be estimated from the total dissolved solids concentration using the correlation (Stumm and Morgan, 1996)

$$I = (2.5 \times 10^{-5}) (\text{TDS}) \quad (5-38)$$

where TDS = total dissolved solids, mg/L

To account for nonideal conditions encountered due to ion–ion interactions (e.g., at high ionic strength), an effective concentration term called “activity” is used.

### Activity and Activity Coefficients

The activity of a substance is defined by the standard state conditions of the substance and is based on commonly used standard conditions. The standard reference conditions for zero free energy are defined as 1 atm of pressure a temperature of 298.15 K (25°C), elements in their lowest energy level (e.g., O<sub>2</sub> as a gas, carbon as graphite), and 1 *molal* hydrogen ion (1 mole of hydrogen ion per 1000 g of water). Some recent chemical references use 1 bar rather than 1 atm as the standard state, but the difference is small (1 atm = 1.01325 bar). Nonetheless, when looking up values for free energy in reference tables, note whether 1 atm or 1 bar is used for the standard state. The activity coefficient of a chemical in water may be determined as discussed below.

For ions and molecules in solution,

$$\{i\} = \gamma_i [i] \quad (5-39)$$

where  $\{i\}$  = activity or effective concentration of ionic species, mol/L(M)  
 $\gamma_i$  = activity coefficient for ionic species  
 $[i]$  = concentration of ionic species in solution, mol/L(M)

In general,  $\gamma_i$  is greater than 1.0 for nonelectrolytes and less than 1.0 for electrolytes. As the solution becomes dilute (applicable to most applications in water treatment),  $\gamma_i$  approaches 1 and  $\{i\}$  approaches  $[i]$ . In the dilute aqueous solutions normally encountered in water treatment, activity coefficients are assumed to be equal to 1.

For pure solids or liquids in equilibrium with a solution  $\{i\} = 1$ , and for gases in equilibrium with a solution, the activity of species  $i$  is

$$\{i\} = \gamma_i P_i \quad (5-40)$$

where  $\{i\}$  = activity or effective gas pressure, atm  
 $P_i$  = partial pressure of  $i$ , atm

When reactions take place at atmospheric pressure (actually, much less than its critical pressure), the activity of a gas is equal to its partial pressure in atmospheres and the activity coefficient is 1.0.

For solvents or miscible liquids in a solution,

$$\{i\} = \gamma_i x_i \quad (5-41)$$

where  $x_i$  = mole fraction of species  $i$

As the solution becomes more dilute,  $\gamma_i$  approaches 1. As stated above, the activity coefficient generally is assumed to be 1 for the dilute solutions, which are typical in water treatment.

When a species in water is an electrolyte, the activity should be considered but is usually ignored in routine calculations. The activity coefficient for electrolytes in solution with ionic strength less than 0.005 M may be estimated from the Debye–Hückel limiting law (Debye and Hückel, 1923):

$$\log_{10} \gamma_i = -AZ_i^2 I^{1/2} \quad (5-42)$$

where  $A$  = constant equal to 0.51 at 25°C (Stumm and Morgan, 1996)

For more concentrated solutions up to  $I \leq 0.1$  M, the following modification of the Debye–Hückel equation, known as the Davies equation, can be applied with acceptable error (Davies, 1967):

$$\log_{10} \gamma_i = -AZ_i^2 \left( \frac{I^{1/2}}{1 + I^{1/2}} - 0.3I \right) \quad (5-43)$$

where  $A$  = constant (see Eq. 5-44)

The Davies equation is typically in error by 1.5 percent and 5 to 10 percent at ionic strengths between 0.1 and 0.5 M, respectively (Levine, 1988).

The constant  $A$  in Eq. 5-43 depends on temperature and can be estimated from the equation (Stumm and Morgan, 1996; Trussell, 1998)

$$A = 1.29 \times 10^6 \frac{\sqrt{2}}{(D_\epsilon T)^{1.5}} \quad (5-44)$$

where  $T$  = absolute temperature, K ( $273 + ^\circ\text{C}$ )  
 $D_\epsilon$  = dielectric constant (see Eq. 5-45)

The dielectric constant may be determined using the equation (Harned and Owen, 1958)

$$D_{\epsilon} \cong 78.54\{1 - [0.004579(T - 298)] + [11.9 \times 10^{-6}(T - 298)^2] + [28 \times 10^{-9}(T - 298)^3]\} \quad (5-45)$$

where  $T$  = absolute temperature, K(273 + °C)

Therefore, the constant  $A$  for water at 0, 15, and 25°C is 0.49, 0.5, and 0.51, respectively.

The equilibrium relationship shown in Eq. 5-32 may now be expressed in terms of activities:

$$\frac{(\gamma_c[C])^c(\gamma_d[D])^d}{(\gamma_a[A])^a(\gamma_b[B])^b} = \frac{\{C\}^c\{D\}^d}{\{A\}^a\{B\}^b} = K \quad (5-46)$$

where  $K$  = equilibrium constant based on ionic activity (note absence of subscript to signify activity basis)

The corresponding equilibrium for Eq. 5-23 is

$$\frac{\{C\}^{c/a}\{D\}^{d/a}}{\{A\}\{B\}^{b/a}} = K \quad (5-47)$$

For most water supplies, the ionic strength is less than 5 millimole/L (mM) and the activity coefficients for monovalent ions are close to one. The calculation of activity coefficients for solutions of different ionic strengths is presented in the following example.

### Example 5-4 Determination of activity coefficients at different ionic strengths

Calculate the activity coefficients of  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{Al}^{3+}$  at ionic strengths of 0.001, 0.005, and 0.01 M at 25°C.

#### Solution

1. Determine the activity coefficients for an ionic strength of 0.001 M at 25°C using the Debye–Hückel limiting law (Eq. 5-42):

$$\log_{10} \gamma_{\text{Na}^+} = -0.51(1)^2 \sqrt{0.001} = -1.61 \times 10^{-2} \quad \therefore \gamma_{\text{Na}^+} = 0.96$$

$$\log_{10} \gamma_{\text{Ca}^{2+}} = -0.51(2)^2 \sqrt{0.001} = -6.45 \times 10^{-2} \quad \therefore \gamma_{\text{Ca}^{2+}} = 0.86$$

$$\log_{10} \gamma_{\text{Al}^{3+}} = -0.51(3)^2 \sqrt{0.001} = -0.14 \quad \therefore \gamma_{\text{Al}^{3+}} = 0.72$$

2. Determine the activity coefficients for an ionic strength of 0.005 M at 25°C using the Debye–Hückel limiting law:

$$\log_{10} \gamma_{\text{Na}^+} = -0.51(1)^2 \sqrt{0.005} = -3.61 \times 10^{-2} \quad \therefore \gamma_{\text{Na}^+} = 0.92$$

$$\log_{10} \gamma_{\text{Ca}^{2+}} = -0.51(2)^2 \sqrt{0.005} = -0.14 \quad \therefore \gamma_{\text{Ca}^{2+}} = 0.72$$

$$\log_{10} \gamma_{\text{Al}^{3+}} = -0.51(3)^2 \sqrt{0.005} = -0.32 \quad \therefore \gamma_{\text{Al}^{3+}} = 0.48$$

3. Determine the activity coefficients for an ionic strength of 0.01 M at 25°C using the Davies equation (Eq. 5-43):

$$\begin{aligned} \log_{10} \gamma_{\text{Na}^+} &= -0.51(1)^2 \left[ \frac{\sqrt{0.01}}{1 + \sqrt{0.01}} - 0.3(0.01) \right] \\ &= -4.48 \times 10^{-2} \quad \therefore \gamma_{\text{Na}^+} = 0.90 \end{aligned}$$

$$\begin{aligned} \log_{10} \gamma_{\text{Ca}^{2+}} &= -0.51(2)^2 \left[ \frac{\sqrt{0.01}}{1 + \sqrt{0.01}} - 0.3(0.01) \right] \\ &= -0.18 \quad \therefore \gamma_{\text{Ca}^{2+}} = 0.66 \end{aligned}$$

$$\begin{aligned} \log_{10} \gamma_{\text{Al}^{3+}} &= -0.51(3)^2 \left[ \frac{\sqrt{0.01}}{1 + \sqrt{0.01}} - 0.3(0.01) \right] \\ &= -0.40 \quad \therefore \gamma_{\text{Al}^{3+}} = 0.40 \end{aligned}$$

### Comment

The activity for all the ions decreases as the ionic strength increases. As the ionic strength of the solution increases, the impact of charge on the species has a large influence on the value of the activity coefficient. For example, as ionic strength increased from 0.001 to 0.01, the activity coefficient for  $\text{Na}^+$  decreased by only about 6 percent as compared to  $\text{Al}^{3+}$ , which decreased by 46 percent.

## 5-3 Thermodynamics of Chemical Reactions

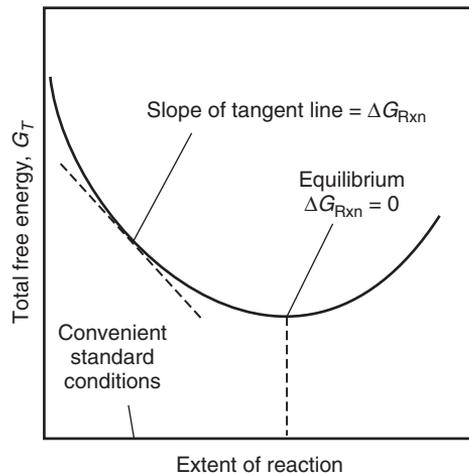

Principles from equilibrium thermodynamics provide a means for determining whether reactions are favorable and are also used in process design calculations to determine the final equilibrium state. The difference between the actual state and the equilibrium state is the driving force for

many processes and reactions. Equilibrium thermodynamics can be used to determine whether the treatment process is feasible, and the reaction kinetics, described in the following sections, will provide a basis for the treatment device size.

To determine whether a reaction will proceed (i.e., is thermodynamically favorable), two fundamental thermodynamic criteria must be considered. The first thermodynamic criterion that must be satisfied is that the change in entropy of the system and its surroundings must be greater than zero for a reaction to proceed. When evaluating chemical reactions, the entropy requirement is typically satisfied, especially when heat is produced by the reaction and, therefore, is not considered further in this text. The second thermodynamic criterion necessary for a reaction to proceed is the requirement that the change in free energy (final energy state minus initial energy state) of the reaction must be less than zero.

### Reference Conditions

To understand how the free energy of reaction changes as a reaction proceeds, it is useful to examine the total free energy of reaction as a function of the reaction extent, as shown on Fig. 5-2. Because the absolute free energy of reaction cannot be determined easily, it is most common to determine the change in free energy of a reaction. The free energy of the reaction curve shown on Fig. 5-2 is compared to a convenient set of standard conditions. For example, a common definition of standard conditions is as follows: (1) solids, liquids, and gases in their lowest energy state at 1 atm (or 1 bar); (2) solutes in solution referenced to a 1 molal hydrogen ion concentration; and (3) a specified temperature, usually 25°C. For most water treatment applications, the molar concentration is essentially equal to the molal concentration and a 1 M solution is 1 mole per 1000 g of solvent.

**Figure 5-2**  
Total free energy as function of the extent of the reaction.

The expression for free energy was developed by J. W. Gibbs and is often referred to as the Gibbs free energy or Gibbs function  $G$ . The free-energy change of formation of a substance  $i$  is given by the expression

$$\Delta G_{F,i} = \Delta G_{F,i}^{\circ} + RT \ln\{i\} \quad (5-48)$$

where  $\Delta G_{F,i}$  = free-energy change of formation of species  $i$ , kJ/mol  
 $\Delta G_{F,i}^{\circ}$  = free-energy change of formation per mole of  $i$  at standard conditions, kJ/mol  
 $R$  = universal gas law constant,  $8.314 \times 10^{-3}$  kJ/mol · K  
 $T$  = absolute temperature, K(273 + °C)  
 $\{i\}$  = activity of species  $i$

Thermodynamic constants may be found in various reference books, including Stumm and Morgan (1996) and *Lange's Handbook* (Dean, 1992).

The free energy of a reaction can be calculated using the definition of activity and the free-energy change of formation. For this purpose, consider the reaction shown in Eq. 5-21, in which  $a$ ,  $b$ ,  $c$ , and  $d$  are stoichiometric coefficients. For this reaction, the free-energy criterion may be determined for a reference reactant A and written per mole of A by dividing by the stoichiometric coefficient  $a$ , as shown in Eq. 5-23 and repeated here:

The free-energy change is defined as the final state minus the initial state (David, 2000; Dean, 1992; Poling et al., 2001). Therefore, the change in free energy of a reaction is the sum of the free-energy change of each product minus the sum of the free-energy change of the reactants, as shown in the following expression written in terms of free-energy change per mole of A:

$$\Delta G_{\text{Rxn},A} = -\Delta G_{F,A} - \frac{b}{a}\Delta G_{F,B} + \frac{c}{a}\Delta G_{F,C} + \frac{d}{a}\Delta G_{F,D} \quad (5-49)$$

where  $\Delta G_{\text{Rxn},A}$  = free-energy change of reaction per mole of A, kJ/mol  
 $\Delta G_{F,A}$  = change in free energy of reactant A, kJ/mol  
 $\Delta G_{F,B}$  = change in free energy of reactant B, kJ/mol  
 $\Delta G_{F,C}$  = change in free energy of product C, kJ/mol  
 $\Delta G_{F,D}$  = change in free energy of product D, kJ/mol

The free-energy change of the formation of each species, as defined in Eq. 5-49, may be substituted into Eq. 5-49 for each reactant and product to obtain the overall free-energy change for the reaction. The resulting expression for the free-energy change of the reaction is shown in the expression

$$\begin{aligned} \Delta G_{\text{Rxn},A} = & \frac{c}{a}\Delta G_{F,C}^{\circ} + RT \ln\{C\}^{c/a} + \frac{d}{a}\Delta G_{F,D}^{\circ} + RT \ln\{D\}^{d/a} \\ & - \Delta G_{F,A}^{\circ} - RT \ln\{A\} - \frac{b}{a}\Delta G_{F,B}^{\circ} - RT \ln\{B\}^{b/a} \end{aligned} \quad (5-50)$$

## Free Energy of Formation

## Free Energy of Reaction

where  $\Delta G_{\text{Rxn},A}$  = free-energy change of reaction per mole of A, kJ/mol  
 $\{A\}$  = activity of reactant A, mol/L  
 $\{B\}$  = activity of reactant B, mol/L  
 $\{C\}$  = activity of product C, mol/L  
 $\{D\}$  = activity of product D, mol/L

The free-energy change of the reaction per mole of A at standard conditions (25°C and 1 atm pressure),  $\Delta G_{\text{Rxn},A}^{\circ}$ , can be written as

$$\Delta G_{\text{Rxn},A}^{\circ} = -\Delta G_{F,A}^{\circ} - \frac{b}{a} \Delta G_{F,B}^{\circ} + \frac{c}{a} \Delta G_{F,C}^{\circ} + \frac{d}{a} \Delta G_{F,D}^{\circ} \quad (5-51)$$

Equation 5-50 can be further simplified by substituting in the relationship shown in Eq. 5-51:

$$\Delta G_{\text{Rxn},A} = \Delta G_{\text{Rxn},A}^{\circ} + RT \ln \frac{\{C\}^{c/a} \{D\}^{d/a}}{\{A\} \{B\}^{b/a}} \quad (5-52)$$

The logarithmic term in Eq. 5-52 is called the reaction quotient  $Q$ :

$$Q = \frac{\{C\}^{c/a} \{D\}^{d/a}}{\{A\} \{B\}^{b/a}} \quad (5-53)$$

If the stoichiometric coefficient  $a$  had not been factored out of Eq. 5-21, then Eq. 5-52 would be written per  $a$  moles of A as

$$a\Delta G_{\text{Rxn},A} = a\Delta G_{\text{Rxn},A}^{\circ} + RT \ln \frac{\{C\}^c \{D\}^d}{\{A\}^a \{B\}^b} \quad (5-54)$$

When examining thermodynamic data, it is important to make certain that the free energy that is reported is per mole of A. Finally, the thermodynamic criterion that must be met for a reaction to proceed as written from the initial state toward the final state may be expressed as

$$\Delta G_{\text{Rxn},A} \text{ must be } < 0 \quad (5-55)$$

While a reaction is thermodynamically feasible when  $\Delta G_{\text{Rxn},A} < 0$ , the rate at which a reaction will proceed is not known because reactants often have to proceed through reactive intermediates that have a higher free energy than the reactants. Alternately, if  $\Delta G_{\text{Rxn},A} > 0$ , the reverse reaction would be thermodynamically feasible.

## Free Energy at Equilibrium

Another useful relationship, known as the equilibrium state, is obtained when  $\Delta G_{\text{Rxn},A} = 0$ . When  $\Delta G_{\text{Rxn},A} = 0$  in Eq. 5-52, the reaction quotient is equal to the equilibrium constant  $K$  as shown below:

$$\Delta G_{\text{Rxn},A} = \Delta G_{\text{Rxn},A}^{\circ} + RT \ln \frac{\{C\}^{c/a} \{D\}^{d/a}}{\{A\} \{B\}^{b/a}} = 0 \quad (5-56)$$

If the relationship shown in Eq. 5-47 for the equilibrium constant is substituted for the reaction quotient, the following expression is obtained:

$$\Delta G_{\text{Rxn},A}^{\circ} = -RT \ln \left[ \frac{\{C\}^{c/a} \{D\}^{d/a}}{\{A\} \{B\}^{b/a}} \right] = -RT \ln [K] \quad (5-57)$$

Rearranging Eq. 5-57 and solving for the equilibrium constant result in the expression

$$K = e^{-\Delta G_{\text{Rxn,A}}^{\circ}/RT} \quad (5-58)$$

The free energy, calculated using Eq. 5-52, is actually the slope of a tangent to the total free-energy curve shown on Fig. 5-2, and equilibrium is represented by the special case where the slope is zero. This means that  $\Delta G_{\text{Rxn,A}}$  is really the change in free energy that results from an infinitesimal conversion of A to products.

A difficulty often encountered when calculating the free energy of reaction is that the free-energy change of formation per mole of A in the aqueous phase,  $\Delta G_{F,A,\text{aq}}^{\circ}$ , is needed to calculate  $\Delta G_{\text{Rxn,A}}$ , and the free energy of formation may be reported for the gas phase,  $\Delta G_{F,A,\text{gas}}^{\circ}$ . However, the relationship shown in Eq. 5-59 can be used to develop an expression for the free energy of formation of slightly soluble gases in the aqueous phase,  $\Delta G_{F,A,\text{aq}}^{\circ}$ , based on the free energy of formation in the gas phase,  $\Delta G_{F,A,\text{gas}}^{\circ}$ :

$$\Delta G_{\text{Vol,A}}^{\circ} = \Delta G_{F,A,\text{gas}}^{\circ} - \Delta G_{F,A,\text{aq}}^{\circ} = -RT \ln H_{\text{PC}} \quad (5-59)$$

where  $\Delta G_{\text{Vol,A}}^{\circ}$  = free-energy change of volatilization per mole of A at standard conditions, kJ/mol  
 $\Delta G_{F,A,\text{gas}}^{\circ}$  = free-energy change of formation per mole of A in gas phase at standard conditions, kJ/mol  
 $\Delta G_{F,A,\text{aq}}^{\circ}$  = free-energy change of formation per mole of A in aqueous phase at standard conditions, kJ/mol  
 $H_{\text{PC}}$  = Henry's law constant atm/(mol/L)

Equation 5-59 can then be rearranged to solve for the aqueous-phase concentration of A as a function of the gas-phase concentration of A:

$$\Delta G_{F,A,\text{aq}}^{\circ} = \Delta G_{F,A,\text{gas}}^{\circ} + RT \ln H_{\text{PC}} \quad (5-60)$$

Consequently,  $\Delta G_{F,A,\text{aq}}^{\circ}$  can be calculated from  $\Delta G_{F,A,\text{gas}}^{\circ}$  if  $H_{\text{PC}}$  is known. Henry's law is presented and discussed in detail in Chap. 14.

Most reactions in water treatment do not occur at 25°C because the water temperature is usually lower. The free-energy change at other temperatures can be determined from the expression

$$\frac{\Delta G_{\text{Rxn}}^{\circ}}{T} \Big|_{T=298 \text{ K}}^T = \int_{T=298 \text{ K}}^T -\frac{\Delta H_{\text{Rxn}}^{\circ}(T)}{T^2} dT \quad (5-61)$$

where  $\Delta H_{\text{Rxn}}^{\circ}(T)$  = standard enthalpy of reaction that depends on temperature

**Calculation  
of Free Energy  
of Formation  
Using Henry's  
Constant**

**Temperature  
Dependence  
of Free-Energy  
Change**

The temperature-dependent standard enthalpy of reaction is defined as

$$\Delta H_{\text{Rxn}}^{\circ}(T) = \int_{T=298 \text{ K}}^T \Delta C_{p,\text{Rxn}} dT + \Delta H_{\text{Rxn},298 \text{ K}}^{\circ} \quad (5-62)$$

where  $\Delta C_{p,\text{Rxn}}$  = change in heat capacity for the reaction, kJ/mol  
 $\Delta H_{\text{Rxn},298 \text{ K}}^{\circ}$  = standard enthalpy at 298 K

The heat capacity term may be calculated using the equation (Poling et al., 2001)

$$C_{p,i} = A + BT + CT^2 + DT^3 \quad (5-63)$$

where  $A, B, C, D$  = constants

$C_{p,i}$  = isobaric (constant-pressure) heat capacity  
 for compound  $i$

To calculate  $\Delta C_{p,\text{Rxn}}$ , the difference of each constant ( $A, B, C,$  and  $D$ ) between products and reactants needs to be calculated:

$$\Delta C_{p,\text{Rxn}} = \Delta A + \Delta BT + \Delta CT^2 + \Delta DT^3 \quad (5-64)$$

For the reaction shown in Eq. 5-23, the terms in Eq. 5-64 are given by the expressions

$$\begin{aligned} \Delta A &= \frac{d}{a} A_D + \frac{c}{a} A_C - \frac{b}{a} A_B - A_A & \Delta B &= \frac{d}{a} B_D + \frac{c}{a} B_C - \frac{b}{a} B_B - B_A \\ \Delta C &= \frac{d}{a} C_D + \frac{c}{a} C_C - \frac{b}{a} C_B - C_A & \Delta D &= \frac{d}{a} D_D + \frac{c}{a} D_C - \frac{b}{a} D_B - D_A \end{aligned} \quad (5-65)$$

Substituting the relationships shown in Eq. 5-64 into Eq. 5-62 and subsequently into Eq. 5-61, the following expression is obtained:

$$\begin{aligned} \frac{\Delta G_{\text{Rxn}}^{\circ}}{T} \Big|_{T=298 \text{ K}}^T &= - \int_{T=298 \text{ K}}^T \left[ \frac{\Delta H_{\text{Rxn},298 \text{ K}}^{\circ}}{T^2} + \frac{\Delta A(T-298)}{T^2} + \frac{\Delta B(T^2-298^2)}{2T^2} \right. \\ &\quad \left. + \frac{\Delta C(T^3-298^3)}{3T^2} + \frac{\Delta D(T^4-298^4)}{4T^2} \right] dT \end{aligned} \quad (5-66)$$

For the case where  $\Delta H_{\text{Rxn}}^{\circ}$  does not depend on temperature ( $\Delta H_{\text{Rxn}}^{\circ}$  is constant), Eq. 5-66 can be simplified as

$$\frac{\Delta G_{\text{Rxn}}^{\circ}}{T} \Big|_{T=298 \text{ K}}^T = \frac{\Delta G_{\text{Rxn},T}^{\circ}}{T} - \frac{\Delta G_{\text{Rxn},298 \text{ K}}^{\circ}}{298 \text{ K}} = \Delta H_{\text{Rxn},298 \text{ K}}^{\circ} \left( \frac{1}{T} - \frac{1}{298 \text{ K}} \right) \quad (5-67)$$

At equilibrium, Eq. 5-57 can be substituted into Eq. 5-61 to yield the van't Hoff relationship, which may be used to determine the equilibrium

constant ( $K_{\text{eq}}$ ) at different temperatures:

$$\ln K \Big|_{T=298 \text{ K}}^T = \int_{T=298 \text{ K}}^T \frac{\Delta H_{\text{Rxn},298 \text{ K}}^\circ}{RT^2} dT \quad (5-68)$$

$$\ln \frac{K_T}{K_{298 \text{ K}}} = \frac{\Delta H_{\text{Rxn},298 \text{ K}}^\circ}{R} \left( \frac{1}{298 \text{ K}} - \frac{1}{T} \right)$$

where  $K_T$  = equilibrium constant at temperature  $T$ , K ( $273 + ^\circ\text{C}$ )  
 $K_{298 \text{ K}}$  = equilibrium constant at 298 K

Using Eq. 5-68, the linear relationship between  $\ln K$  and  $1/T$  can be determined by plotting the function

$$\ln K = -\frac{\Delta H_{\text{Rxn},298 \text{ K}}^\circ}{RT} + \text{const} \quad (5-69)$$

For most reactions occurring in water treatment processes,  $\Delta H_{\text{Rxn}}^\circ$  can be assumed to be constant because  $\Delta H_{\text{Rxn}}$  does not change significantly over the temperature range encountered in water treatment (0 to  $30^\circ\text{C}$ ).

### Example 5-5 Dependence of pH and free-energy change on temperature

For the dissociation reaction of water, the free-energy change and enthalpy change for each species in the reaction

are as follows:

$$\Delta G_{\text{F},\text{H}_2\text{O}}^\circ = -237.18 \text{ kJ/mol} \quad \Delta H_{\text{F},\text{H}_2\text{O}}^\circ = -285.83 \text{ kJ/mol}$$

$$\Delta G_{\text{F},\text{H}^+}^\circ = 0 \text{ kJ/mol} \quad \Delta H_{\text{F},\text{H}^+}^\circ = 0 \text{ kJ/mol}$$

$$\Delta G_{\text{F},\text{OH}^-}^\circ = -157.29 \text{ kJ/mol} \quad \Delta H_{\text{F},\text{OH}^-}^\circ = -230.0 \text{ kJ/mol}$$

Calculate the pH of neutrality and free-energy change of the reaction at  $10^\circ\text{C}$ . Assume that  $\Delta H_{\text{Rxn}}^\circ$  does not change with temperature.

#### Solution

- Calculate the equilibrium constant, using Eq. 5-58, for water at  $25^\circ\text{C}$ .
  - Calculate  $\Delta G_{\text{Rxn},\text{H}_2\text{O}}^\circ$  using Eq. 5-51:

$$\begin{aligned} \Delta G_{\text{Rxn},\text{H}_2\text{O}}^\circ &= \Delta G_{\text{F},\text{OH}^-}^\circ + \Delta G_{\text{F},\text{H}^+}^\circ - \Delta G_{\text{F},\text{H}_2\text{O}}^\circ \\ &= -157.29 + 0 - (-237.18 \text{ K}) = 79.89 \text{ kJ/mol} \end{aligned}$$

b. Calculate the equilibrium constant at 25°C (298 K) using Eq. 5-58:

$$\begin{aligned} K &= \exp\left(\frac{-\Delta G_{\text{Rxn},\text{H}_2\text{O}}^\circ}{RT}\right) \\ &= \exp\left[\frac{-79.89 \text{ kJ/mol}}{(8.314 \times 10^{-3} \text{ kJ/mol} \cdot \text{K})(298 \text{ K})}\right] \\ &= 9.90954 \times 10^{-15} \approx 10^{-14} \end{aligned}$$

The value for  $K$  for the dissociation of water at standard conditions is generally reported as  $K_w$ .

2. Calculate the equilibrium constant at 10°C (283 K):

a. Calculate  $\Delta H_{\text{Rxn}}^\circ$ :

$$\begin{aligned} \Delta H_{\text{Rxn},\text{H}_2\text{O}}^\circ &= \Delta H_{\text{F},\text{OH}^-}^\circ + \Delta H_{\text{F},\text{H}^+}^\circ - \Delta H_{\text{F},\text{H}_2\text{O}}^\circ \\ &= -230.0 + 0 - (-285.83) = 55.83 \text{ kJ/mol} \end{aligned}$$

b. Calculate the equilibrium constant using Eq. 5-68:

$$\begin{aligned} \ln K \Big|_{T=298 \text{ K}}^T &= \int_{T=298 \text{ K}}^T \frac{\Delta H_{\text{Rxn},298 \text{ K}}^\circ}{RT^2} dT \\ \ln \frac{K_T}{K_{298 \text{ K}}} &= \frac{\Delta H_{\text{Rxn},298 \text{ K}}^\circ}{R} \left( \frac{1}{298 \text{ K}} - \frac{1}{T} \right) \\ K_T &= K_{298 \text{ K}} \exp \left[ \frac{\Delta H_{\text{Rxn},298 \text{ K}}^\circ}{R} \left( \frac{1}{298 \text{ K}} - \frac{1}{T} \right) \right] \\ &= 10^{-14} \exp \left[ \frac{55.83 \text{ kJ/mol}}{8.314 \times 10^{-3} \text{ kJ/mol} \cdot \text{K}} \left( \frac{1}{298 \text{ K}} - \frac{1}{283 \text{ K}} \right) \right] \\ &= 3.0015 \times 10^{-15} \end{aligned}$$

3. Calculate the pH at neutrality at 10°C.

At neutral conditions,  $[\text{H}^+]$  is equal to  $[\text{OH}^-]$ :

$$[\text{H}^+][\text{OH}^-] = K_{\text{eq},283} = 3.0015 \times 10^{-15}$$

$$[\text{H}^+] = [\text{OH}^-] = \sqrt{3.0015 \times 10^{-15}} = 5.48 \times 10^{-8}$$

$$\text{pH} = \text{pOH} = -\log(5.48 \times 10^{-8}) = 7.26$$

4. Calculate  $\Delta G_{\text{Rxn}}^{\circ}$  at 10°C using Eq. 5-67:

$$\begin{aligned} \left. \frac{\Delta G_{\text{Rxn}}^{\circ}}{T} \right|_{T=298 \text{ K}}^T &= \frac{\Delta G_{\text{Rxn},T}}{T} - \frac{\Delta G_{\text{Rxn},298 \text{ K}}}{298 \text{ K}} \\ &= \Delta H_{\text{Rxn},298 \text{ K}}^{\circ} \left( \frac{1}{T} - \frac{1}{298 \text{ K}} \right) \\ \Delta G_{\text{Rxn},T}^{\circ} &= T \left[ \frac{\Delta G_{\text{Rxn},298 \text{ K}}^{\circ}}{298 \text{ K}} + \Delta H_{\text{Rxn},298 \text{ K}}^{\circ} \left( \frac{1}{T} - \frac{1}{298 \text{ K}} \right) \right] \\ &= 283 \text{ K} \left[ \frac{79.89 \text{ kJ/mol}}{298 \text{ K}} + 55.83 \text{ kJ/mol} \right. \\ &\quad \left. \times \left( \frac{1}{283 \text{ K}} - \frac{1}{298 \text{ K}} \right) \right] \\ &= 78.68 \text{ kJ/mol} \end{aligned}$$

### Comment

According to Le Chatelier's principle, as the temperature decreases, the reaction for the dissociation of water would be less favorable because it takes energy to dissociate water; consequently, the equilibrium constant is lower at 10°C than at 25°C.

## 5-4 Reaction Kinetics

While thermodynamic calculations provide a means for estimating the likelihood and maximum possible extent of a given reaction, they cannot be used to determine the rate of the reaction. This section discusses reaction rate laws which describe how fast a reaction proceeds in the absence of mass transfer limitations.

The rate of a chemical reaction depends on the activity of the reacting species and the temperature of the system. As noted earlier for organic compounds (nonelectrolytes) or monovalent ions in water, the activity is nearly equivalent to concentration when the ionic strength is less than 0.005 M. For divalent and trivalent ions, the activity coefficients should be calculated to determine whether activity coefficients are needed.

The rate of a reaction is expressed as the change in the concentration of a constituent with time:

$$\text{Rate of reaction} = \frac{\text{change in concentration}}{\text{change in time}} \quad (5-70)$$

### Reaction Rate

The reaction rate is used to describe the rate of formation of a product or the rate of decomposition of a reactant. As a reaction proceeds, the reaction rate changes; for example, as the concentration of reactants is decreased, the rate of a reaction may decrease. The reaction rate usually changes as the concentrations of the reactants and products change. The rate of change is described by an expression known as a rate law, as discussed in the following section.

### Rate Law and Reaction Order

In the following discussion, the term  $r_A$  is used to represent the reaction rate. It should be noted that  $dC_A/dt$  is not the reaction rate law but is obtained from a mass balance on a completely mixed batch reactor, which has a constant volume. The subscript A is used to designate the species described by the reaction rate. The units of the reaction rate are given by the expression

$$r_A = \frac{\text{moles A lost (-) or generated (+) due to reaction}}{(\text{volume}) (\text{time})} = \frac{\text{mol}}{\text{L} \cdot \text{s}} \quad (5-71)$$

A negative or positive sign for the reaction rate indicates that species A is either disappearing or appearing, respectively. The following irreversible reaction is used to develop the reaction rate.

For an irreversible reaction, the rate law depends on the concentrations of reactants. For the reaction shown in Eq. 5-72, the rate law may take the form

$$r_A = -k[A]^m[B]^n \quad (5-73)$$

where  $r_A$  = reaction rate, mol/L · s

$k$  = reaction rate constant, units vary depending on reaction order as discussed later

$m, n$  = constants, unitless

The concentration dependence of the reaction rate is accounted for in the reactant exponents  $m$  and  $n$  and is known as the reaction order. For Eq. 5-73, the reaction order is  $m$  for species A and  $n$  for species B, and the overall reaction order is  $m + n$ . The reaction order is typically a small positive integer; however, it may also be negative, zero, or fractional.

### Relationship between Reaction Rates

For an elementary reaction with the following reaction stoichiometry, a relationship between relative rates of reaction can be determined from stoichiometry:

To simplify the expression, Eq. 5-21 can be divided by the stoichiometric coefficient  $a$ , which yields the expression

Assuming the reaction shown in Eq. 5-23 is proceeding to the right, the following relationship between the reaction rates can be written using the stoichiometry from Eq. 5-23:

$$\frac{-r_A}{1} = \frac{-r_B}{b/a} = \frac{r_C}{c/a} = \frac{r_D}{d/a} \quad (5-74)$$

The reaction rates for reactants A and B,  $-r_A$  and  $-r_B$ , are negative because they are disappearing to form products, and the reaction rates for products C and D,  $r_C$  and  $r_D$ , are positive because they are being produced. If the reaction rate for A is known, the stoichiometric coefficients, as given by Eq. 5-74, can be used to determine the reaction rate for reactant B and products C and D. The use of stoichiometric coefficients is illustrated in the following example.

### Example 5-6 Determination of reaction rates using stoichiometry

Given the reaction  $4\text{Fe}^{2+} + \text{O}_2 + 10\text{H}_2\text{O} \rightarrow 4\text{Fe}(\text{OH})_3 + 8\text{H}^+$ , estimate the loss rates of oxygen and water and production rates of iron hydroxide and acid when the rate of loss of  $\text{Fe}^{2+}$  is  $2 \times 10^{-7} \text{ mol/L} \cdot \text{min}$ .

#### Solution

1. Write the relevant reaction using the form shown in Eq. 5-23. To cancel out the coefficient for  $\text{Fe}^{2+}$ , the reaction must be divided by 4, resulting in the expression

2. Based on Eq. 5-74, the rate expression can be written as follows:

$$-r_{\text{Fe}^{2+}} = \frac{-r_{\text{O}_2}}{\frac{1}{4}} = \frac{-r_{\text{H}_2\text{O}}}{\frac{5}{2}} = \frac{+r_{\text{Fe}(\text{OH})_3}}{1} = \frac{+r_{\text{H}^+}}{2}$$

3. Estimate the loss rates for oxygen ( $-r_{\text{O}_2}$ ) and water ( $-r_{\text{H}_2\text{O}}$ ) given that the rate of loss of  $\text{Fe}^{2+}$  ( $-r_{\text{Fe}^{2+}}$ ) is  $2 \times 10^{-7} \text{ mol/L} \cdot \text{min}$ :

$$-r_{\text{O}_2} = \frac{1}{4}(-r_{\text{Fe}^{2+}}) = \frac{1}{4}(2 \times 10^{-7}) = 0.5 \times 10^{-7} \text{ mol/L} \cdot \text{min}$$

$$-r_{\text{H}_2\text{O}} = \frac{5}{2}(-r_{\text{Fe}^{2+}}) = \frac{5}{2}(2 \times 10^{-7}) = 5 \times 10^{-7} \text{ mol/L} \cdot \text{min}$$

4. Estimate the production rates for iron hydroxide [ $+r_{\text{Fe(OH)}_3}$ ] and acid ( $+r_{\text{H}^+}$ ):

$$+r_{\text{Fe(OH)}_3} = -r_{\text{Fe}^{2+}} = 2 \times 10^{-7} \text{ mol/L} \cdot \text{min}$$

$$+r_{\text{H}^+} = 2(-r_{\text{Fe}^{2+}}) = 4 \times 10^{-7} \text{ mol/L} \cdot \text{min}$$

### Comment

For reactions that are given by Eq. 5-23, the reaction rates are related to one another. If one knows the rate of reaction of any at the components, then reaction rates of the other components can be calculated using Eq. 5-74.

### Rate Constants

The units of the rate constant depend on the reaction order; but, it should be noted that the units of the reaction rate  $r$  are always of the form mol/L · s. For a zero-order reaction, the rate constant would have the following units:

$$r_A = -k \quad k = \text{mol/L} \cdot \text{s} \quad (5-75)$$

For a first-order reaction, the rate constant would have the following units:

$$r_A = -k[A] \quad k = \text{s}^{-1} \quad (5-76)$$

For a second-order reaction, the rate constant would have the following units:

$$r_A = -k[A][B] \quad k = \text{L/mol} \cdot \text{s} \quad (5-77)$$

For Eq. 5-77, the rate is first order in A and B and second order overall. For a third-order reaction, the rate constant would have the following units:

$$r_A = -k[A][B][C] \quad k = \text{L}^2/\text{mol}^2 \cdot \text{s} \quad (5-78)$$

For Eq. 5-78, the rate is first order in A, B, and C and third order overall.

### Factors Affecting Reaction Rate Constants

A distinctive feature of water treatment is the varying character of each water source. A wide range in values of temperature, pH, and ionic composition is encountered in water treatment practice. In addition, environmental conditions often produce wide seasonal fluctuations in these intensive variables. Quantitative estimates of the dependence of empirical rate constants on temperature, pH, ionic composition, and other factors are essential for proper control of the reactions of interest.

#### EFFECT OF TEMPERATURE AND CATALYSIS ON REACTION RATE CONSTANT

Reaction rate constants are known to be dependent on temperature. A relationship known as the Arrhenius equation is used to describe the temperature dependence:

$$k = A e^{-E_a/RT} \quad (5-79)$$

where  $E_a$  = activation energy, kJ/mol  
 $A$  = frequency factor, same units as  $k$

The irreversible elementary reaction shown below may be used to illustrate the physical phenomenon causing rate constants to follow this temperature dependence:

According to collision theory, only colliding pairs of molecules that have sufficient kinetic energy to overcome the activation energy  $E_a$  will react, as shown on Fig. 5-3. In addition, the molecular collisions with sufficient kinetic energy must also have proper orientation for the reaction to proceed. The rate of reaction is given by

$$-r_A = \left( \begin{array}{c} \text{frequency of collisions} \\ \text{that have} \\ \text{proper orientation} \end{array} \right) \times \left( \begin{array}{c} \text{fraction of collisions} \\ \text{that have} \\ \text{sufficient energy} \end{array} \right) \quad (5-81)$$

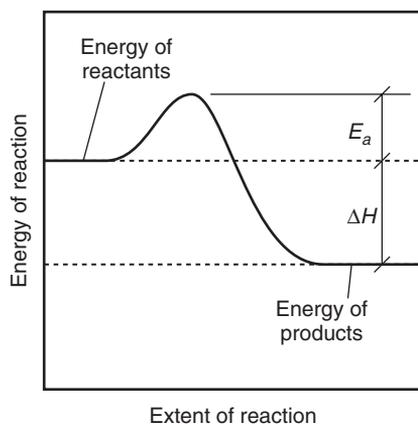

The frequency of collisions that have the proper orientation is proportional to the product of the concentrations of A and B. To estimate the fraction of collisions that have sufficient energy, Arrhenius postulated that the energy of the resulting collisions followed a Maxwell-Boltzmann distribution, which is given by the expression

$$N = C e^{-E_a/RT} \quad (5-82)$$

where  $N$  = number of collisions with energy equal to or greater than  $E_a$   
 $C$  = constant

Accordingly, the number of collisions with energy equal to or greater than the amount of energy required to overcome  $E_a$  is proportional to  $e^{-E_a/RT}$ :

$$\text{Fraction of collisions that have energy } \geq E_a \propto e^{-E_a/RT} \quad (5-83)$$

**Figure 5-3**  
 Reaction energy as function of reaction extent.

The rate expression can therefore be written as

$$-r_A = [A][B]Ae^{-E_a/RT} \quad (5-84)$$

Molecules in solution have translational, rotational, and vibrational motion, and this motion may make it more difficult for molecules to collide in the proper orientation and react. These effects are incorporated into the frequency factor  $A$ .

The constants in the Arrhenius equation can be determined by taking the natural logarithm of Eq. 5-79, which yields the expression

$$\ln(k) = \ln(A) + \left(-\frac{E_a}{R}\right) \times \left(\frac{1}{T}\right) \quad (5-85)$$

The rate constant can be determined experimentally at several temperatures, and when  $\ln(k)$  is plotted as a function of  $1/T$ , the slope is equal to  $-E_a/R$  and the  $y$  intercept is equal to  $\ln(A)$ . The temperature dependence of rate constants is sensitive to the magnitude of the activation energy  $E_a$ . Values of  $E_a$  for reactions in solution range from 4 to 125 kJ/mol (1 to 30 kcal/mol) (Moelwyn-Hughes, 1974). For example, the hydrolysis of aqueous  $\text{CO}_2$  ( $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3$ ) has an  $E_a$  of approximately 55 kJ/mol (13 kcal/mol) (Kern, 1960). Reactions with high  $E_a$  values show a much greater sensitivity to temperature increases as compared to reactions with low  $E_a$  values. In general, it has been observed that many rate constants double for every  $10^\circ\text{C}$  increase in temperature. However, as shown in the following example, this rule only holds for an activation energy of approximately 50 kJ/mol (12 kcal/mol), which is in the median range of most reactions in solution (Frost and Pearson, 1961).

### Example 5-7 Determination of the activation energy from rate constants that are known at two temperatures

If the rate of a chemical reaction doubles for each  $10^\circ\text{C}$  increase in temperature, estimate the value of the activation energy. Assume the initial temperature is  $25^\circ\text{C}$ .

#### Solution

1. Write an expression for Eq. 5-79 to isolate the activation energy term:

$$k = Ae^{-E_a/RT} \quad \ln(k) = \ln(A) - \frac{E_a}{RT}$$

2. Write expressions for the relationship between the reaction rate  $k_{T_1}$  and  $k_{T_2}$  at temperatures  $T_1$  and  $T_2$ , respectively.

- a. At temperature  $T_1$ , the expression developed in step 1 may be written as

$$\ln(k_{T_1}) = \ln(A) - \frac{E_a}{RT_1}$$

- b. A similar expression may be written for  $T_2$ :

$$\ln(k_{T_2}) = \ln(A) - \frac{E_a}{RT_2}$$

3. Solve the equations in step 2a and 2b for  $E_a$ .
- a. Develop a relationship for  $E_a$  by subtracting the expression developed in step 2b from the one developed in step 2a:

$$\ln\left(\frac{k_{T_1}}{k_{T_2}}\right) = \frac{E_a}{R} \left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

$$E_a = \frac{R \ln(k_{T_1}/k_{T_2})}{1/T_2 - 1/T_1}$$

- b. Substitute known values and solve for  $E_a$ :

$$T_1 = (273 + 25^\circ\text{C}) = 298 \text{ K}$$

$$T_2 = (273 + 25^\circ\text{C} + 10^\circ\text{C}) = 308 \text{ K}$$

$$k_{T_2} = 2k_{T_1}$$

$$E_a = \frac{(8.3144 \times 10^{-3} \text{ kJ/mol} \cdot \text{K}) \ln(k_{T_1}/2k_{T_1})}{(1/308 - 1/298)\text{K}^{-1}}$$

$$= 52.90 \text{ kJ/mol} \quad (12.63 \text{ kcal/mol})$$

While increases in the reaction rate with temperature occur with chemical reactions, the reaction rate for microbial reactions do not always increase with temperature. It has been shown that Arrhenius-type behavior is exhibited up to a limiting temperature, where enzyme deactivation occurs, and then the reaction rate decreases rapidly with an additional increase in temperature.

In many cases, the addition of a catalyst may speed up a reaction by lowering the activation energy, as shown on Fig. 5-4. In heterogeneous and enzyme catalysis, the catalyst can also increase the rate because the catalyst/enzyme can help orient the reactants in the proper manner for reaction.

**IMPACT OF IONIC STRENGTH ON REACTION RATE CONSTANTS**

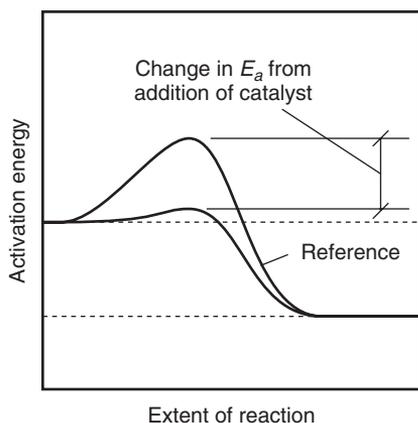

As discussed previously, the rate of chemical reactions depends on activities of the reactants and products. For an irreversible second-order elementary reaction, the rate of disappearance of either reactant would be given by the following expressions:

$$r_A = r_B = -k\{A\}\{B\} = -k\gamma_a[A]\gamma_b[B] \quad (5-87)$$

The observed rate constant then becomes

$$k_{\text{obs}} = -k\gamma_a\gamma_b \quad (5-88)$$

**Figure 5-4**

Change in activation energy when catalyst is added to reaction.

Generally, potable water sources have ionic strengths less than  $10^{-2}$  M [approximately 400 mg/L TDS or 600  $\mu\text{S}/\text{cm}$  (600  $\mu\text{S}/\text{cm}$ )], and the effect of ionic strength on rate constants for ionic species can be estimated from the Davies equation (Eq. 5-43). The activity coefficients for monovalent and divalent ions are 0.90 and 0.66 at an ionic strength of 0.01 M, respectively. The activity coefficients for neutral species are negligible for ionic strengths less than  $10^{-2}$  M. Weil and Morris (1949) demonstrated that the rate constant for the formation of chloramine was independent of ionic strength, supporting the reaction mechanism hypothesis that the neutral molecules  $\text{NH}_3$  and  $\text{HOCl}$  are the principal reactants.

Accordingly, if experiments are conducted on a given water, the observed rate constant will be a function of the specific nonideality of the solution, and the observed rate constant can be used in reactor modeling as long as the ionic strength does not change. However, rate constants that were determined in low-ionic-strength waters for ionic reactions cannot be extrapolated to high-ionic-strength systems unless activity coefficients are used.

**PH EFFECTS ON REACTION RATE CONSTANTS**

In water treatment practice, the hydrogen ion concentration (pH) is a process variable that has a major role in the control of reaction selectivity and product distribution. The pH influences reaction rates through direct reaction pathways (e.g., precipitation of aluminum or magnesium hydroxide), determines whether reactant species are ionic, or acts as a reaction catalyst. It is only in the latter case, however, that the actual rate constant is affected; in the other cases, it is the activity (concentration) of the reactants that are affected. Often, control of the pH will permit acceleration of desired reaction pathways. The influence of pH on reaction rates is illustrated by the monochloramine formation reaction in the following example.

### Example 5-8 Effect of pH on monochloramine formation

Monochloramine ( $\text{NH}_2\text{Cl}$ ) is formed when ammonia ( $\text{NH}_3$ ) and hypochlorous acid ( $\text{HOCl}$ ) react, as shown in the following second-order reaction:

Because of the long-lasting residual disinfecting properties of  $\text{NH}_2\text{Cl}$ , it is desirable to maximize the rate of formation of this chemical. Develop an expression for the change in the rate constant for the formation of  $\text{NH}_2\text{Cl}$  as a function of pH and present the results graphically, assuming the activity coefficients are unity. The following ionic equilibria relationships will be needed for developing the solution expression:

Dissociation of hypochlorous acid:

Dissociation of ammonium:

#### Solution

- Write the second-order rate expression for the formation of chloramines:

$$r_{\text{NH}_2\text{Cl}} = -r_{\text{NH}_3} = -r_{\text{HOCl}} = k[\text{NH}_3][\text{HOCl}]$$

- Develop expressions for the concentration of hypochlorous acid  $[\text{HOCl}]$  and ammonia  $[\text{NH}_3]$ , using the equilibria relationships given in the problem statement.
  - The total concentration of HOCl,  $C_{T,\text{HOCl}}$  may be written as

$$C_{T,\text{HOCl}} = [\text{HOCl}] + [\text{OCl}^-]$$

- The equilibrium relationship may be arranged to obtain an expression for  $[\text{OCl}^-]$ :

$$[\text{OCl}^-] = \frac{[\text{HOCl}]K_{\text{HOCl}}}{[\text{H}^+]}$$

- The expression from step 2b may be substituted into the  $C_{T,\text{HOCl}}$  expression from step 2a and rearranged to obtain an expression for  $[\text{HOCl}]$  as a function of pH:

$$C_{T,\text{HOCl}} = [\text{HOCl}] + \frac{[\text{HOCl}]K_{\text{HOCl}}}{[\text{H}^+]}$$

$$[\text{HOCl}] = \frac{C_{T,\text{HOCl}}}{1 + K_{\text{HOCl}}/[\text{H}^+]}$$

d. The expression for ammonia is developed using a similar procedure:

$$C_{T,\text{NH}_3} = [\text{NH}_3] + \frac{[\text{NH}_3][\text{H}^+]}{K_{\text{NH}_4^+}}$$

$$[\text{NH}_3] = \frac{C_{T,\text{NH}_3}}{1 + [\text{H}^+]/K_{\text{NH}_4^+}}$$

3. The rate expression can now be written in terms of the total ammonia,  $C_{T,\text{N}}$ , and total hypochlorous acid,  $C_{T,\text{HOCl}}$ , by substituting the expression developed in step 2 into the rate expression from step 1:

$$r_{\text{NH}_2\text{Cl}} = k[\text{NH}_3][\text{HOCl}] = k \frac{(C_{T,\text{NH}_3})(C_{T,\text{HOCl}})}{(1 + [\text{H}^+]/K_{\text{NH}_4^+})(1 + K_{\text{HOCl}}/[\text{H}^+])}$$

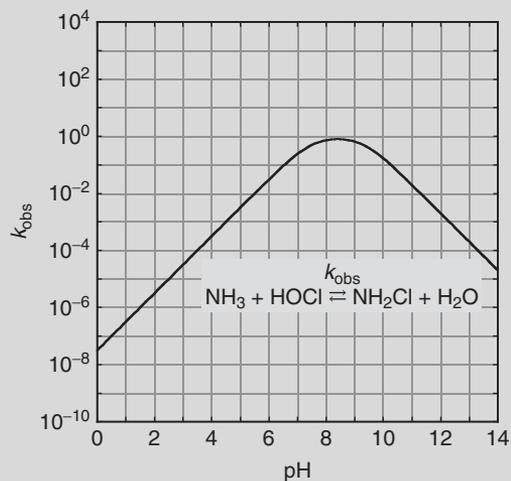

4. Write an expression for the observed rate constant that can be plotted as a function of pH. An observed rate constant can be expressed in terms of the actual rate constant  $k$ , hydrogen ion concentration  $[\text{H}^+]$ , and equilibrium constants  $K_{\text{HOCl}}$  and  $K_{\text{NH}_4^+}$ :

$$k_{\text{obs}} = \frac{k}{(1 + [\text{H}^+]/K_{\text{NH}_4^+})(1 + K_{\text{HOCl}}/[\text{H}^+])}$$

where

$$[\text{H}^+] = 10^{-\text{pH}}$$

5. Plot the expression from step 4:

**Comment**

The observed rate constant depends strongly on pH, as shown on the plot from step 5, with a maximum formation rate occurring at pH 8.3, corresponding to the pH at which the product of the concentrations of the undissociated reactants is also a maximum. It is also interesting to note that the true rate constant has remained unchanged. Thus, the control of the system pH is an important factor in proper design and operation of water treatment plants.

The rate at which reactions occur usually is determined experimentally by measuring the concentration of either a reactant or a product as the reaction proceeds to completion. The measured results are then compared to the corresponding results obtained from various standard rate equations by which the reaction under study is expected to proceed (see Chap. 6).

The chemical structure of a compound may also be used to predict its behavior in a chemical system, known as a quantitative structure–activity relationship (QSAR). One such method for determining rate constants is the linear free-energy relationship (LFER), which was proposed by Hammett (1935, 1938). For example, Valentine and Jafvert (1988) studied the mechanisms of monochloramine destruction, an important step involved the acid-catalyzed reaction that forms  $\text{NH}_3\text{Cl}^+$ , as shown in the reaction

where  $\text{HA}_i$  = proton-donating species,  $i$

$k_{c,i}$  = specific catalysis rate constant for  $i$ th proton-donating species

Valentine and Jafvert (1988) developed an LFER to relate species-specific catalysis rate constants to acid dissociation constants to predict the effect of carbonate and silicate on the rate constant. The LFER relationship can be expressed in the form

$$\log\left(\frac{k_{c,i}}{N_{P,i}}\right) = C_1 \left[ \text{p}K_{a,i} + \log\left(\frac{N_{P,i}}{N_{Q,i}}\right) \right] + C_2 \quad (5-90)$$

where  $N_{P,i}$  = number of exchangeable protons on species  $\text{HA}_i$

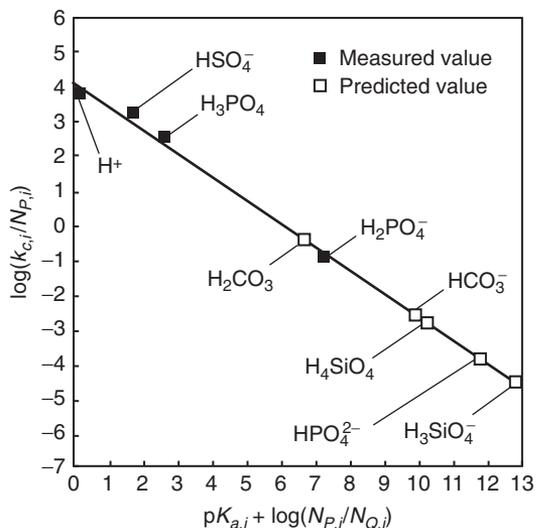

$N_{Q,i}$  = maximum number of protons with which conjugate base could combine

$K_{a,i}$  = acid dissociation constant for species  $\text{HA}_i$

$C_1, C_2$  = constants determined based on experimental rate constants

Using Eq. 5-90, a linear relationship may be obtained if  $\log(k_{c,i}/N_{P,i})$  is plotted versus  $\text{p}K_{a,i} + \log(N_{P,i}/N_{Q,i})$ , as displayed on Fig. 5-5. As shown in

**Determination  
of Reaction Rate  
Constants**

**Figure 5-5**

Linear free-energy relationship relating monochloroamine degradation rate constants to acid dissociation constants. (Adapted from Valentine and Jafvert, 1988.)

Eq. 5-90, the activation energy is related linearly to the free energy of losing a proton and the number of protons that the acid can donate, hence the name linear free-energy relationship.

As LFER methods are developed and refined, they will be very useful in elucidating reaction mechanisms and predicting rate constants in water treatment. Brezonik (1990) and Schwarzenbach et al. (2003) present additional discussion on QSARs, LFERs, and their application to water chemistry.

## 5-5 Determination of Reaction Rate Laws

The relationship between the reaction mechanism and the rate expression is examined briefly in this section. This relationship can (1) explain why thermodynamics provides the necessary condition for reactions to proceed but not the sufficient condition and (2) provide insight into the functional form of the rate law. Empirical rate laws will be presented later in this chapter and are often used for reactor design because the reaction mechanism is not known.

### Reaction Rate Laws for Individual Reaction Steps

The rate mechanism often includes numerous reaction steps, and the reaction rate depends on which of these reaction steps is the slowest or rate controlling. An individual reaction rate step is called an elementary reaction and corresponds to one step in the reaction pathway. Also, an elementary reaction is used to identify the number of atoms or molecules involved in the reaction mechanism. Consequently, the rate law for that step depends on the concentrations of the reacting species raised to the power

given by the stoichiometric coefficients. If a certain fraction of reactant A produces products, then the elementary reaction is given by the expression

For the reaction shown in Eq. 5-91 the rate law is first order because the reaction rate depends on the amount of reactant that is present:

$$r_A = -k[A] \quad (5-92)$$

If the elementary reaction involves the collision of two molecules, the reaction rate will depend on the product of the concentrations of both reactants because the product of the concentrations is proportional to the probability of two molecules colliding. For the collision of two molecules, A and B, the elementary reaction and the rate law are given by the following expressions, respectively:

$$r_A = -k[A][B] \quad (5-94)$$

It is also possible to have a bimolecular elementary reaction that involves the collisions of just A, and the elementary reaction and rate law are given by the following expressions, respectively:

$$r_A = -k[A][A] = -k[A]^2 \quad (5-96)$$

If the elementary reaction involves the collision of A, B, and C, the rate law will depend on the product of the concentrations of A, B, and C because the product of the concentrations is proportional to the probability of the three molecules colliding. In this case, the elementary reaction and the rate law are given by the following expressions, respectively:

$$r_A = -k[A][B][C] \quad (5-98)$$

From a practical point of view, reactions that involve the simultaneous collision of three molecules are highly unlikely.

The reaction shown in Eq. 5-21 may be written to show the relationship between the forward- and reverse-reaction rate constants  $k_f$  and  $k_r$  when considering a reversible elementary reaction:

where  $k_f$  = reaction rate constant for forward reaction  
 $k_r$  = reaction rate constant for reverse reaction

The rate law for the reaction shown in Eq. 5-99 may be written as

$$r_A = -k_f[A]^a[B]^b + k_r[C]^c[D]^d \quad (5-100)$$

At equilibrium, the net rate is equal to zero; and, if the activity coefficients are equal to 1, the ratio of the product concentrations to reactant concentrations raised to the respective stoichiometric powers is equal to the equilibrium constant  $K_c$ . In addition, the equilibrium constant is equal to the ratio of the forward rate constant divided by the reverse rate constant:

$$\frac{k_f}{k_r} = \frac{[C]^c[D]^d}{[A]^a[B]^b} = K_c \quad \text{when } r_A = 0 \quad (5-101)$$

### Reaction Rate Expressions for Overall Reaction

The reaction mechanism is often different than what is given by the stoichiometric equation. In such cases, the rate expression is not necessarily related to the stoichiometric equation. If the details of the chemistry involved in the reaction are known, we may be able to develop the reaction pathway and rate expression from the reaction pathway. This will involve proposing a reaction pathway. For example, suppose that the stoichiometric equation for a reaction is given by the reaction

We then must propose a pathway for this reaction to proceed. Based on the chemistry that is involved, we propose the following elementary reactions:

When we add all the elementary reactions in Eqs. 5-103 to 5-105, the elementary reactions must add up to the stoichiometric equation, Eq. 5-102. While this is not shown here, the sum of Eqs. 5-103 to 5-105 do add up to Eq. 5-102. According to Eqs. 5-103 to 5-105, the rate of formation of A is given by this expression

$$r_A = -k_1[A][B] + k_{-1}[C] - k_2[C][A] \quad (5-106)$$

While Eq. 5-106 is perfectly valid, it is not particularly useful because it involves a reactive intermediate, C, which may be difficult to measure. Accordingly, the rate law that is given by Eq. 5-106 is not useful because reactor mass balances will be written on the principal reactants and products, A, B, and D. So we must develop an expression for C that we can substitute into Eq. 5-106. In this case, we assume that all the highly reactive species (e.g., radicals) achieve a pseudo-steady-state concentration. For purposes of illustration, we assume C is a highly reactive intermediate. For this example, the net rate of C formation,  $r_C$ , can be assumed to be zero (pseudo-steady-state assumption).

$$r_C = 0 = k_1[A][B] - k_{-1}[C] - k_2[C][A] \quad (5-107)$$

The concentration of C can be determined by solving Eq. 5-107 for C:

$$[C] = \frac{k_1 [A][B]}{k_{-1} + k_2 [A]} \quad (5-108)$$

According to Eq. 5-108, the concentration of C depends on A and B, and A and B are functions of time. C rapidly adjusts its concentration according to Eq. 5-107 because it is highly reactive. According to Eq. 5-107, three reactions are responsible for the creation and disappearance of C. By assuming that the net rate is zero, we assume that the reaction is at steady state. However, the concentration of C will in fact change with time because the concentrations of A and B change with time. This is why we call it pseudo-steady state. The final rate expression may be obtained by substituting Eq. 5-108 into Eq. 5-106:

$$r_A = -k_1 [A][B] + \frac{k_{-1} k_1 [A][B]}{k_{-1} + k_2 [A]} - \frac{k_2 k_1 [A]^2 [B]}{k_{-1} + k_2 [A]} \quad (5-109)$$

After algebraic manipulation, the final form of the rate law may be obtained:

$$r_A = -\frac{2k_1 k_2 [A]^2 [B]}{k_{-1} + k_2 [A]} \quad (5-110)$$

Because catalytic and/or radical species concentrations are often small, as compared to the products and reactants, and they are highly reactive, their concentration can change rapidly in response to solution conditions. In such situations, the formation rate of these intermediate species can be assumed to be zero and the pseudo-steady-state assumption can be invoked. By setting the rate expressions of the reactive species equal to zero, an algebraic equation for each expression is obtained and the algebraic equations may be solved to express the concentrations of the highly reactive species in terms of the reactants or products, which are easily measured. Alternatively, in catalytic or enzyme-facilitated reactions, a mass balance may be performed on the total concentration of the catalyst or enzyme, which does not change with time. The resulting equation is rearranged and solved for reactive intermediates or catalytic species in terms of the reactants, products, or constants. The rate law may then be expressed in terms of only the reactants and products.

In practice, the process of obtaining a valid rate expression includes the postulation of a rate mechanism and collecting data for a variety of reactant concentrations. The proposed rate law is compared to the data and the validity of the rate law can be examined, as discussed in Chap. 6. Finding the appropriate rate law often involves an iterative solution process. However, in many instances, the rate mechanism is complex, and empirical rate laws are fit to data and used in mass balances. Empirical rate laws are discussed later in the following section.

In summary, the steps used to determine a rate law are

1. Propose the reaction pathway.
2. Write out the rate laws for each species in the pathway.
3. Invoke the pseudo-steady-state assumption for reactive intermediates and/or perform a mass balance on the catalytic species. Rearrange these expressions to obtain expressions of the reactive intermediates or catalytic species in terms of the reactants or products, which are easily measured.
4. Obtain a rate expression and eliminate the hard-to-measure species from the rate law using the results from step 3.
5. Check to see that the sum of all the elementary reactions equals the overall stoichiometric equation.
6. Collect data in various reactors and compare the concentration profiles to what would be predicted using postulated kinetic mechanisms.
7. Repeat steps 1 through 6 until good agreement is obtained.

### Empirical Reaction Rate Expressions

In many cases, there is not sufficient data or resources available to determine a general expression for a rate law (especially given the unique composition of water sources); consequently, empirical forms are fit to data and used in reactor mass balances. For example, a first-order rate expression is often used to describe biochemical oxygen demand (BOD) degradation in receiving waters:

$$r_L = -k_L L \quad (5-111)$$

where  $r_L$  = rate of BOD loss

$L$  = BOD concentration

$k_L$  = observed first-order rate constant

Equation 5-111 represents a major simplification of all the processes that are occurring, given the variety of the types of organic compounds that are being oxidized and the enzyme pathways that are used. Nevertheless, this empirical approach appears to describe the demand for dissolved oxygen in the BOD test.

When rate laws are not available, the following rate expressions may be fit to rate data:

$$r_i = \begin{cases} -k_i & (5-112) \\ -k_i C_i & (5-113) \\ -k_i C_i^2 & (5-114) \\ -k_i C_i^{n_i} & (5-115) \end{cases}$$

where  $r_i$  = reaction rate for species  $i$

$k_i$  = rate constant for species  $i$

$C_i$  = concentration of species  $i$  (more correctly the activity should be used rather than the concentration, but the activity coefficient is often assumed to equal 1 and/or included in the rate constant)  
 $n_i$  = reaction order

Another useful empirical rate law uses first-order kinetics (Eq. 5-113) and declining first-order rate constants:

$$k_{1st} = \begin{cases} \frac{k_{1st,0}}{(1 + F_i t)^{n_i}} & (5-116) \\ \frac{k_{1st,0}}{(1 + F_i z)^{n_i}} & (5-117) \end{cases}$$

where  $k_{1st}$  = retarded first-order rate constant  
 $k_{1st,0}$  = initial first-order rate constant  
 $F_i, n_i$  = empirical parameters  
 $t$  = time  
 $z$  = position in reactor

Equations 5-116 and 5-117 can be used to describe trends that have been observed in ozone mass transfer studies, particle removal, and biodegradation rates. When dealing with particle removal,  $n_i$  would be related to the particle size distribution. For biological reactions, the rate of reaction declines over time because the more readily degradable compounds are consumed first followed by the more recalcitrant compounds. In biological reactions,  $n_i$  is related to variability of the biodegradability of the individual constituents (soluble, colloidal, and particulate) that comprise BOD.

## 5-6 Reactions Used in Water Treatment

---

The major chemical reactions that occur in water are (a) acid–base reactions, (b) precipitation (dissolution reactions), (c) complexation reactions with ligands (metal anion reactions), and (d) redox reactions (oxidation and reduction reactions). Acid–base reactions are very fast (reaching equilibrium in less than a second) because they often involve only a proton transfer. Precipitation reactions often involve the coordination of anions around a cation and are relatively fast in the formation of amorphous solids (10 to 1000 min) and much slower (1 to 10,000 years) in the subsequent formation of crystals. Oxidation–reduction reactions follow many steps through specific single-electron transfers and, therefore, can be either very fast or very slow depending on the reaction mechanism. In general, acid–base, complexation, and precipitation reactions tend to be reversible and redox reactions are often not reversible, because a significant amount of energy is often released for each of the elementary reactions that are involved in the overall reaction.

## Acid–Base Reactions

Acid–base reactions are common in water treatment, and pH has a significant effect on the chemical species present in water and on the efficiency of many treatment processes. In addition, acid–base reactions proceed faster than many other equilibrium reactions, making these reactions feasible given the time scale available for water treatment. Alkalinity, as discussed in Chap. 2, should be reviewed because of its importance to acid–base chemistry. Many acid–base reactions can be described by the loss of a proton, as shown by the expression

where HA = acid species

H<sup>+</sup> = hydrated proton (i.e., H<sub>3</sub>O<sup>+</sup>)

A<sup>-</sup> = conjugate base species

At equilibrium, the following expression can be used to relate the activities of the species in Eq. 5-118 to one another:

$$\frac{\gamma_{\text{H}^+} [\text{H}^+] \gamma_{\text{A}^-} [\text{A}^-]}{\gamma_{\text{HA}} [\text{HA}]} = \frac{\{\text{H}^+\} \{\text{A}^-\}}{\{\text{HA}\}} = K_a \quad (5-119)$$

where  $K_a$  = equilibrium constant for acid (HA) dissociation, used when acid donates a proton to a water molecule

Alternately, the reaction that occurs when a conjugate base accepts a proton from water may be written as

The equilibrium relationship for the reaction shown in Eq. 5-120 is expressed as

$$\frac{\{\text{HA}\}}{\{\text{H}^+\} \{\text{A}^-\}} = K_b$$

where  $K_b$  = equilibrium constant for base (A<sup>-</sup>), used when base accepts a proton from a water molecule

Another relationship that is used when analyzing acid–base reactions is a mass balance on the conjugate base:

$$C_{T,A} = [\text{HA}] + [\text{A}^-] \quad (5-121)$$

where  $C_{T,A}$  = total concentration of species A

The use of the concepts shown above is presented in the following example.

The charge balance and proton condition relationships are also used to solve acid–base equilibrium problems. Charge balance is given by the expression

$$\sum \left( \begin{array}{c} \text{final concentration} \\ \text{of species with} \\ \text{positive charge} \end{array} \right) = \sum \left( \begin{array}{c} \text{final concentration} \\ \text{of species with} \\ \text{negative charge} \end{array} \right) \quad (5-122)$$

### Example 5-9 Acid–base chemistry

For water containing an acid, HA, with  $pK_a = 5$  and  $C_{T,A} = 10^{-3}$  mol/L, determine the concentration and percentage of [HA] and  $[A^-]$  as a function of pH. Plot the concentration of [HA] and  $[A^-]$  as a function of pH on a logarithmic scale. Assume all activity coefficients are equal to 1.0.

#### Solution

1. Determine the concentration of [HA] and  $[A^-]$  as a function of pH.
  - a. Solve Eq. 5-119 for  $[A^-]$ :

$$[A^-] = K_a \frac{[HA]}{[H^+]}$$

- b. Substitute the result from step 1a into Eq. 5-121:

$$C_{T,A} = [HA] + [A^-] = [HA] + K_a \frac{[HA]}{[H^+]}$$

- c. Solve the expression developed in step 1b for [HA]:

$$[HA] = \frac{C_{T,A}}{1 + K_a/[H^+]}$$

- d. The expression for  $[A^-]$  is developed following a similar procedure:

$$[A^-] = \frac{C_{T,A}}{1 + [H^+]/K_a}$$

2. Determine the [HA] and  $[A^-]$  concentrations at pH values ranging from 0 to 14. A sample calculation for pH 4 is shown below.
  - a. The concentration of [HA] at pH 4, or  $[H^+] = 10^{-4}$ , is as follows:

$$[HA] = \frac{C_{T,A}}{1 + K_a/[H^+]} = \frac{10^{-3} \text{ mol/L}}{1 + 10^{-5}/10^{-4}} = 9.09 \times 10^{-4} \text{ mol/L}$$

- b. The concentration of  $[A^-]$  at pH 4, or  $[H^+] = 10^{-4}$ , is as follows:

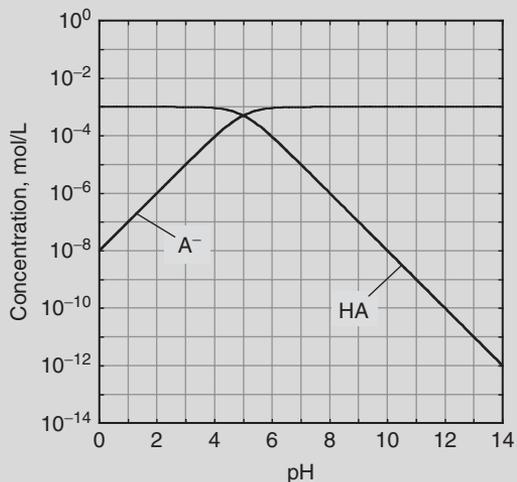

$$[A^-] = \frac{C_{T,A}}{1 + [H^+]/K_a} = \frac{10^{-3} \text{ mol/L}}{1 + 10^{-4}/10^{-5}} = 9.09 \times 10^{-5} \text{ mol/L}$$

- c. Determine the fraction of the total concentration of [HA] and  $[A^-]$  at pH 4:

$$\frac{[A^-]}{C_{T,A}} \times 100 = \frac{9.09 \times 10^{-5}}{10^{-3}} \times 100 = 9.1\%$$

$$\frac{[\text{HA}]}{C_{T,A}} \times 100 = \frac{9.09 \times 10^{-4}}{10^{-3}} \times 100 = 90.9\%$$

3. Plot concentration profiles (log concentration) for [HA] and [A<sup>-</sup>] versus pH:

### Comment

As shown in the plot constructed in step 3, the acid is undissociated at pH values less than 2 units below  $pK_a$  and nearly completely dissociated 2 units above  $pK_a$ . Further, the acid is 50 percent dissociated at a pH equal to  $pK_a$ .

The proton condition, a mass balance on protons starting with the species that are added to the solution, is given by the expression

$$\sum \left( \begin{array}{c} \text{concentration of species} \\ \text{that donate protons} \end{array} \right) = \sum \left( \begin{array}{c} \text{concentration of species} \\ \text{that receive protons} \end{array} \right) \quad (5-123)$$

Use of the relationships defined in the above equations is presented in the following example.

### Example 5-10 Solving acid–base problems as system of equations with unknown values

The acid HA is dissolved in water. Set up the four general equations that can be used to determine [HA], [A<sup>-</sup>], [H<sup>+</sup>], and [OH<sup>-</sup>].

#### Solution

1. Set up the general solution as a series of four equations with four unknowns ([H<sup>+</sup>], [OH<sup>-</sup>], [HA], [A<sup>-</sup>]) that must be solved simultaneously to arrive at a solution.
  - a. Mass balance on A:

$$C_{T,A} = [\text{HA}] + [\text{A}^-]$$

- b. Definition of equilibrium constant for water,  $K_w$ :

$$K_w = 10^{-14} = [\text{H}^+][\text{OH}^-]$$

- c. Definition of equilibrium constant for the acid,  $K_a$ :

$$K_a = \frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]}$$

- d. For the proton condition the initial reactants are H<sub>2</sub>O and HA. Consequently, the species that are formed from the loss of a proton are A<sup>-</sup> and OH<sup>-</sup>, and the species that is formed from the addition of a proton is H<sup>+</sup>. In this case, the proton condition is equal to the charge balance. Thus

$$[\text{A}^-] + [\text{OH}^-] = [\text{H}^+]$$

2. The system of four equations with four unknowns can be solved using various methods; however, for complex chemical systems, chemical equilibrium models such as MINTQA2 (U.S. EPA, 1999) or Visual MINTEQ (Gustafsson, 2011), may be required.

#### Comment

Note that the chemical species CO<sub>3</sub><sup>2-</sup> also participates in the acid–base reactions (see Eqs. 5-5 and 5-6). Thus, equilibrium of the species H<sub>2</sub>CO<sub>3</sub>, HCO<sub>3</sub><sup>-</sup>, and H<sup>+</sup> would have to be calculated simultaneously, which is illustrative of the complexity that can result in many of the reactions encountered in water chemistry.

### Precipitation– Dissolution Reactions

The equilibrium constant for a compound in its solid phase and its ions in solution is known as the solubility product. A compound that has a low solubility in water is not likely to dissolve or, if present in excess of its equilibrium value and, given sufficient time, the compound will precipitate. A compound with a high solubility is more likely to be dissolved in water. The general solubility equilibrium equation may be written as

The equilibrium relationship for the reaction shown in Eq. 5-124 is

$$\gamma_A^a \gamma_B^b [A^{m+}]^a [B^{n-}]^b = K_{S0} \quad (5-125)$$

where  $K_{S0}$  = solubility equilibrium constant for reaction shown in Eq. 5-124

$\gamma_A, \gamma_B$  = activity coefficients for species A and B, respectively

For the equilibrium relationship shown in Eq. 5-125, if the product of the reactants,  $[A^{m+}]^a [B^{n-}]^b$ , is less than the  $K_{S0}$  value (assuming  $\gamma_A = \gamma_B = 1$ ), precipitation will not occur. However, if the product of the reactants is greater than the  $K_{S0}$  value, the solid phase will precipitate until the  $K_{S0}$  value is obtained. It is important to note that the solubility product is an equilibrium constant. As shown in Eq. 5-125, it is the ratio of the activities of the products raised to their stoichiometric power divided by the reactant activity. In this case the reactant activity is a pure solid and a pure solid has an activity of 1.0.

### Example 5-11 Solubility of calcium carbonate

The  $pK_{S0}$  value for the precipitation–dissolution reaction of calcium carbonate in water at 25°C is 8.48, and the reaction may be written as

If a sufficient amount of  $CaCO_3(s)$  is added to pure water so that equilibrium is reached, determine how much  $CaCO_3(s)$  is dissolved in the water. Neglect ionic strength effects and the formation of bicarbonate and carbonic acid (assume the pH is high).

#### Solution

1. Determine the concentration of  $Ca^{2+}$  present using the solubility constant and by noting that for every mole of calcium ion formed there is an equivalent mole of carbonate ion (i.e.,  $Ca^{2+} = CO_3^{2-}$ ):

$$K_{S0} = [Ca^{2+}][CO_3^{2-}] = [Ca^{2+}]^2$$

$$[\text{Ca}^{2+}] = (K_{S0})^{1/2} = (10^{-8.48})^{1/2} = 5.75 \times 10^{-5} \text{ mol/L Ca}^{2+}$$

2. Compute the amount of  $\text{CaCO}_3$  dissolved in solution. For each mole of  $\text{Ca}^{2+}$  formed, 1 mole of  $\text{CaCO}_3(\text{s})$  is dissolved; therefore, the concentration of  $\text{CaCO}_3(\text{s})$  dissolved may be computed:

$$[\text{CaCO}_3] = (5.75 \times 10^{-5} \text{ mol Ca}^{2+}) \left( \frac{1 \text{ mol CaCO}_3}{1 \text{ mol Ca}^{2+}} \right)$$

$$= 5.75 \times 10^{-5} \text{ mol/L}$$

$$\text{CaCO}_3 = (5.75 \times 10^{-5} \text{ mol/L})(100 \text{ g/mol CaCO}_3)(1000 \text{ mg/g})$$

$$= 5.75 \text{ mg/L}$$

Solubility is affected by temperature, competing ions, and solution pH. A given solid in solution may be present and in equilibrium with one or more of its dissolved species. Further, the chemical equation used to explain the precipitation–dissolution reaction may be expressed in terms of pH (see the following discussion on complexation). The concentration of the dominant species present may be plotted together for a graphical presentation of solubility, as shown in the following example. Care should be taken when selecting chemical species relevant to a particular precipitation–dissolution reaction (Morel and Hering, 1993).

### Example 5-12 Solubility of aluminum hydroxide

Amorphous aluminum hydroxide  $\text{Al}(\text{OH})_3(\text{s})$  is a form of  $\text{Al}(\text{III})$  that is formed when alum is added to water as part of coagulation or the destabilization of particles in solution. Given the following information, calculate the total  $\text{Al}(\text{III})$  concentration in a solution at equilibrium with  $\text{Al}(\text{OH})_3(\text{s})$  at pH 7.5. Also develop appropriate equations for each species and plot the results to obtain the equilibrium  $\text{Al}(\text{III})$  concentration.

**Solution**

1. Write the mass balance equation on Al(III):

$$\text{Al(III)} = [\text{Al}^{3+}] + [\text{AlOH}^{2+}] + [\text{Al(OH)}_2^+] + [\text{Al(OH)}_3^0] + [\text{Al(OH)}_4^-]$$

2. Replace each aluminum species with its respective  $K$  relationship.  
 a. The relationship for Al(III) is shown below:

$$K_{S0} = 10^{10.8} = \frac{[\text{Al}^{3+}][\text{H}_2\text{O}]^3}{[\text{H}^+]^3 [\text{Al(OH)}_3(\text{s})]}$$

The terms that are crossed out in the above expression have an activity of 1.

$$[\text{Al}^{3+}] = 10^{10.8}[\text{H}^+]^3 = K_{S0}[\text{H}^+]^3$$

- b. Other species are derived using a similar procedure, resulting in the following expression for the total Al(III) concentration:

$$\text{Al(III)} = K_{S0}[\text{H}^+]^3 + K_{S1}[\text{H}^+]^2 + K_{S2}[\text{H}^+] + K_{S3} + K_{S4}/[\text{H}^+]$$

3. Substitute in a pH value of 7.5 and solve for Al(III):

$$\begin{aligned} [\text{Al(III)}] &= (10^{10.8})(10^{-7.5})^3 + (10^{5.8})(10^{-7.5})^2 + (10^{1.5})(10^{-7.5}) \\ &\quad + (10^{-4.2}) + (10^{-12.2})/(10^{-7.5}) = 8.4 \times 10^{-5} \text{ M} \end{aligned}$$

4. Develop appropriate equations for each species and plot the results to obtain an Al(III) concentration.  
 a. Write an equation for each species as a function of pH, as shown in step 2:

$$[\text{Al}^{3+}] = K_{S0}[\text{H}^+]^3 = 10^{10.8}[\text{H}^+]^3$$

$$[\text{AlOH}^{2+}] = K_{S1}[\text{H}^+]^2 = 10^{5.8}[\text{H}^+]^2$$

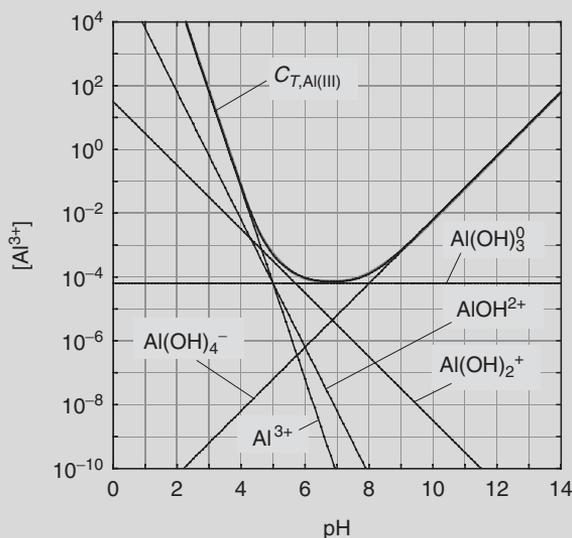

$$[\text{Al(OH)}_2^+] = K_{S2}[\text{H}^+] = 10^{1.5}[\text{H}^+]$$

$$[\text{Al(OH)}_3^0] = K_{S3} = 10^{-4.2}$$

$$[\text{Al(OH)}_4^-] = K_{S4}/[\text{H}^+] = 10^{-12.2}/[\text{H}^+]$$

where  $[\text{H}^+] = 10^{-\text{pH}}$

- b. Plot the equations for each species and identify the line that represents the total Al(III) concentration:

### Comment

It should be noted that on a log Al species versus pH scale, the equilibrium Al species concentrations are linear functions of pH in most cases. The slope is determined by the concentration dependence of the species as a function of hydrogen ion concentration. For example,  $\text{Al(OH)}_4^-$  depends on the hydrogen ion concentration raised to the  $-1$  power and this means it will be linearly related to the pH and have a slope of  $+1$ . On a  $\text{pC} - \text{pH}$  diagram it will have a slope of  $-1$  because  $\text{pC}$  is the negative of the log of the concentration.

Complexation reactions are important in water treatment because the reactions may be used to reduce the concentration of free-metal concentrations. In addition, complexation reactions can be used to reduce toxicity or change the adsorptive properties of metals. The formation of complexes in water generally involves the reaction between a metal ion (M) and a ligand (L). Ligands may be added individually or cumulatively, as shown in the reaction

where     M = metal ion  
           L = ligand  
           m, n = number of ligands added

### Complexation Reactions

$x, y$  = valences of cationic complex and anionic ligand, respectively

The equilibrium relationship for the reaction shown in Eq. 5-126 is written as

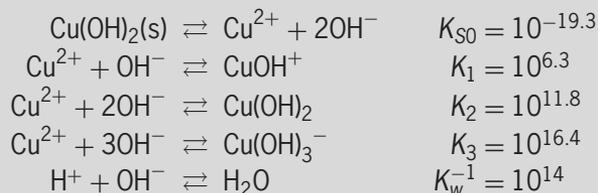

$$\frac{\{M(L)_{m+n}^{x-ny}\}}{\{M(L)_m^{x+}\} \{L^{y-}\}^n} = K_{m+n} \quad (5-127)$$

where  $K_{m+n}$  = stability constant for formation of metal complex containing  $m + n$  ligands

The reactions of ligands and metals may be modeled as a system of reactions, as described previously for precipitation–dissolution reactions. In some cases the reaction equation will need to be balanced with other reaction equations to obtain an equation expressed in terms of the solid phase and the metal complex of interest. Several examples of Al and Cu complexation with  $\text{OH}^-$  are presented in Examples 5-12 and 5-13, respectively. When reaction equations are added and balanced to arrive at an appropriate expression for the metal complex, the equilibrium constants for the resulting reaction is determined by multiplying the equilibrium constants of the participating reactions or just adding the powers of the equilibrium constants. The sign of the power of the equilibrium constant is reversed when the chemical equation is reversed. Summing chemical equations and the powers of the equilibrium constants is illustrated in the following example.

### Example 5-13 Complexation reactions for copper hydroxide

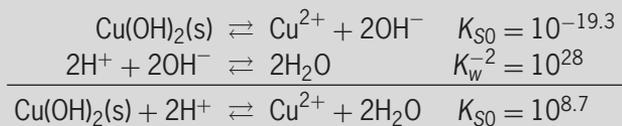

For the following dissolution and complexation reactions, determine the reactions needed to create a  $pC - pH$  ( $pC$  is the negative logarithm of the concentration) diagram for the following complexation reactions. The solution is in equilibrium with solid copper hydroxide,  $\text{Cu}(\text{OH})_2(\text{s})$ . Ignore the effects of ionic strength:

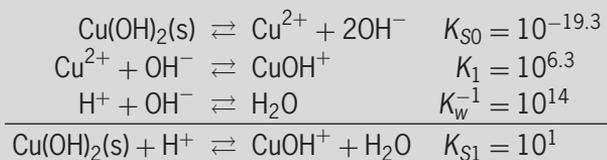

#### Solution

1. Rearrange the equations given in the problem statement so that  $\text{H}^+$  and the metal–ligand complex  $\text{Cu}(\text{OH})_x$  are the only variables:

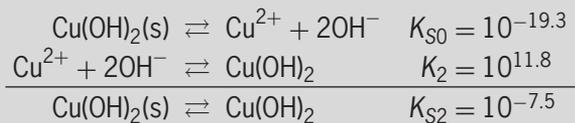

a. For  $\text{Cu}^{2+}$ ,

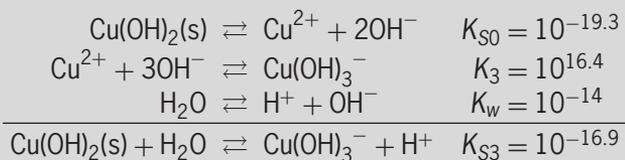

b. For  $\text{CuOH}^+$ ,

c. For  $\text{Cu(OH)}_2$ ,

d. For  $\text{Cu(OH)}_3^-$ ,

2. Using the equations developed in step 1, develop equations that may be plotted on a pC – pH diagram.

a. The equation from step 1a may be rearranged for the equilibrium constant:

$$K_{\text{S0}} = \frac{[\text{Cu}^{2+}][\text{H}_2\text{O}]^2}{[\text{H}^+]^2[\text{Cu(OH)}_2(\text{s})]}$$

resulting in the expression

$$\log[\text{Cu}^{2+}] = \log K_{\text{S0}} - 2\text{pH}$$

$$-\log[\text{Cu}^{2+}] = -\log K_{\text{S0}} + 2\text{pH}$$

$$\text{p}[\text{Cu}^{2+}] = \text{p}K_{\text{S0}} + 2\text{pH}$$

The corresponding expressions for the remaining equations developed in step 1 are

- b. For the equation derived in step 1b, the expression may be written as

$$\log[\text{CuOH}^+] = \log K_{S1} - \text{pH}$$

$$\text{p}[\text{CuOH}^+] = \text{p}K_{S1} + \text{pH}$$

- c. For the equation derived in step 1c, the expression may be written as

$$\text{p}[\text{Cu}(\text{OH})_2] = \text{p}K_{S2}$$

- d. For the equation derived in step 1d, the expression may be written as

$$\log[\text{Cu}(\text{OH})_3^-] = \log K_{S3} + \text{pH}$$

$$\text{p}[\text{Cu}(\text{OH})_3^-] = \text{p}K_{S3} - \text{pH}$$

### Comment

Using these equations, it is possible to create a pC – pH diagram that will show the major constituents for this water at a range of pH values. The pC – pH diagrams are also useful for developing an understanding of a specific water quality system.

Ligands that are commonly involved in complexation reactions include  $\text{CN}^-$ ,  $\text{OH}^-$ ,  $\text{Cl}^-$ ,  $\text{F}^-$ ,  $\text{CO}_3^{2-}$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{NH}_3$ ,  $\text{S}$ ,  $\text{SO}_3^{2-}$ ,  $\text{PO}_4^{3-}$ , and many organic molecules with appropriate functional groups (Morel and Hering, 1993). Complexes can also form with NOM. The NOM complex that forms with aluminum ion (see Example 5-12) is thought to control the amount of alum addition in the coagulation process (see Chaps. 8 and 9 for more discussion). The NOM complex that forms with Fe(II) is very strong and makes it difficult to oxidize Fe(II) using chemical oxidation. Iron is removed by oxidizing it to Fe(III) and precipitating it as  $\text{Fe}(\text{OH})_3$  (see Chap. 8 for a more detailed discussion; see also Stumm and Morgan, 1996).

### Oxidation–Reduction Reactions

Reactions that involve the transfer of electrons between two chemical species are known as oxidation–reduction, or redox, reactions. In a redox reaction, one species is reduced (gains electrons) and one species is oxidized (loses electrons). Redox reactions are typically reported as half reactions to show the number of electrons transferred. Thus, to obtain a complete oxidation–reduction reaction, an oxidation half reaction and a reduction half reaction must be combined. The general expression of a

half reaction for the reduction of a species is as follows:

where  $\text{Ox}_A$  = oxidized species A  
 $n$  = number of electrons transferred  
 $e^-$  = electron  
 $\text{Red}_A$  = reduced species A

Although the oxidized species A is reduced during this reaction, it is called an oxidant (or electron acceptor) because the oxidized species A oxidizes another species as it is reduced. The half reaction for the oxidation of a species may be expressed as

where  $\text{Ox}_B$  = oxidized species B  
 $\text{Red}_B$  = reduced species B

Although the reduced species B is oxidized during this reaction, it is called a reductant (or electron donor) because the reduced species B reduces another species as it is oxidized.

The two half reactions may be combined to obtain the following overall oxidation–reduction reaction:

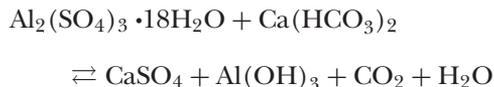

Water treatment often involves oxidation–reduction reactions in a variety of processes such as disinfection and chemical oxidation. Redox reactions are discussed in detail in Chap. 8.

## Problems and Discussion Topics

---

- 5-1 Using the principles of stoichiometry presented in the text, (a) balance the reaction for the coagulation of water with alum,  $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$ , shown below and (b) compute the amount of alkalinity,  $\text{Ca}(\text{HCO}_3)_2$ , consumed during the reaction:

- 5-2 During the process of photosynthesis, algae respiration can cause the pH and dissolved oxygen ( $\text{O}_2$ ) concentration of water to increase. Photosynthesis can be described by the chemical reaction presented below. Balance the chemical reaction and calculate the milligrams of oxygen formed per milligram of carbon dioxide removed.

- 5-3 A water contains organic matter and ammonia. For disinfection, 2 mg/L of hypochlorous acid (HOCl) is added to the water, forming 5 mg/L monochloramine (desired end product) and 1 mg/L total organic chlorine (TOCl) as Cl. Determine the selectivity of the formation of monochloramine versus TOCl formation.
- 5-4 Lime,  $\text{Ca}(\text{OH})_2$ , is added to water for the removal of calcium and magnesium. In many cases,  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  are associated with carbonate, as shown in the reaction below for calcium. The addition of lime results in the precipitation of  $\text{CaCO}_3(s)$  and  $\text{Mg}(\text{OH})_2(s)$ . For the precipitation reaction shown, write expressions for the concentration of each species after 50 percent conversion of calcium bicarbonate,  $\text{Ca}(\text{HCO}_3)_2$ ; assuming there is no volume change upon reaction.

- 5-5 Determine the ionic strength of a solution with the following constituents:

$$\begin{aligned} [\text{Ca}^{2+}] &= 10^{-3} \text{ mol/L} & [\text{CO}_3^{2-}] &= 10^{-5} \text{ mol/L} \\ [\text{Mg}^{2+}] &= 10^{-5} \text{ mol/L} & [\text{HCO}_3^-] &= 5 \times 10^{-3} \text{ mol/L} \\ [\text{Na}^+] &= 10^{-4} \text{ mol/L} \end{aligned}$$

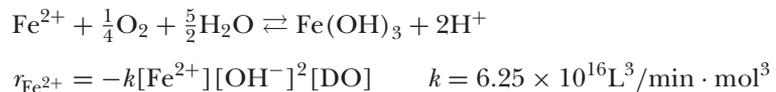

If the pH was measured at 7.0, what is the corresponding concentration of hydrogen ion?

- 5-6 Un-ionized ammonia ( $\text{NH}_3$ ) is toxic to fish at low concentrations. The dissociation of ammonia in water has an equilibrium constant of  $\text{p}K_a = 9.25$ , described with the reaction

Determine the ratio of  $\text{NH}_3$  to  $\text{NH}_4^+$  at pH values of 6, 7, 8, 9, and 10.

- 5-7 Given the following reaction and rate law for the oxidation of Fe(II), where DO = dissolved oxygen, determine the rate of production/loss of  $\text{Fe}^{2+}$ :

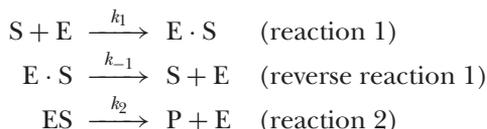

where DO = 0.268 mmol/L  
 $\text{Fe}^{2+}$  = 5.58 mg/L  
 pH = 6.0

- 5-8 Using the data provided in Problem 5-7, determine the concentration and rate of production/loss of dissolved oxygen (DO),  $\text{Fe}(\text{OH})_3$ , and acid ( $\text{H}^+$ ) when  $\text{Fe}^{2+} = 0.3 \text{ mg/L}$  at pH 6 (assume constant).
- 5-9 A common reaction pathway in biological systems involves the conversion of substrate (S) to product (P). The stoichiometric equation is

The elementary reactions are given by the pathways given below that include an enzyme that is neither created nor destroyed:

Derive a rate law in terms of the total enzyme and substrate concentrations and the rate constants.

- 5-10 Using information obtained from the local water utility, compute the ionic strength of your drinking water. In addition, estimate the TDS concentration and electrical conductivity (EC) of the water. If available, measure the TDS and/or EC of the water and compare to the computed values.
- 5-11 Plot the activity coefficients of  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{Al}^{3+}$  for ionic strengths from 0.001 M (very fresh water) to 0.5 M (seawater). Determine the ionic strength at which the activity coefficient corrections become important (activity coefficient less than 0.95) for monovalent, divalent, and trivalent ions.
- 5-12 The temperature dependence of the reaction rate is frequently expressed quantitatively using parameters other than  $E_a$ . For example, the following expression for the reaction rate constant for the BOD test is often used:

$$k_{T_2} = k_{20}(\theta)^{T_2 - 293}$$

where  $T_2$  = temperature, K

$k_{T_2}$  = rate constant at temperature  $T_2$

- Show that  $\theta = \exp(E_a/RT_1 T_2)$ .
  - Determine  $E_a$  if  $\theta = 1.047$  and  $T_2 = 293 \text{ K}$ .
  - If  $T_2 = 283 \text{ K}$  and  $\theta$  remains constant, what is the value of  $E_a$ ?
- 5-13 In the field of biology, the  $Q_{10}$  term is frequently used to define the increase in reaction rate constant with temperature:

$$Q_{10} = \frac{k_{T+10}}{k_T}$$

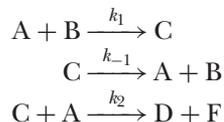

Although  $Q_{10}$  does vary with  $E_a$  and temperature, if  $E_a$  is approximately a constant for certain reactions,  $Q_{10}$  values can be used as a good approximation. If the temperature is  $25^\circ\text{C}$ , what is  $E_a$  if  $Q_{10} = 1.8$ ?

- 5-14 Prior to the design of chemical reactor systems, it is necessary to know the sensitivity of the reaction rate to temperature. It was stated by Arrhenius that the rate of most chemical reactions would double for every  $10^\circ\text{C}$  increase in temperature. Test the validity of this statement by calculating the temperature rise needed to double the rate of reaction for activation energies of 4, 55, and 125 kJ/mol for initial temperatures of 0, 20, 100, and  $300^\circ\text{C}$  using the Arrhenius law for temperature dependency of the rate constant. From the calculations, what conclusions can be drawn about the temperature sensitivity of reactions at various energies and temperatures, including conditions expected for water treatment processes.
- 5-15 For the reactions given below, what is the rate expression for the disappearance of A assuming that C is a highly reactive intermediate? An acceptable answer would propose a rate law that only involves the principal reactants and products as given in the following stoichiometric equation.

Stoichiometric equation:

Elementary reactions:

- 5-16 Using a linear free-energy relationship (LFER), write an expression that could be used to estimate the reaction rate constant,  $k_{c,i}$ , for the following reaction:

Outline a procedure that could be used to estimate the reaction rate constant using the expression.

- 5-17 Construct plots of (a) the log concentration and (b) the percent distribution of  $\text{H}_2\text{CO}_3$ ,  $\text{HCO}_3^-$ , and  $\text{CO}_3^{2-}$  as a function of pH at  $25^\circ\text{C}$ . Consider a pH range of 0 to 14. Use a  $C_{T,\text{CO}_3}$  value of  $10^{-3}$  and assume the system is closed to the atmosphere and that the following reactions apply:

- 5-18 Using the thermodynamic data given below, calculate the equilibrium constants and free energy of reaction for the following reaction at 10, 25, and 35°C:

Thermodynamic data:

$$\begin{aligned} \Delta H_{F,\text{H}_2\text{CO}_3(\text{aq})}^\circ &= -698.7 \text{ kJ/mol} & \Delta G_{F,\text{HCO}_3^-(\text{aq})}^\circ &= -587.1 \text{ kJ/mol} \\ \Delta H_{F,\text{HCO}_3^-(\text{aq})}^\circ &= -691.1 \text{ kJ/mol} & \Delta G_{F,\text{H}_2\text{CO}_3(\text{aq})}^\circ &= -623.4 \text{ kJ/mol} \\ \Delta H_{F,\text{H}^+(\text{aq})}^\circ &= 0 \text{ kJ/mol} & \Delta G_{F,\text{H}^+(\text{aq})}^\circ &= 0 \text{ kJ/mol} \end{aligned}$$

- 5-19 Calculate the equilibrium constant  $K_w$  at (a) 25°C and (b) 40°C using the following free energy of formation values:  $[\text{H}^+] = 0$  kJ/mol,  $[\text{OH}^-] = -157.29$  kJ/mol, and  $[\text{H}_2\text{O}] = -237.18$  kJ/mol. Determine if the dissociation of water is an endothermic or exothermic reaction. The enthalpy values for the various constituents are  $[\text{H}^+] = 0$  kT/mol,  $[\text{OH}^-] = -230$  kT/mol, and  $[\text{H}_2\text{O}] = -285.83$  kT/mol.
- 5-20 Determine if HOCl is thermodynamically stable in water at 25°C given the reaction

Assume  $\text{HOCl} = 5$  mg/L as  $\text{Cl}_2$ ,  $\text{pH} = 7$ ,  $\text{O}_{2(\text{aq})} = 9$  mg/L, and  $\text{Cl}^- = 10^{-3}$  M. The free energies of formation for the compounds involved are given as

$$\text{H}^+ = 0 \text{ kJ/mol} \quad \text{O}_2(\text{aq}) = 16.44 \text{ kJ/mol} \quad \text{H}_2\text{O} = -237.18 \text{ kJ/mol}$$

$$\text{Cl}^- = -131.29 \text{ kJ/mol} \quad \text{HOCl} = -79.91 \text{ kJ/mol}$$

- 5-21 Using the reactions shown below for the solubility of  $\text{Fe}(\text{OH})_3(\text{s})$ , construct a  $\text{pC} - \text{pH}$  diagram and determine the  $\text{Fe}^{3+}$  concentration at pH values of 3, 5, 7, 9, and 11:

Reaction	Equilibrium Constant	Value
$\text{Fe}(\text{OH})_3(\text{s}) + 3\text{H}^+ \rightleftharpoons \text{Fe}^{3+} + 3\text{H}_2\text{O}$	$\log K_{S0}$	3.2
$\text{Fe}(\text{OH})_3(\text{s}) + 2\text{H}^+ \rightleftharpoons \text{Fe}(\text{OH})^{2+} + 2\text{H}_2\text{O}$	$\log K_{S1}$	1.0
$\text{Fe}(\text{OH})_3(\text{s}) + \text{H}^+ \rightleftharpoons \text{Fe}(\text{OH})_2^+ + \text{H}_2\text{O}$	$\log K_{S2}$	-2.5
$\text{Fe}(\text{OH})_3(\text{s}) \rightleftharpoons \text{Fe}(\text{OH})_3^0$	$\log K_{S3}$	-12.0
$\text{Fe}(\text{OH})_3(\text{s}) + \text{H}_2\text{O} \rightleftharpoons \text{Fe}(\text{OH})_4^- + \text{H}^+$	$\log K_{S4}$	-18.4

- 5-22 Manganese, Mn(II), is soluble in water and is present in many groundwaters because insoluble forms (e.g.,  $\text{MnO}_2$ ) that are contained in minerals are reduced to soluble forms. (The subsurface is

a reducing environment because electron acceptors such as oxygen have been used up by heterotrophic bacteria in the A horizon of soil, comprised mainly of mineral material and organic detritus such as peat.) Ozone ( $O_3$ ) is sometimes used to remove Mn according to the reaction

Compute the equilibrium constant for the reaction and plot the free energy as a function of the conversion of  $Mn^{2+}$  from 0.01 to 0.999 using the following data:

$$\Delta G_{Rxn}^{\circ} = -164.05 \text{ kJ/mol}$$

Assume that the initial reactant concentrations are  $DO = 10 \text{ mg/L}$ ,  $O_3 = 0.5 \text{ mg/L}$ ,  $Mn^{2+} = 2 \text{ mg/L}$ , and  $MnO_2 = 0 \text{ mg/L}$ .

## Terminology for Reactor Analysis and Mixing

Term	Definition
Agitation	Motion induced in a fluid to achieve flocculation, maintain particles in suspension, or promote mass transfer.
Batch reactor	Vessel in which reactants are introduced and reactions are allowed to proceed with no additional inputs to or outputs from the reactor during the reaction period.
Blending	Process of combining two liquid streams to achieve a specified level of uniformity as defined by the COV.
Completely mixed flow reactor (CMFR)	An ideal flow reactor in which the contents are continuously mixed and completely homogenous; no variation in concentration or other condition exists from one location to another in the reactor. Called continuously-stirred tank reactor (CSTR) in some older texts.
Coefficient of variation (COV)	Normalized standard deviation of the concentration in a stream used to define the uniformity (also homogeneity) of blending.
Conservative constituent	Constituent that does not react, transform, adsorb, or otherwise change as it passes through a reactor.

<b>Term</b>	<b>Definition</b>
Control volume	System in which a mass balance analysis is performed.
Diffusion	Movement of molecules from a higher concentration to a lower concentration due to Brownian motion.
Dispersion	Mixing in which a constituent is transported from a higher concentration to a lower concentration by eddies formed by turbulent flow or shearing forces between fluid layers.
Flow reactor	Reactor that operates on a continuous basis with flow into and out of the reactor.
Hydraulic residence time	Theoretical time that fluid remains in a reactor, defined as the reactor volume divided by the flow rate.
Mass balance analysis	Application of the law of conservation of mass, to account for changes in any component due to fluid flow, mass transfer, or chemical transformations.
Mean residence time	Average time that fluid remains in a reactor, defined as the first moment of tracer curve.
Mixer	Device used to bring about motion in a fluid for the purpose of agitation or blending.
Mixing	General term used to refer to agitation and blending
Nonconservative constituent	Constituent that reacts or transforms as it passes through a reactor.
Plug flow reactor (PFR)	An ideal flow reactor in which no dispersion, diffusion, or mixing of contents occurs in the axial direction.
Reactor	Tank, basin, or other vessel used in environmental and chemical engineering as a container in which chemical or biological reactions for treatment or transformation can take place.
Residence time distribution (RTD)	Probability distribution function that describes the range of time that fluid elements remain within a reactor.
Steady-state analysis	Analysis conducted when a reactor is operated for a long enough period of time with a constant influent concentration such that the concentration profile in the reactor does not change with time.
System boundary	Border used to identify all of the material flows into and out of a control volume.
Tracer, chemical	Conservative chemical used to assess the flow conditions through a reactor.
Velocity gradient $G$	Measure of the power input per unit volume $(P/\mu V)^{1/2}$

In the environment, many of the contaminants in water are removed gradually by naturally occurring physical, chemical, and biological processes. In water treatment, the same processes that occur in nature are carried out in vessels or tanks, commonly known as *reactors*. Through the use of engineered reactors, the processes used to treat water can be accelerated under controlled conditions. The rate at which such processes occur depends on the constituents involved and conditions in the reactor, including temperature and hydraulic (mixing) characteristics.

The topics presented in this chapter include (1) the types of reactors used in water treatment processes; (2) the mass balance analysis, which is the fundamental basis for the analysis of the physical, chemical, and biological processes used for water treatment; (3) ideal reactors used in modeling; (4) the modeling of reactions occurring in completely mixed batch reactors; (5) the modeling of reactions occurring in ideal continuous-flow reactors; (6) the use of tracer curves to characterize nonideal flow patterns; (7) the modeling of nonideal flow through reactors; (8) modeling the performance of nonideal reactors; (9) using tracer curves to model reactor performance; and (10) mixing.

## 6-1 Types of Reactors Used in Water Treatment

---

Unit operations and unit processes in water treatment can be carried out in a variety of reactors, which include large square and rectangular basins, cylindrical tanks, pipes, long channels, columns, and towers. Stoichiometric and kinetic descriptions of chemical reactions combined with knowledge of practical flow patterns provide the basis for reactor selection and design. Other factors to be considered include the quantity of material being processed and the structural requirements of the reactor selected (Froment and Bischoff, 1979; Kramer and Westerterp, 1963; Levenspiel, 1998; Green and Perry, 2007; Smith, 1981). The types of reactors and their applications and the hydraulic characteristics of reactors are introduced in this section.

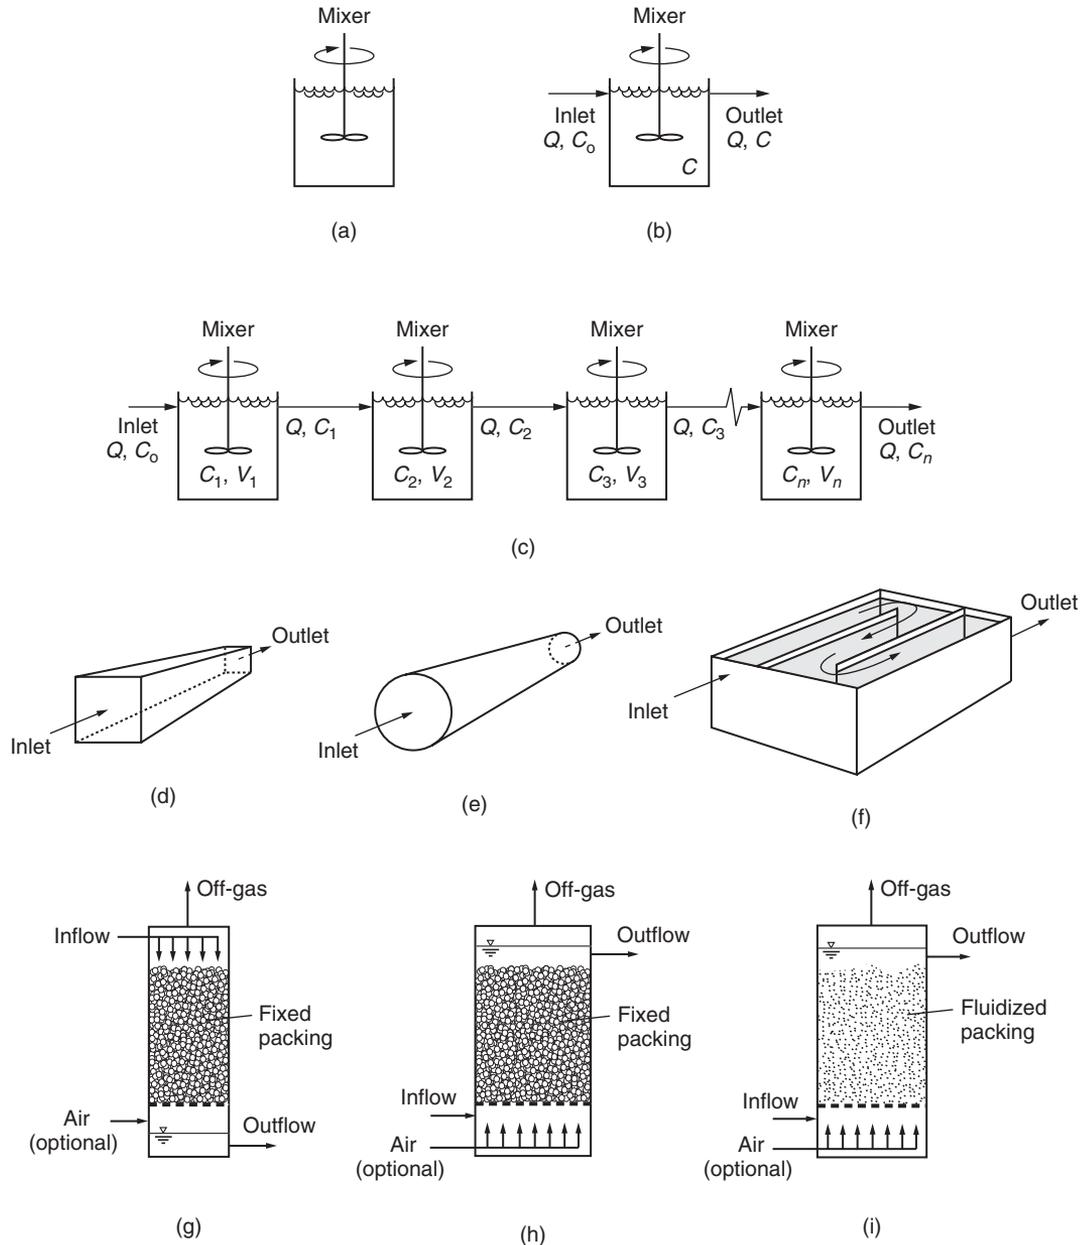

### Types of Reactors

The reactors used for water treatment can be categorized based on the operation pattern, hydraulic characteristics, unit operation occurring, and entrance and exit conditions. Several types of reactors are shown on Fig. 6-1.

### Reactors Characterized by Operation Pattern

Batch and continuous-flow reactors are the principal types of reactors. *Batch* reactors are characterized by noncontinuous operation (see Fig. 6-1a). Reactants are mixed together, and the reaction is allowed to proceed to completion. *Continuous-flow* reactors operate on a continuous basis with flow into and out of the reactor (see Fig. 6-1b). Continuous-flow reactors may also be arranged sequentially to change the flow characteristics (see Fig. 6-1c).

Batch reactors are used widely in the production of small-volume, specialty chemicals in the chemical processing industries. However, the use

**Figure 6-1**

Typical reactors used in water treatment processes: (a) batch reactor; (b) continuous-flow mixed reactor; (c) continuous-flow mixed reactors in series, also known as tanks in series; (d) rectangular channel plug flow reactor; (e) circular pipe plug flow reactor; (f) serpentine configuration plug flow reactor; (g) packed-bed downflow reactor; (h) packed-bed upflow reactor; and (i) expanded-bed upflow reactor. (Adapted from Tchobanoglous et al., 2003.)

of batch reactors in water treatment applications is generally restricted to laboratory-scale investigations and chemical coagulant preparation. Continuous-flow reactors are used most commonly in full-scale water treatment plants because of the large volumes of water processed.

### Reactors Characterized by Hydraulic Characteristics

Reactors used for carrying out reactions can be characterized as ideal or nonideal, according to the nature of the hydraulic and mixing conditions. In nonideal reactors, the hydraulic and mixing conditions tend to be complex (e.g., the mixing conditions in Lake Superior or a chlorine contact chamber). Ideal reactors are assumed to have uniform mixing and hydraulic conditions, depending on the specific reactor configuration. Common reactor configurations include (1) completely mixed batch reactors (CMBRs), (2) completely mixed flow reactors (CMFRs), and (3) plug flow reactors (PFRs). Reactor configurations are defined in Table 6-1 and discussed in detail in the following sections.

**Table 6-1**  
Definition of reactors used in water treatment

Reactor	Definition
Ideal reactors	Reactors defined for purposes of modeling. Ideal assumptions, such as no dispersion or diffusion, are nearly achievable under closely controlled laboratory conditions. Definitions assume extreme fluid conditions, such as complete mixing or no mixing of reactants or products in the direction of flow.
Nonideal reactors	Mixing and/or the residence time distribution in the reactor does not meet ideal assumptions, for example, complete mixing. Often reactors that are used in practice are nonideal reactors.
Completely mixed batch reactor (CMBR) <sup>a</sup>	An ideal reactor in which no reactants or products flow into or out of the reactor. Complete mixing occurs instantaneously and uniformly throughout the reactor, and the reaction rate proceeds at the identical rate everywhere in the reactor.
Completely mixed flow reactor (CMFR) <sup>b</sup>	An ideal reactor in which reactants and products flow into and out of the reactor. Complete mixing occurs instantaneously and uniformly throughout the reactor. The reaction rate proceeds at the identical rate everywhere in the reactor, and the concentrations throughout the reactor are the same as the effluent concentration.
Plug flow reactor (PFR)	An ideal reactor in which fluid moves through the reactor as a plug and the fluid does not mix with fluid elements in front of or behind it. As a result, the reaction rate and concentrations of the reactants decrease as the fluid moves down the PFR. (Except for zero-order reactions) The composition at any travel time down the reactor is identical to the composition in the CMBR after the same period of time has passed.

<sup>a</sup>A CMBR may also be referred to as a batch reactor.

<sup>b</sup>A CMFR may also be referred to as a complete-mix reactor (CMR), continuous stirred-tank reactor (CSTR), constant-flow stirred-tank reactor (CFSTR), or backmix reactor.

## Reactors Characterized by Unit Process

Reactors may be classified according to the type of water treatment process to be carried out. Many reactions of importance in water treatment are heterogeneous because they consist of reactions occurring in more than one phase, so-called multiphase reactions. For example, ozone gas is sometimes mixed with water to achieve the transformation of some undesired constituent (e.g., oxidation of manganese or inactivation of pathogens). In other cases, a solid precipitate is formed that may be removed by sedimentation or filtration.

Various types of reactors are used to carry out multiphase reactions. Some reactors are used to mix reactants and to provide high contact areas between water and gas. Others are used for reactions that occur on or within the solid phase and some are used for precipitation reactions. Various multiphase reaction processes, the type of reactors used, and specific examples of the multiphase reactions used in water treatment processes are listed in Table 6-2.

### REACTORS USED FOR MIXING

In reactors used for the mixing of reactants, the mixing can be either intense or slow depending upon the reactions desired. In the mixing of

**Table 6-2**

Examples of reactors used in water treatment

Process	Reactor Type	Examples
Oxidation	Stirred tanks, tanks in series, diffused gas contactors, Venturi reactor	Oxidation of iron, oxidation of manganese, dechlorination by SO <sub>2</sub> , ozone reactions
Disinfection	Tanks with serpentine baffling, long channels, diffused gas contactors, pipes	Chlorination, ozonation, chlorine dioxide, chloramination
Coagulation and flocculation	Stirred tanks in series, sludge blanket reactors	Removal of particulates and NOM using Al(III) or Fe(III), removal of As(V)
Lime softening	Stirred tanks in series, recycle reactors, sludge blanket reactors, upflow fluidized beds	Removal of hardness
Air stripping	Packed tower, diffused gas contactors	VOC removal, CO <sub>2</sub> removal
Adsorption	Fixed-bed reactor, stirred tanks in series	SOC removal, taste and odor control
Ion exchange	Fixed-bed reactor, stirred tanks in series	Removal of hardness, nitrate, perchlorate, barium, NOM, etc.
Filtration	Fixed bed	Particulate removal, turbidity removal, microbial removal, assimilable organic carbon (AOC) removal
Membranes	Fixed bed	Particulate removal, microbial removal

coagulants, intense mixing is desirable to disperse the reactants quickly. Flocculation, on the other hand, requires moderate agitation to increase the rate of particle collision and formation of large aggregate particles. *Venturi reactors* are in-line mixers with a section of the pipe that is restricted to a throat section, where chemicals are applied. Mixing occurs in a turbulent region following the throat section. Venturi-type reactors are often used for injection of chlorine, carbon dioxide, and other soluble gases into water. *Static mixers* and *pumped flash mixers* are useful for rapid mixing of coagulants and polymers with large volumes of water. Various types of mixing devices are discussed further in Sec. 6-10.

#### REACTORS USED FOR CONTACT TIME

Reactors designed for a specified detention or reaction time are commonly known as *plug flow reactors* and are not subject to backmixing. For example, the disinfection of water is typically carried out by the exposure of the water to the disinfectant of interest for a specified duration of time. Sedimentation processes also require time for particles to fall out of solution. For reactions of this nature, where holding time is important, reactors may be designed as long, narrow channels (see Fig. 6-1d), long pipe or tubular vessels (see Fig. 6-1e), or a series of long channels (see Fig. 6-1f).

#### REACTORS USED FOR CONTACT BETWEEN WATER AND GAS

*Packed columns* consist of a cylindrical column containing appropriate packing materials that provide high interfacial areas between water and a gas, usually air. Packed columns are used for stripping of undesirable gases or volatile organic compounds (VOCs) from water. Two-phase flow in packed towers is typically countercurrent, with liquid entering at the top of the reactor and air forced in the bottom of the reactor (see Fig. 6-1g). As the liquid flows over the packing, a thin liquid film is produced and volatile compounds and gases are transferred into the gas phase. Other reactors used to contact water and gases include *bubble tanks*, where a gas is bubbled into the water in tanks, and *spray towers*, where water is sprayed into the air, used primarily for removal of volatile materials. Air-liquid contactors are discussed in Chap. 14.

#### REACTORS USED FOR REACTIONS OCCURRING ON OR WITHIN SOLID PHASE

In adsorption (see Chap. 15) and ion exchange (see Chap. 16), the reaction occurs on or within the solid phase of the adsorbent (e.g., activated carbon) or ion exchange resin, respectively. Reactors for adsorption and ion exchange may consist of a fixed bed (i.e., packed bed; see Fig. 6-1h without airflow) or a fluidized bed (i.e., the packing media is suspended in the reactor; see Fig. 6-1i without airflow). Filters (covered in Chap. 11) and membranes (covered in Chap. 12) can be used in a reactor to retain reactants and reaction products that must be removed from the water. Combined unit processes may also be occurring in a single reactor; for example, hybrid membrane adsorption reactors are used in water treatment processes (powdered activated carbon addition before ultrafiltration).

**REACTORS WITH RECYCLE USED FOR PRECIPITATION REACTIONS**

Recycle reactors operate with a portion of the flow returned to the reactor inlet. Such reactors are used principally for precipitation reactions in which a portion of the precipitated solids is recycled to accelerate the rate of precipitation as in softening.

Open- and closed-reactor terminology is used to describe the entrance and exit conditions when dispersion (longitudinal mixing caused by fluid turbulence) and molecular diffusion (see discussion in Sec. 6-7) are important reactant/product transport mechanisms. A reactor is classified as an *open* reactor when either dispersion or diffusion contributes to solute fluxes into and out of the reactor. An example of an open reactor is groundwater with a contaminant plume that moves with the bulk groundwater flow but also by diffusion. In such situations, the contaminants may be found upstream of the groundwater flow direction. Reactors in which neither dispersion nor diffusion contributes to solute flux into or out of the reactor are classified as *closed* reactors. Most reactors used in water treatment are closed reactors because reactants and products are typically conveyed into or out of basins by pipes and weirs and no backmixing can occur at the entrance or exit.

**Reactors  
Characterized by  
Entrance and Exit  
Conditions**

## 6-2 Mass Balance Analysis

---

The quantitative description of a water treatment process begins with an accounting of all materials that enter, leave, accumulate in, or are transformed within the boundaries of a system. The basis for this accounting procedure, known as a *mass balance*, is the law of conservation of mass, which accounts for changes in any component due to fluid flow, mass transfer, or chemical transformations. The materials involved in a system, the scale and system chosen to write a mass balance, and the general mass balance analysis are introduced in this section.

A constituent that passes through a processing system without reacting in the reactor and remains unchanged in total mass (but not perhaps in concentration) is known as a *conservative* constituent. Constituents that undergo reaction, are transformed, or accumulate within the reactor during processing, resulting in less mass exiting with the reactor effluent than entered, are known as *nonconservative* constituents. For example, the chloride ion will pass through a water filtration plant unchanged because this inorganic ion does not adsorb on particulate matter or undergo biological transformations. Thus, the chloride ion acts as a conservative constituent. On the other hand, the ferrous ion, an ion often found in ground and surface waters, undergoes oxidation and hydrolysis in the presence of oxygen or other oxidizing agents, leading to the formation and sedimentation of an insoluble precipitate at appropriate chemical conditions. Therefore, a ferrous ion is a nonconservative constituent.

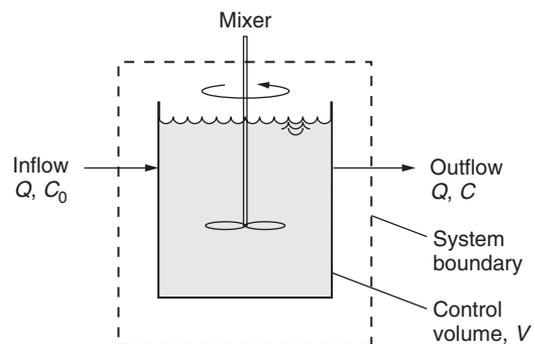

**Conservative and  
Nonconservative  
Constituents**

### Scale and System Selection

Accounting for the fate of a constituent in a water treatment plant or in an individual treatment process can be approached from various levels. While not commonly used in engineering design, the time and spatial variations of a constituent may be predicted based on forces operating at the ionic or molecular level. At the opposite extreme, it is possible to ignore all molecular interactions as well as the internal details of the system or unit and assume no local gradients of mass or temperature exist. The loss of mechanistic insight with this approach may still be correct, depending on what design issue is being investigated. Moreover, simpler approaches have the benefit of requiring much less complex mathematical analysis. Design based on mechanistic considerations is a desirable goal, but the complexity and uncertainty of the processes involved make mechanistic design unattainable in many cases, requiring the use of simplified but often still reasonable approaches. For example, if the amount of sludge that is generated by a coagulation/flocculation process is to be determined, then an overall mass balance on the process will be adequate. On the other hand, if the flocculator is to be designed for particle agglomeration and breakup on the microscale, then fluid velocity gradients in the flocculator on which microscale mixing occurs must be considered.

### General Mass Balance Analysis

Two concepts needed to write a mass balance on a reactor include correct drawing of the system boundary and the choice of a time interval over which to write the mass balance. The *system boundary* is used to identify all of the material flows into and out of the system. The guiding principle in choosing the system is to have a uniform concentration (i.e., intensive properties such as concentration, temperature, and pressure are assumed isotropic) so that the kinetic expression can be evaluated at one concentration within the system. The actual volume in which change is occurring is often referred to as the *control volume*, and the control volume should be chosen so the mass flux (in and out) across the boundaries can be easily determined. A definition sketch of a control volume for a completely mixed reactor with inflow and outflow is shown on Fig. 6-2. For any control volume, a materials

**Figure 6-2**  
Definition sketch for a materials balance analysis of a completely mixed continuous-flow reactor (CMFR).

balance can be expressed as

$$\begin{aligned}
 & \text{Mass of constituent entering system} \\
 & \quad - \text{mass of constituent leaving system} \\
 & \quad - \text{mass of constituent disappearing} + \text{mass of constituent} \quad (6-1) \\
 & \quad \quad \text{appearing within system due to reaction} \\
 & \quad = \text{mass of constituent accumulation in system}
 \end{aligned}$$

The simplified word statement for the mass balance expression shown in Eq. 6-1 is written as

$$\text{In} - \text{out} - \text{loss} + \text{generation} = \text{accumulation} \quad (6-2)$$

Mass may be transported across system boundaries by bulk fluid flow (advection) or by molecular diffusion or turbulent mixing (dispersion). The distinction between molecular diffusion and dispersion is described in detail in Sec. 6-7. Transformations or losses may occur because of chemical reactions and mass transfer between phases within the system boundaries. The spatial and temporal variation of the concentration of conservative and nonconservative constituents, depending on the scale of its application, can be determined using Eq. 6-1.

A mass balance on a single reaction only needs to be written for one component. The concentrations and pressures of the other components can be determined from the stoichiometry of the reaction, as shown previously in Chap. 5.

## 6-3 Hydraulic Characteristics of Ideal Reactors

---

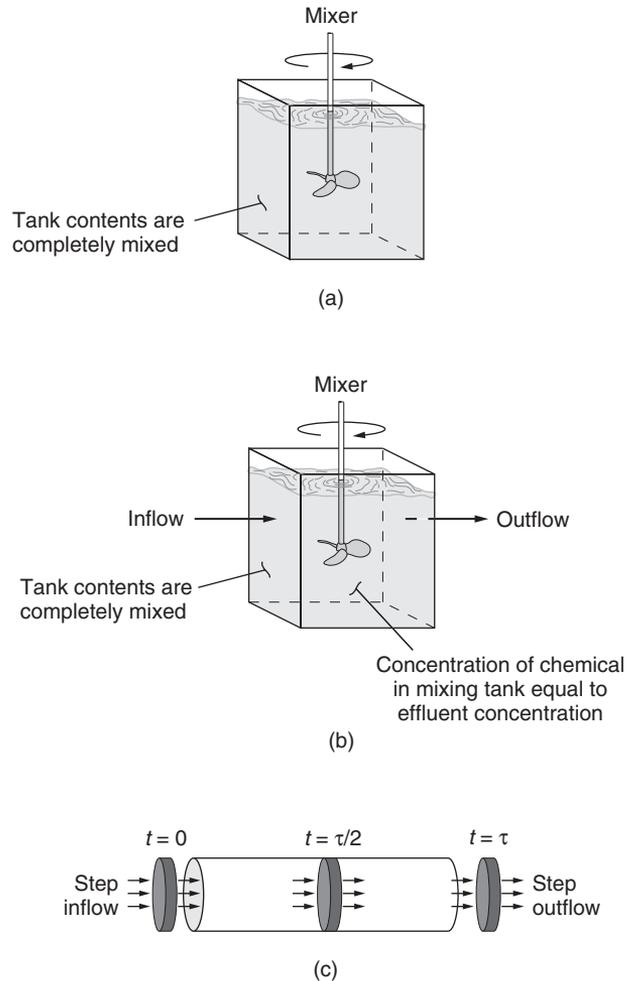

Ideal reactors provide the basic conceptual foundation upon which an understanding of real reactors can be built. On the laboratory bench, with carefully managed conditions, reactors can be made to provide nearly ideal performance. For many processes, pilot-scale systems often come close to ideal performance as well. These ideal systems can be used to provide useful estimates of the performance of even the largest scale systems. Thus, a thorough understanding of the behavior of ideal reactors, including the necessary assumptions, is essential to testing and modeling full-scale process performance.

When considering an ideal CMBR, the following assumptions are made: (1) the contents of the tank are completely uniform with no density gradients or dead space, (2) the probability of a particle of water being in any one part of the tank at any time is the same, (3) the temperature is uniform throughout the reactor, and (4) any chemical added to the contents is instantly and uniformly distributed throughout the reactor. A diagram sketch of the CMBR is shown on Fig. 6-3a.

**Completely Mixed  
Batch Reactor**

The assumptions made when modeling a CMFR are similar to those made for the CMBR, namely (1) the contents of the tank are completely uniform

**Completely Mixed  
Flow Reactor**

**Figure 6-3**

Concept diagrams for three ideal reactors: (a) completely mixed batch reactor, (b) completely mixed continuous-flow reactor, and (c) plug flow reactor.

with no density gradients or dead space, (2) the probability of a particle of water being in any part of the tank at any time is the same, (3) the temperature is uniform throughout the reactor, and (4) any chemical added to the contents is instantly and uniformly distributed throughout the reactor. Because of the first assumption of complete mixing, it is also assumed that the effluent of a CMFR has precisely the same composition as the contents. A diagram sketch of the CMFR is shown on Fig. 6-3b.

There are two important differences between the assumptions of the CMBR and the CMFR when reactions are occurring in the reactor: (1) In the CMBR all the reactants are in the reactor for the same residence time, whereas in the CMFR the reactants are in the reactor for a variety of residence times; and (2) in the CMBR the concentration of the reactants changes with time as the reaction takes place, whereas in the CMFR the

concentration of all the reactants is the same throughout the reactor all the time (once the reactor has reached steady state).

The water traversing an ideal PFR flows uniformly without mixing with the water in front of or behind it in the reactor. The plug flow concept can also be described as flow consisting of a series of plugs with the same diameter as the inside diameter of the reactor. Each time a new plug is introduced in one end of the reactor, another plug of the same size must exit the other end. If the plugs are introduced at a constant rate, then each plug is in the reactor for the same amount of time. Thus, the performance of a PFR is, by definition, precisely the same as the performance of a CMBR that has operated for the same period of time as the residence time of a PFR.

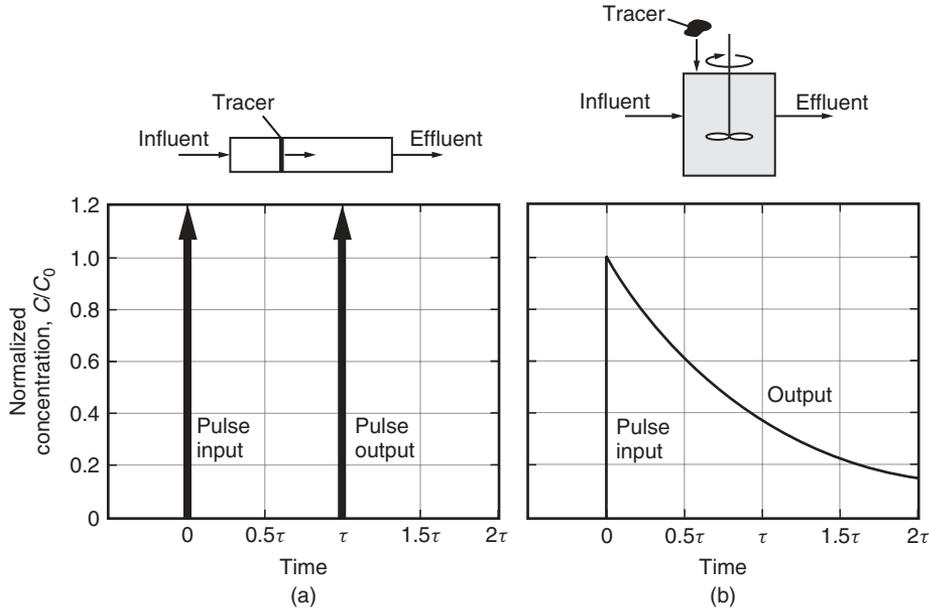

It is common for practitioners to conduct a bench-scale, batch experiment and then assume the same result will be obtained for the same conditions (e.g., chemical dosing, mixing intensity) and the same contact time in a full-scale continuous PFR facility, known as the plug flow assumption. The jar test, used to determine the optimum coagulant chemical dose, is an example of a bench-scale experiment. Reactors can be designed to operate as near-ideal PFRs; however, in many cases the performance is not ideal. Because of the desirable characteristics of the PFR for water treatment operations, it is important to understand what can be done to make a design approach plug flow and know when the plug flow assumption is erroneous. In addition, it is necessary to be able to estimate the performance of PFRs under nonideal conditions. A sketch of ideal flow in a PFR is shown on Fig. 6-3c.

A tracer is a conservative chemical that is used to assess the flow conditions through a reactor. To compare the hydraulic performance of a continuous-flow reactor to the ideal model, a tracer is introduced into the reactor's influent, and its concentration is then observed in the reactor's effluent. Three techniques are used: (1) the instantaneous addition of a pulse or slug of tracer in the influent followed by observation of the same pulse as it exits the reactor, (2) the addition of the tracer at a steady rate followed by observation until the effluent of the reactor equals the influent concentration, or (3) the addition of a tracer at a steady rate until the effluent concentration equals the influent concentration, then a cessation of the tracer feed followed by continued observation until no tracer is found in the effluent. All three tracer addition methods yield information about the exit age distribution, the cumulative exit distribution, and the internal age distribution, respectively. Conducting tracer studies is discussed in greater depth in Sec. 6-6.

The tracer curves that occur from the addition of the same pulse input to both a PFR and a CMFR are illustrated on Fig. 6-4. A pulse that passes through the PFR has exactly the same shape it had initially and with a detention time  $\tau = V/Q$  (volume/flow rate) after the tracer is added.

## Plug Flow Reactor

## Tracer Curves for Ideal Reactors

**Figure 6-4**  
Tracer curves from ideal reactors: (a) plug flow reactor and (b) completely mixed flow reactor.

The tracer curve for a pulse input to a CMFR has a significantly different shape from that obtained for a PFR. The effluent tracer concentration from a CMFR instantly reaches a maximum as the tracer is uniformly distributed throughout the reactor and then gradually dissipates in an exponential manner as the tracer material leaves the effluent. The shape of the tracer curve is exponential because, as the tracer leaves the reactor, the concentration of the tracer is reduced, which in turn reduces the rate at which the tracer mass leaves the reactor. A mass balance analysis for a nonreactive substance (generation term is zero) can be used to determine the characteristics of a pulse tracer (in term is zero) in a CMFR:

In – out + generation = accumulation

$$0 - QC + 0 = V \frac{dC}{dt} \quad (6-3)$$

where  $Q$  = flow rate through reactor, L/s

$V$  = reactor volume, L

$C$  = effluent concentration of tracer at time  $t$ , mg/L

$t$  = time since slug of tracer was added to reactor, s

Equation 6-3 can be rearranged to obtain the expression

$$-\frac{Q}{V} dt = \frac{dC}{C} \quad (6-4)$$

At  $t = 0^+$  (time immediately after tracer is added), the tracer slug has entered the reactor and is uniformly dispersed within the CMFR. Consequently, Eq. 6-4 may be integrated:

$$-\int_0^t \frac{Q}{V} dt = \int_{C_0}^C \frac{dC}{C} \quad (6-5)$$

where  $C_0$  = initial mass of tracer added divided by volume of reactor, mg/L

The following expression is obtained after substitution of  $\tau = V/Q$ , the theoretical hydraulic detention time, into Eq. 6-5:

$$C = C_0 e^{-t/\tau} \quad (6-6)$$

where  $\tau = V/Q$  = hydraulic detention time, s

The tracer curve shown on Fig. 6-4b may be obtained using the expression presented in Eq. 6-6.

In environmental engineering, it is common to employ a series of CMFRs to improve the hydraulic performance of a reactor. The improved efficiency that may be gained from CMFRs in series is discussed in Sec. 6-5. The impact of putting a few CMFRs in series (commonly known as tanks in series) on the tracer curve is described below. A definition sketch of CMFRs in series is shown on Fig. 6-5. The development of the CMFRs in series analysis is based on a constant total volume because the tank volume is an important factor controlling capital cost, and the purpose of the exercise is to determine if dividing that volume into several smaller compartments will improve efficiency. Assuming that both the total reactor volume and the mass of tracer added remain constant, the volume of each reactor is

$$V_R = \frac{V}{n} \quad (6-7)$$

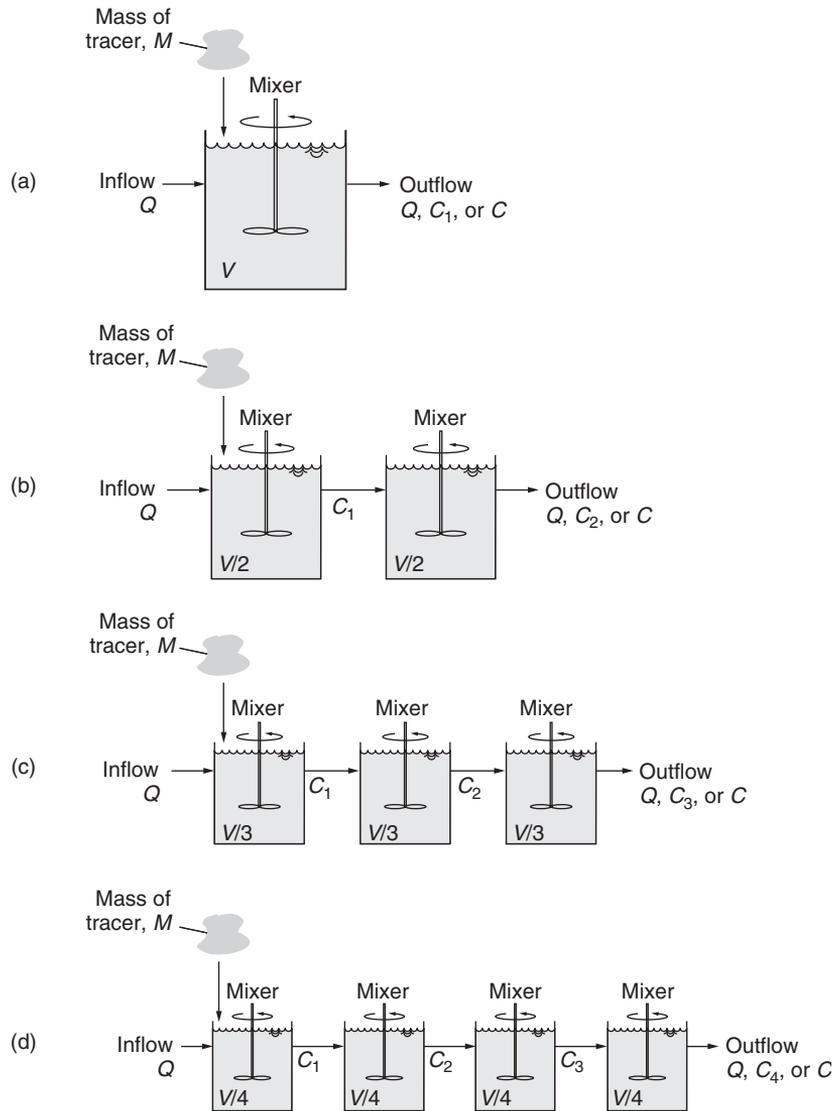

where  $V_R$  = volume of each reactor in series,  $m^3$   
 $V$  = total volume of all reactors in series,  $m^3$   
 $n$  = number of reactors in series

If the same mass of tracer is used in all tracer studies, the initial concentration of the tracer would be equivalent to the concentration that would result if the entire mass of tracer were placed in one tank having the same volume as all of the tanks in the series:

$$C_0^* = \frac{M}{V_R} \quad (6-8)$$

where  $M$  = mass of tracer added, g  
 $C_0^*$  = initial concentration, mg/L (equivalent to  $g/m^3$ )

### Completely Mixed Flow Reactors in Series

**Figure 6-5**

Definition sketch: comparing a tracer test in (a) one, (b) two, (c) three, or (d) four CSTRs in series. Each series receives the same mass dose of tracer,  $M$ , and each series has the same total volume,  $V$ .

If, however, all of the tracer is added to the first reactor, the initial concentration is given by the expression

$$C_0^* = \frac{nM}{V} = nC_0 \quad (6-9)$$

The mass balance (see Eq. 6-2) for a pulse input of conservative tracer in the first reactor in a series of  $n$  reactors incorporates the following assumptions: (1) the generation term can be assumed to be zero because the tracer substance is conservative (no reaction) and (2) the influent concentration

of tracer is zero because the tracer is added as a pulse input (single event). These assumptions result in the mass balance expression

$$0 - QC_1 + 0 = \frac{V}{n} \frac{dC_1}{dt} \quad (6-10)$$

where  $C_1$  = effluent concentration exiting first reactor in series, mg/L

The expression shown in Eq. 6-10 can be simplified and rearranged for integration as

$$\int_{C_0^*}^{C_1} \frac{dC_1}{C_1} = - \int_0^t \frac{nQ}{V} dt \quad (6-11)$$

Integrating, as shown previously in Eq. 6-5, results in the expression

$$\ln \frac{C_1}{C_0^*} = - \frac{nQ}{V} t \quad (6-12)$$

Substituting  $nC_0$  for  $C_0^*$ , the effluent concentration from the first CMFR in a series of ideal CMFRs as a function of time is written as

$$\frac{C_1}{C_0} = ne^{-(nQ/V)t} = ne^{-n\theta} \quad (6-13)$$

where  $\theta$  = relative (normalized) detention time  
 $= Qt/V = t/\tau$ , dimensionless

For the second reactor in the series, the generation term is still zero. The influent concentration changes with time and is equal to the effluent concentration from the first CMFR in the series:

$$QC_1 - QC_2 + 0 = \frac{V}{n} \frac{dC_2}{dt} \quad (6-14)$$

The expression from Eq. 6-14 can be simplified and rearranged as

$$\frac{dC_2}{dt} + \frac{nQ}{V} C_2 = \frac{nQ}{V} C_1 \quad (6-15)$$

where  $C_2$  = effluent concentration exiting second reactor in series, mg/L

Substituting Eq. 6-13 into Eq. 6-15 yields

$$\frac{dC_2}{dt} + \frac{nQ}{V} C_2 = \frac{nQ}{V} nC_0 e^{-(nQ/V)t} \quad (6-16)$$

The integrating factor method is used to solve Eq. 6-16. The method involves multiplying Eq. 6-16 by the integrating factor  $e^{(nQ/V)t}$ , which results in the expression

$$\frac{dC_2}{dt} e^{(nQ/V)t} + \frac{nQ}{V} e^{(nQ/V)t} C_2 = \frac{n^2 Q}{V} C_0 e^{-(nQ/V)t} e^{(nQ/V)t} \quad (6-17)$$

The two terms on the left-hand side of Eq. 6-17 are the derivative of the product of the functions  $C_2$  and  $\exp[(nQ/V)t]$ . Combining these terms yields

$$\frac{d\left[C_2 e^{(nQ/V)t}\right]}{dt} = \frac{n^2 Q}{V} C_0 \quad (6-18)$$

Integrating Eq. 6-18 yields the following expression for the effluent concentration of tracer from the second CMFR in the series after some algebraic manipulation:

$$\frac{C_2}{C_0} = \frac{n^2 Q t}{V} e^{-(nQ/V)t} = n(n\theta) e^{-n\theta} \quad (6-19)$$

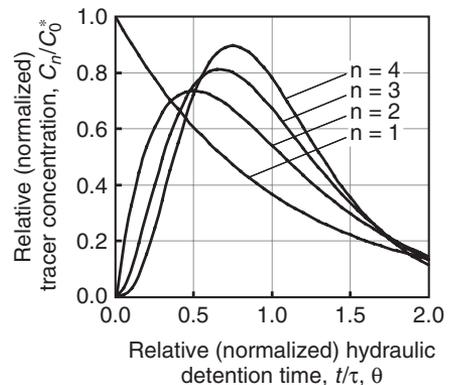

Using the same approach as shown above, the effluent concentration for any number of reactors in series can be obtained. The corresponding effluent concentration expression for the third and fourth CMFRs in series is given by Eqs. 6-20 and 6-21, respectively:

$$\frac{C_3}{C_0} = \frac{n(n\theta)^2}{2} e^{-n\theta} \quad (6-20)$$

$$\frac{C_4}{C_0} = \frac{n(n\theta)^3}{6} e^{-n\theta} \quad (6-21)$$

where  $C_3$  = effluent concentration exiting third reactor in series,  
mg/L  
 $C_4$  = effluent concentration exiting fourth reactor in series,  
mg/L

The tracer curves from one, two, three, and four CMFRs in series, with each reactor series having an equivalent volume, are shown on Fig. 6-6. The tracer curve changes dramatically as the number of CMFRs increases. In addition, the use of CMFRs in series can also result in significant improvements in reactor performance, as discussed in the following sections.

**Figure 6-6**

Tracer curves from one, two, three, and four CMFRs in series. Each series has the same total reactor volume and the same total mass of tracer added at the start.

## 6-4 Modeling Reactions in Completely Mixed Batch Reactors

The CMBR is the ideal reactor most widely used in the laboratory to gather and understand reaction data. The contents of the CMBR are mixed completely and the concentration is uniform throughout the reactor, as shown on Fig. 6-3a. The focus of this section is on modeling the reactions that occur in a CMBR.

For the system shown on Fig. 6-7, a boundary can be drawn around the system (see dashed line) and a mass balance can be written that accounts for the mass entering, leaving, reacting, or accumulating within that boundary during the time period from  $t$  to  $t + \Delta t$ :

$$0 - 0 + \Delta t rV = N|_{t+\Delta t} - N|_t \quad (6-22)$$

where  $V =$  reactor volume, L  
 $\Delta t =$  time interval, s  
 $N|_{t+\Delta t} =$  amount of reactant in reactor evaluated at  $t + \Delta t$ , mol  
 $N|_t =$  amount of reactant in reactor evaluated at  $t$ , mol  
 $r =$  average reaction rate during interval from  $t$  to  $t + \Delta t$ , mol/L · s

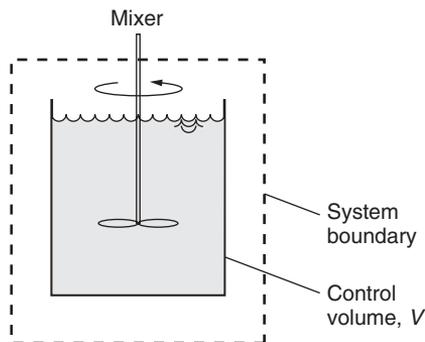

If Eq. 6-22 is rearranged and the limit as  $\Delta t$  approaches 0 is taken, the following general expression is obtained for a CMBR:

$$rV = \lim_{\Delta t \rightarrow 0} \left( \frac{N|_{t+\Delta t} - N|_t}{\Delta t} \right) = \frac{dN}{dt} \quad (6-23)$$

Writing Eq. 6-23 in terms of concentrations yields

$$r = \frac{1}{V} \frac{dC V}{dt} = \frac{dC}{dt} + \frac{1}{V} C \frac{dV}{dt} \quad (6-24)$$

where  $C =$  concentration of reactant in CMBR, mol/L  
 $N =$  amount of reactant in reactor, mol  
 $t =$  time, s

**Figure 6-7**  
 Definition sketch for mass balance analysis of batch reactor.

### Mass Balance Analysis

For a constant volume CMBR, Eq. 6-24 becomes

$$r = \frac{dC}{dt} \quad (6-25)$$

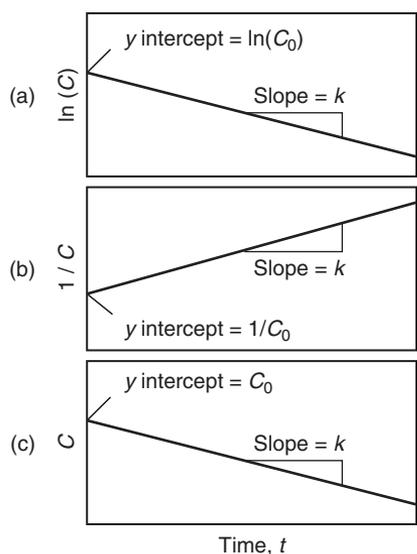

As shown in Eq. 6-25,  $C$  is a function of time. Equations 6-24 and 6-25 are valid regardless of the order of the reaction.

### Reaction Rates in a Completely Mixed Batch Reactor

If the progress of a reaction is observed while it takes place in a CMBR, common kinetic rate expressions can be evaluated to determine the correlation between the data and the reaction kinetics. If the reaction is first order, Eq. 6-25 may be written as

$$r = -kC = \frac{dC}{dt} \quad (6-26)$$

where  $k$  = first-order rate constant,  $s^{-1}$

**Figure 6-8**  
Graphical display of (a) first-, (b) second-, and (c) zero-order reactions.

Integrating the expression shown in Eq. 6-26 yields

$$\frac{C}{C_0} = e^{-kt} \quad (6-27)$$

where  $C_0$  = initial concentration, mol/L

Taking the natural logarithm of both sides, the following relationship is obtained:

$$\ln(C) - \ln(C_0) = -kt \quad (6-28)$$

For a first-order reaction, a plot of  $\ln(C)$  as a function of  $t$ , as shown in Eq. 6-28, will result in a linear relationship. Such a plot is illustrated on Fig. 6-8a. The slope of the line in the plot is equal to the first-order rate constant  $k$  and the intercept is equal to  $\ln(C_0)$ .

Similar, straightforward graphical solutions can be demonstrated for reactions of zero order (Fig. 6-8c) and second order (Fig. 6-8b). Analytical solutions for all these reaction orders as well as for  $n$ th-order reactions are shown in Table 6-3. There is no linear graphical solution for an  $n$ th-order reaction, but a spreadsheet can be used to determine which reaction order results in the best fit.

### Half-Life Concept for Irreversible Reactions

A widely used parameter to compare reaction rates is the half-life, the time within which half of the initial concentration of a reactant has disappeared, that is,  $C/C_0 = 0.5$ . For first-order, irreversible reactions, the half-life is obtained by rearrangement of Eq. 6-28 as follows:

$$\ln\left(\frac{1}{2}C_0\right) - \ln(C_0) = -kt_{1/2} \quad (6-29)$$

Equation 6-29 can also be written as

$$t_{1/2} = \frac{\ln(2)}{k} = \frac{0.693}{k} \quad (6-30)$$

### Example 6-1 Determination of reaction rate constant for decomposition of ozone

In laboratory experiments, ozone was added to a beaker (batch) of water and the concentration of ozone remaining was measured periodically. The initial concentration of ozone,  $C_0$ , was 5 mg/L for all experiments. The fraction of ozone remaining in the water at pH values of 7.6, 8.5, and 9.2 are presented in the following table (from Stumm, 1956):

Time, min	Ozone Concentration, C (mg/L)		
	pH = 7.6	pH = 8.5	pH = 9.2
0	5	5	5
1	4.95	—	4.25
2.3	—	4.15	—
5.5	—	—	2.1
6.8	4.55	—	—
7.4	—	3.05	—
8.9	—	2.75	—
9	4.35	—	1.1
14.3	—	2	—
18	3.7	—	—

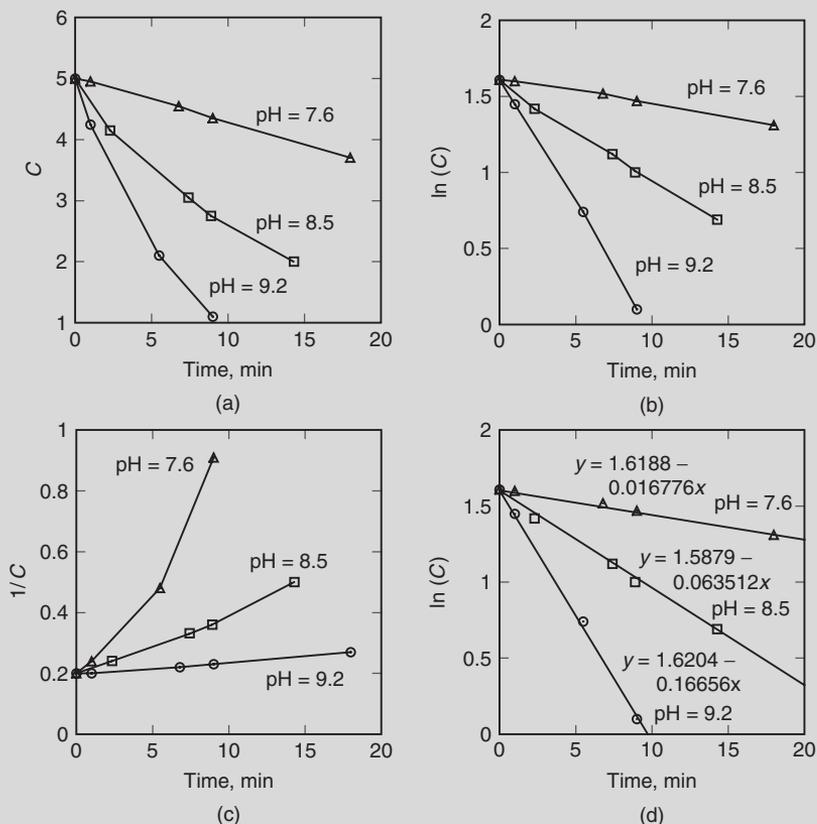

Determine the reaction order and reaction rate constant for the decomposition of ozone in water at three pH values (7.6, 8.5, and 9.2), considering zero-, first-, and second-order reactions.

#### Solution

- Determine the order of the reaction by plotting various concentration quantities as a function of time.
  - Construct a computation table for the values to be plotted.

Time, min	C			ln(C)			1/C		
	pH = 7.6	pH = 8.5	pH = 9.2	pH = 7.6	pH = 8.5	pH = 9.2	pH = 7.6	pH = 8.5	pH = 9.2
0	5	5	5	1.61	1.61	1.61	0.20	0.20	0.20
1	4.95	—	4.25	1.60	—	1.45	0.20	—	0.24
2.3	—	4.15	—	—	1.42	—	—	0.24	—
5.5	—	—	2.1	—	—	0.74	—	—	0.48
6.8	4.55	—	—	1.52	—	—	0.22	—	—
7.4	—	3.05	—	—	1.12	—	—	0.33	—
8.9	—	2.75	—	—	1.01	—	—	0.36	—
9	4.35	—	1.1	1.47	—	0.10	0.23	—	0.91
14.3	—	2	—	—	0.69	—	—	0.50	—
18	3.7	—	—	1.31	—	—	0.27	—	—

- b. For a zero-order reaction, a plot of concentration  $C$  as a function of time  $t$  is shown in panel (a) of the figure below.
- c. For a first-order reaction, a plot of the natural log of concentration,  $\ln(C)$ , as a function of time  $t$  is shown in panel (b) below.
- d. For a second-order reaction, a plot of inverse concentration  $1/C$  as a function of time  $t$  is shown in panel (c) below.

Because the plot constructed in panel (b) results in a linear relationship, ozone decomposition in water can be described using first-order kinetics.

- Determine the reaction rate constants for each pH value. The reaction rate constant is determined by finding the slope of the best-fit line for the data. As shown in panel (d) above, the first-order reaction rate constants for the decomposition of ozone in water are 0.0168, 0.0635, and 0.167  $\text{min}^{-1}$  for water with pH values of 7.6, 8.5, and 9.2, respectively.

**Table 6-3**

Solutions to reactions with different orders

Reaction Order	Rate Expression	Solution <sup>a</sup>	Units for Rate Constant
Zero order	$r = -k = \frac{dC}{dt}$	$C = C_0 - kt$	mol/L · s
First order	$r = -kC = \frac{dC}{dt}$	$C = C_0 e^{-kt}$	s <sup>-1</sup>
Second order	$r = -kC^2 = \frac{dC}{dt}$	$\frac{1}{C} = \frac{1}{C_0} + kt$	L/mol · s
n <sup>th</sup> order	$r = -kC^n = \frac{dC}{dt}$	$C = \sqrt[n+1]{(-n+1) \left( -kt + \frac{C_0^{-n+1}}{-n+1} \right)}$ ( $n \geq 0, n \neq 1$ )	(L/mol) <sup>n</sup> · s <sup>-1</sup>

<sup>a</sup>For reactions in a PFR, the reaction time  $t$  is replaced by the hydraulic detention time  $\tau$  ( $\tau = V/Q$ ) in the solution equation.

Through a similar exercise, the half-life for a second-order irreversible reaction can be determined from the second-order rate expression solution given in Table 6-3. The half-life is inversely proportional to both the rate constant and the initial reactant concentration:

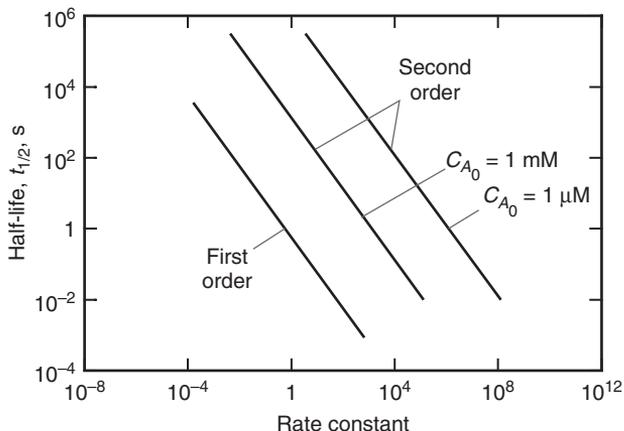

$$t_{1/2} = \frac{1}{kC_0} \quad (6-31)$$

Rate constants for common first-order reactions used in water treatment applications are listed in Table 6-4. Additional reaction rate constants can be found in compendiums in the literature (e.g., Hoffmann, 1981; Hoigne and Bader, 1983; Pankow and Morgan, 1981; Stumm and Morgan, 1996). The relationship between the half-life and the rate constant for first- and second-order reactions is illustrated on Fig. 6-9. Note that, where second-order reactions are concerned, the initial reactant concentration must be considered as well as the second-order rate constant.

**Table 6-4**

Selected first-order rate constants for reactions common to water treatment

Reaction	Conditions of Measurement	Rate Constant, s <sup>-1</sup>	Reference
$\text{Cl}_2(\text{aq}) + \text{H}_2\text{O} \rightarrow \text{HOCl} + \text{H}^+ + \text{Cl}^-$	20°C	11	Eigen and Kustin (1962)
$\text{SO}_2(\text{aq}) + \text{H}_2\text{O} \rightarrow \text{HOSO}_3^- + \text{H}^+$	20°C	$3.4 \times 10^6$	Eigen et al. (1961)
$\text{CO}_2(\text{aq}) + \text{H}_2\text{O} \rightarrow \text{HCO}_3^- + \text{H}^+$	20°C	0.02	Kern (1960)
$\text{Al}(\text{H}_2\text{O})_6^{3+} \rightarrow [\text{Al}(\text{H}_2\text{O})_5\text{OH}]^{2+} + \text{H}^+$	25°C, pH 4	$4.2 \times 10^4$	Holmes et al. (1968)

**Figure 6-9**

Comparison of reaction half-life for first- and second-order reactions in water treatment ( $C_0$  = initial concentration in reactor).

First-order reactions with rate constants greater than  $1 \text{ s}^{-1}$  are characterized as fast reactions. For example, the hydrolysis of chlorine in water has a first-order rate constant of  $11 \text{ s}^{-1}$  at  $20^\circ\text{C}$  (Eigen and Kustin, 1962). The reaction has a  $t_{1/2}$  of 0.06 s and is essentially complete (99 percent conversion) in less than 0.5 s at a pH greater than 5. When the initial concentration is  $10^{-3} \text{ mol/L}$  or greater and the rate constant is greater than  $10^2 \text{ L/mol}\cdot\text{s}$ , second-order reactions are also considered fast.

## 6-5 Modeling Reactions in Ideal Continuous-Flow Reactors

Models for ideal, continuous-flow reactors are useful for gaining an understanding of the behavior of reactors that are used in full-scale systems. The models for these systems are constructed easily and often provide practical estimates of full-scale behavior. The progress of reactions in CMFRs and PFRs with and without recycle are analyzed in this section. Although CFMRs in series will also be considered, combinations of CFMRs and PFRs will not be discussed. The student may want to seek other resources (Fogler, 1999; Levenspiel, 1998) to examine these questions, which can also have practical value.

### Completely Mixed Flow Reactor

Four assumptions are made when considering an ideal CMFR (Sec. 6-3), and because of the assumption that the contents are mixed completely, it follows that the effluent has precisely the same composition as the reactor contents. Therefore, the rate of reaction in a CMFR proceeds according to the effluent concentration, resulting in the need for a larger reactor volume as compared to PFRs.

#### CMFR MASS BALANCE

Design of a CMFR is typically based on *steady-state* conditions, meaning the effluent concentration does not change with respect to time, there is no

accumulation, and reactor volume and flow rate are constant. Mathematically, this mass balance may be written as

$$Q(C_0 - C) + Vr|_C = 0 \quad (6-32)$$

where  $C_0$  = influent concentration, which may be a function of time,  
mg/L

$Q$  = flow rate, L/s

$C$  = effluent concentration, mg/L

$r|_C$  = reaction rate in reactor at effluent concentration  $C$ , mg/L · s

$V$  = reactor volume, L

In Eq. 6-32, the value of  $r|_C$  will be less than zero if the component of interest is consumed by the reaction; the value of  $r|_C$  will be greater than zero if the component of interest is produced by the reaction.

Dividing Eq. 6-32 by  $Q$  results in the expression

$$0 = C_0 - C + \frac{V}{Q}r|_C = C_0 - C + \tau r|_C \quad (6-33)$$

where  $\tau$  = hydraulic detention time, which is equal to  $V/Q$ , s.

The hydraulic detention time or the volume of the reactor needed can be estimated if the chemical kinetics, treatment objective (effluent concentration), influent concentration, and flow rate are known, as follows:

$$\tau = \frac{C_0 - C}{-r|_C} \quad (6-34)$$

$$V = \frac{Q(C_0 - C)}{-r|_C} \quad (6-35)$$

The specific form that is taken by these equations depends on the rate of the reaction. The reaction rate takes different forms for zero-, first-, and second-order reactions, as shown in Table 6-3. Putting Eqs. 6-34 and 6-35 in proper form for these three reaction rates, the following expressions for determining the hydraulic detention time  $\tau$  and volume  $V$  are obtained:

$$\tau = \frac{C_0 - C}{k} \quad V = \frac{Q(C_0 - C)}{k} \quad (\text{zero order}) \quad (6-36)$$

$$\tau = \frac{C_0 - C}{kC} \quad V = \frac{Q(C_0 - C)}{kC} \quad (\text{first order}) \quad (6-37)$$

$$\tau = \frac{C_0 - C}{kC^2} \quad V = \frac{Q(C_0 - C)}{kC^2} \quad (\text{second order}) \quad (6-38)$$

where  $k$  = reaction rate constant (see Table 6-3 for units)

#### EXPRESSION OF CONCENTRATION IN TERMS OF REMOVAL

In many drinking water treatment operations, the focus is on removal of contaminants, so it is often relevant to determine the amount of

### Example 6-2 Effluent concentration from a CMFR

A CMFR has an influent concentration of 200 mg/L and a first-order reaction rate constant of  $4 \text{ d}^{-1}$ . Assuming steady-state conditions, calculate the effluent concentration for a hydraulic detention time of 12 h. Calculate the required hydraulic detention time for an effluent concentration of 10 mg/L.

#### Solution

1. Determine the effluent concentration by rearranging Eq. 6-37. For steady state, the following result is obtained:

$$C = \frac{C_0}{1 + \tau k} = \frac{200 \text{ mg/L}}{1 + (4/\text{d})(0.5 \text{ d})} = 66.6 \text{ mg/L}$$

2. Determine the detention time using Eq. 6-37. The required hydraulic detention is given by the expression

$$\tau = \frac{C_0 - C}{kC} = \frac{(200 - 10) \text{ mg/L}}{(4/\text{d})(10 \text{ mg/L})} = \frac{190 \text{ mg/L}}{40 \text{ mg/L} \cdot \text{d}} = 4.75 \text{ d}$$

contaminant removal, that is,

$$\text{Removal} = R = 1 - \frac{C}{C_0} \quad (6-39)$$

Each of the equations for detention time given above (Eqs. 6-36, 6-37, and 6-38) can be rearranged so that (1) the amount of contaminant removal for a reactor with a given detention time may be determined and (2) the detention time necessary for a specified degree of removal may be determined. For example, rearranging Eq. 6-36, the removal for a zero-order reaction may be defined as

$$1 - \frac{C}{C_0} = R = \frac{\tau k}{C_0} \quad (6-40)$$

#### CMFR TANKS-IN-SERIES ANALYSIS

Treatment processes are frequently staged to meet treatment objectives (e.g., ozonation may be carried out in three or four consecutive stages). Staged treatment processes may be analyzed as tanks in series by building upon Eq. 6-32 developed for a single CMFR. The following analysis of CMFR in series is for first-order reactions, which are frequently encountered in water treatment engineering. The first step is to write Eq. 6-32 in terms of a rate law, instead of a reaction rate, and to include the number of equally sized tanks. The following expression is obtained for a first-order reaction for the first tank in a series of CMFRs.

$$0 = C_0 - C_1 - \frac{V}{nQ} k C_1 \quad (6-41)$$

where  $C_1$  = effluent concentration of first CMFR, mg/L  
 $n$  = number of CMFRs  
 $k$  = first-order reaction rate constant,  $s^{-1}$

Rearranging Eq. 6-41 yields an expression to solve for  $C_1$ :

$$C_1 = \frac{C_0}{1 + (V/nQ)k} \quad (6-42)$$

Following the same steps, the expression for the effluent concentration of the second CMFR,  $C_2$ , can be obtained:

$$C_2 = \frac{C_1}{1 + (V/nQ)k} \quad (6-43)$$

Substituting the equation for  $C_1$ , Eq. 6-42, into Eq. 6-43 yields the expression

$$C_2 = \frac{C_0}{[1 + (V/nQ)k]^2} \quad (6-44)$$

A general expression for the effluent concentration of the  $n$ th equally sized CMFR, when the influent concentration is known, may be expressed as

$$C_n = \frac{C_0}{[1 + (V/nQ)k]^n} \quad (6-45)$$

The total volume required for  $n$  CMFRs in series may be determined by rearranging Eq. 6-45 as follows:

$$V = \left[ \left( \frac{C_0}{C_n} \right)^{1/n} - 1 \right] \left( \frac{nQ}{k} \right) \quad (6-46)$$

#### UNSTEADY-STATE ANALYSIS

Reactors of concern in water treatment engineering typically operate at steady-state conditions. However, there are times that it is important to analyze reactors operating under unsteady-state conditions, such as when a reactor is first brought online. The unsteady-state analysis begins with a mass balance equation, which is written for a first-order reaction assuming constant volume and using detention time,  $\tau = V/Q$ , as follows:

$$\tau \frac{dC}{dt} = (C_0 - C) - \tau(kC) = C_0 - C(1 + k\tau) \quad (6-47)$$

The integral form of the mass balance analysis shown in Eq. 6-47 is expressed as

$$\int_{C_0^*}^C \frac{dC}{C_0 - C(1 + k\tau)} = \frac{1}{\tau} \int_0^t dt \quad (6-48)$$

where  $C_0^*$  = initial concentration in reactor at time zero, mg/L

Performing the integration of the unsteady-state mass balance results in the expression

$$-\left( \frac{1}{1 + k\tau} \right) \ln \left[ \frac{C_0 - C(1 + k\tau)}{C_0 - C_0^*(1 + k\tau)} \right] = \frac{t}{\tau} \quad (6-49)$$

Solving Eq. 6-49 for  $C$  results in the final form of the unsteady-state mass balance:

$$C = \left( \frac{C_0}{1 + k\tau} \right) - \left[ \left( \frac{C_0}{1 + k\tau} \right) e^{-(1+k\tau)t/\tau} \right] + (C_0^* e^{-(1+k\tau)t/\tau}) \quad (6-50)$$

The first term in Eq. 6-50 corresponds to the steady-state condition, and as  $t \rightarrow \infty$ , the second and third terms in Eq. 6-50 will drop out, indicating that the system has reached steady state.

#### TIME REQUIRED TO ACHIEVE STEADY STATE

When a process is brought online, it may be important to determine how long it will take for the process to achieve steady state. For instance, when bringing an ozone contactor online, it is important to know how long it will take for the effluent quality to meet treatment goals. To determine the time required to achieve steady state, the case of a first-order reaction is addressed. The initial concentration in the reactor ( $C_0^*$ ) is set equal to the influent concentration ( $C_0$ ) in Eq. 6-48 and the expression is integrated. The final form of the unsteady-state mass balance for this special condition is

$$C = \frac{C_0}{1 + k\tau} + \frac{k\tau C_0 e^{-(1+k\tau)t/\tau}}{1 + k\tau} \quad (6-51)$$

Equation 6-51 may now be simplified by dividing by  $C_0$  and considering time as a fraction or multiple of the theoretical detention time,  $t/\tau$ . The term  $t/\tau$ , also known as normalized time, is used to allow comparison of reactors with different hydraulic detention times:

$$\frac{C}{C_0} = \frac{1}{1 + k\tau} + \frac{k\tau e^{-(1+k\tau)(t/\tau)}}{1 + k\tau} \quad (6-52)$$

As shown in Eq. 6-52,  $k\tau$ , which is the *Damköhler* number, is used to determine the dimensionless steady-state concentration and the profile of dimensionless concentration versus time.

In theory, it takes an infinite amount of time to achieve steady state; however, a reasonable steady state can generally be achieved within several detention times. To estimate an acceptable time, the following operational definition of steady state is introduced:

$$\frac{C}{C_0} - \frac{C_\infty}{C_0} \leq 0.01 \quad (6-53)$$

where  $C_\infty$  = steady-state concentration, mg/L

Substituting for  $C_\infty/C_0 = 1/(1 + k\tau)$  and rearranging Eq. 6-53 yields the expression

$$\frac{C}{C_0} \leq 0.01 + \frac{1}{1 + k\tau} \quad (6-54)$$

The expression shown in Eq. 6-52 may be substituted for  $C/C_0$  and Eq. 6-54 is rearranged to solve for time to steady state:

$$\frac{1}{1+k\tau} + \frac{k\tau e^{-(1+k\tau)(t/\tau)}}{1+k\tau} \leq 0.01 + \frac{1}{1+k\tau} \quad (6-55)$$

The resulting expression for time to reach steady state is

$$\frac{t}{\tau} \geq \frac{1}{1+k\tau} \ln \left[ \frac{100(k\tau)}{1+k\tau} \right] \quad (6-56)$$

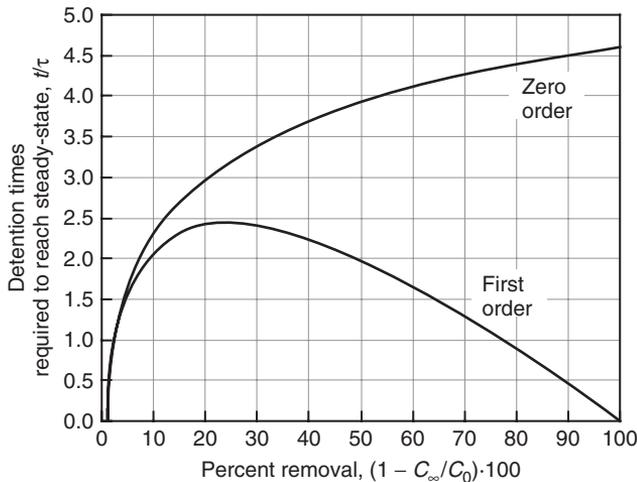

Based on the criterion developed in Eq. 6-53, operation times greater than those estimated using Eq. 6-56 will be adequate to achieve steady state. Using the expression for first-order reactions shown in Eq. 6-37, the term  $k\tau$  can be substituted into Eq. 6-56, resulting in the equation

$$\frac{t}{\tau} \geq \frac{C_\infty}{C_0} \ln \left[ 100 \left( 1 - \frac{C_\infty}{C_0} \right) \right] \quad (6-57)$$

To plot all possible scenarios, all possible Damköhler numbers need to be examined, which can be accomplished by plotting the number of hydraulic detention times that are required to achieve steady state as a function of the reduced steady-state concentration. As shown on Fig. 6-10, approximately 2.5 hydraulic detention times are adequate for all of the scenarios to achieve steady state. The time required to reach steady state for zero-order reactions can be computed using the procedure shown above, and the resulting equation is

$$\frac{t}{\tau} \geq -\ln \left( \frac{0.01}{1 - C_\infty/C_0} \right) \quad (6-58)$$

A plot of hydraulic detention time versus reduced steady-state concentration for zero-order reaction is shown on Fig. 6-10. Approximately five hydraulic

**Figure 6-10**

Number of detention times,  $\tau$ , required to reach steady state. For purposes of this graph, steady state is defined as the condition when the effluent concentration is within 1 percent of long-term steady-state concentration.

detention times are adequate for all of the scenarios to achieve steady state, as shown on Fig. 6-10.

### Plug Flow Reactor

In a PFR (see Fig. 6-3c), the fluid moves as a plug, and under perfect flow conditions there is no mixing in the axial direction, and there are neither velocity gradients nor concentration gradients in the direction perpendicular to flow. The PFRs of interest in water treatment engineering typically have a constant cross-sectional area (e.g., pipes, channels, or ditches), although a PFR can have a varying cross-sectional area, such as an irregularly shaped river (see Fig. 6-11). In general, a PFR usually requires less reactor volume than a CMFR for an equivalent degree of removal.

#### PFR MASS BALANCE

There are two possible points of view in which mass balances can be written for PFRs: (1) Eulerian and (2) Lagrangian. For the Eulerian point of view, the observer is stationary and fluid flows through the system that the observer has chosen. For the Lagrangian point of view, the observer moves with the fluid at its velocity and the system has no flow entering or leaving it.

The concentration in a PFR is dependent upon the independent variables of volume and time, and according to the mean-value theorem, there is at least one value of the dependent variable ( $C$ ) that is equal to the mean value over the time and volume intervals ( $t, t + \Delta t$ ) and ( $V, V + \Delta V$ ), respectively. Thus, a general mass balance on the small element  $\Delta V$  using the Eulerian point of view can be written as

$$\Delta t Q C|_{V,t} - \Delta t Q C|_{V+\Delta V,t} + r \Delta V \Delta t = \Delta V [C|_{t+\Delta t,V} - C|_{t,V}] \quad (6-59)$$

where

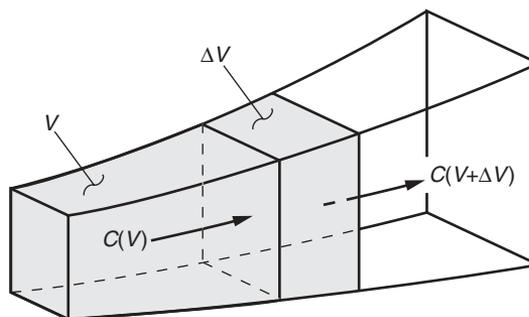

$Q$  = flow rate, L/s

$\Delta t$  = elapsed time on interval  $t \rightarrow t + \Delta t$ , s

$C|_{V,t}$  = average concentration in reactor evaluated at  $V$  for interval  $t \rightarrow t + \Delta t$ , mg/L

$C|_{V+\Delta V,t}$  = average concentration in reactor evaluated at  $V + \Delta V$  for interval  $t \rightarrow t + \Delta t$ , mg/L

$r$  = average reaction rate on interval  $t \rightarrow t + \Delta t$  in element  $\Delta V$ , mg/L · s

**Figure 6-11**

Illustration of plug flow reactor with variable cross-sectional area.

$C|_{t+\Delta t, V}$  = average concentration in element  $\Delta V$  evaluated  
at  $t + \Delta t$ , mg/L

$C|_{t, V}$  = average concentration in element  $\Delta V$  evaluated  
at  $t$ , mg/L

Dividing Eq. 6-59 by  $\Delta t$  and  $\Delta V$  yields the equation

$$-\frac{QC|_{V+\Delta V, t} - QC|_{V, t}}{\Delta V} + r = \frac{C|_{t+\Delta t, V} - C|_{t, V}}{\Delta t} \quad (6-60)$$

Taking the limit as  $\Delta t$  and  $\Delta V$  approach zero and assuming there is no volume change upon reaction (which is common for water treatment), the general material balance for a PFR is obtained as

$$-Q\frac{\partial C}{\partial V} + r = \frac{\partial C}{\partial t} \quad (6-61)$$

As shown in Eq. 6-61, the dependent variable  $C$  changes with the independent variables  $V$  and  $t$ . Consequently, one boundary condition and one initial condition are needed to solve this equation.

#### STEADY-STATE ANALYSIS

As discussed for the CMFR, when a reactor is operated for a long enough period of time with a constant influent concentration, it reaches steady state, meaning the concentration profile in the reactor does not change with time. As described in the following discussion, steady state will be established for a PFR after one hydraulic detention time. For steady-state operation, Eq. 6-61 may be written as

$$-Q\frac{\partial C}{\partial V} + r = \frac{\partial C}{\partial t} = 0 \quad (6-62)$$

The general equation for describing the fate of the component of interest in a PFR assuming steady state and constant  $Q$  is expressed as

$$\int_0^V dV = Q \int_{C_0}^C \frac{dC}{r} \quad (6-63)$$

The final form of the general equation is obtained by switching the order of the limits of integration (multiplying by  $-1$ ):

$$V = Q \int_C^{C_0} \frac{dC}{-r} \quad (6-64)$$

In addition to calculating the volume of the reactor, the steady-state concentration profile in the reactor can be determined. For example, considering a first-order irreversible reaction, the following expression can be obtained for the concentration profile in the reactor by substituting the rate expression  $r = -kC$  into Eq. 6-64 and performing the integration results in

$$C = C_0 e^{-k\tau} = C_0 e^{-k(V/Q)} \quad (6-65)$$

### Example 6-3 Steady-state operation for PFR

For steady-state operation, calculate the required hydraulic detention time for a first-order reaction occurring in a PFR. The influent concentration of  $C_0$  is 5 mg/L and the treatment objective is  $C = 0.5$  mg/L. The reaction rate constant  $k = 0.2 \text{ min}^{-1}$ . Compare the detention time required for a PFR to the time obtained for a CMFR at a flow rate of 25 L/min.

#### Solution

1. Determine the steady-state residence time and volume for the CMFR using Eq. 6-37. At steady state for a CMFR, the required residence time is estimated as

$$\tau_{\text{CMFR}} = \frac{C_0 - C}{kC} = \frac{(5 - 0.5) \text{ mg/L}}{(0.2 \text{ min}^{-1})(0.5 \text{ mg/L})} = \frac{4.5 \text{ mg/L}}{0.1 \text{ mg/L} \cdot \text{min}} = 45 \text{ min}$$

The required volume is calculated as

$$V_{\text{CMFR}} = Q\tau_{\text{CMFR}} = (25 \text{ L/min})(45 \text{ min}) = 1125 \text{ L}$$

2. Determine the steady-state residence time and volume for the PFR by rearranging Eq. 6-65. At steady state the required residence time and volume are as follows:

$$\tau_{\text{PFR}} = \frac{1}{k} \ln \left( \frac{C_0}{C} \right) = \frac{1}{0.2 \text{ min}} \ln \left( \frac{5 \text{ mg/L}}{0.5 \text{ mg/L}} \right) = 11.5 \text{ min}$$

$$V_{\text{PFR}} = Q\tau_{\text{PFR}} = (25 \text{ L/min})(11.5 \text{ min}) = 288 \text{ L}$$

3. Compare the PFR with the CMFR:

$$\tau_{\text{CMFR}} > \tau_{\text{PFR}}$$

$$V_{\text{CMFR}} > V_{\text{PFR}}$$

For a PFR with constant influent concentration steady state is achieved after an elapsed time equal to the hydraulic detention time because each fluid element travels through the reactor for one detention time.

#### Comparison of Residence Time and Volume Required for PFRs and CMFRs

It is important to compare the residence time and volume required for PFRs to CMFRs to evaluate the efficiency of reactors. The results differ greatly for irreversible reactions, as discussed below. As defined in Chap. 5, irreversible reactions are reactions that do not proceed in the reverse direction at any measurable rate. In such reactions the concentration of reactants decreases with time, and the reaction rate decreases from its initial value.

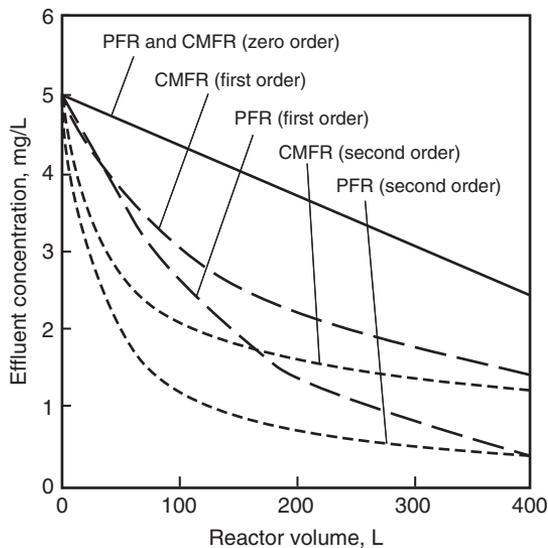

A PFR is much more efficient as compared to a CMFR for irreversible reactions, as may be determined by comparing the rates at which the reaction proceeds in a PFR versus a CMFR. In the CMFR, the rate of reaction proceeds at a rate governed by the concentration within the reactor, which corresponds to the effluent concentration. At the inlet of a PFR, the reaction proceeds at a rate governed by the influent concentration, and the rate declines as the fluid moves through the reactor. The final reaction rate in a PFR is governed by the effluent concentration. Effluent concentrations as a function of reactor volume required for PFRs and CMFRs are compared on Fig. 6-12. For a PFR, the concentration profile illustrated on Fig. 6-12 corresponds to the concentration within the reactor, whereas the concentration profile in a CMFR is a horizontal line corresponding to the effluent concentration. For any irreversible reaction of order greater than zero, the reaction rate will proceed at its lowest rate for the CMFR and the highest rate for the PFR.

The equation to determine  $V$  or  $\tau$  for  $n$ th order ( $n \geq 0, n \neq 1$ ) can be obtained by substituting the appropriate rate expression into Eq. 6-64:

$$V = Q \int_C^{C_0} \frac{dC}{kC^n} = \frac{Q}{k} \left. \frac{C^{-n+1}}{-n+1} \right|_C^{C_0} = \frac{Q}{k} \left( \frac{C_0^{-n+1}}{-n+1} - \frac{C^{-n+1}}{-n+1} \right) \quad (6-66)$$

$$\tau = \frac{V}{Q} = \frac{1}{k} \left( \frac{C_0^{-n+1}}{-n+1} - \frac{C^{-n+1}}{-n+1} \right) \quad (6-67)$$

where  $V$  = reactor volume, L  
 $Q$  = flow rate, L/s  
 $C_0$  = influent concentration, mg/L

**Figure 6-12**

Effluent concentration as function of reactor volume for PFRs and CMFRs with zero-, first-, and second-order reactions occurring. The curves were generated using a flow  $Q = 26.3$  L/min, rate constant  $k = 0.168$  min<sup>-1</sup>, and initial concentration  $C_0 = 5$  mg/L.

$C$  = effluent concentration, mg/L  
 $k$  = reaction rate constant, (mg/L)<sup>-n+1</sup>/s  
 $n$  = reaction order  
 $\tau$  = hydraulic detention time, s

The PFR and CMFR equations are now used to represent the volume of a CMFR divided by the volume of a PFR versus percent removal, as presented on Fig. 6-13. As the percent removal increases, the volume required for a CMFR compared to a PFR increases. The CMFR volume also increases relative to a PFR as the reaction order increases.

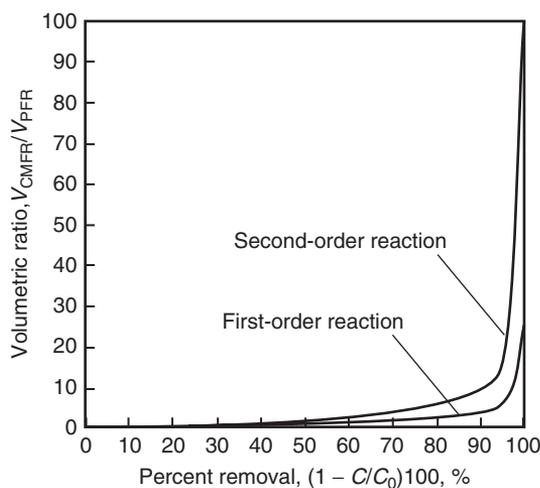

A graphical representation of the hydraulic detention time of the CMFR and PFR, as given by the following equations, is shown on Fig. 6-14a:

$$\tau_{\text{CMFR}} = \frac{V_{\text{CMFR}}}{Q} = \frac{C_0 - C}{-r} \quad (6-68)$$

$$\tau_{\text{PFR}} = \frac{V_{\text{PFR}}}{Q} = \int_C^{C_0} \frac{dC}{-r} \quad (6-69)$$

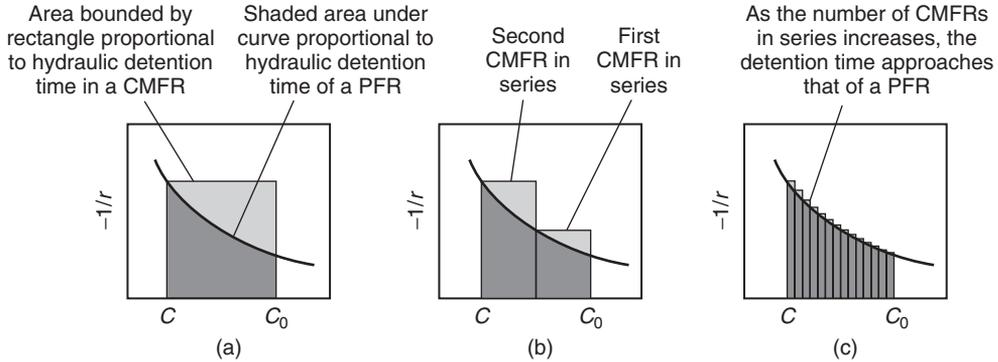

The hydraulic detention time of a CMFR can be computed as the area of a rectangle with a base equal to  $C_0 - C$  and a height equal to  $-1/r$ . The hydraulic detention time of a PFR is equal to the area under the  $-1/r$  curve from  $C$  to  $C_0$ .

It should be noted that a monotonically decreasing function for  $-1/r$  versus  $C$  is obtained for reaction order  $n$  greater than zero, with the decrease being larger as  $n$  increases. Accordingly, there is a greater difference in the volumes of a CMFR and a PFR for a second-order reaction as compared to a first-order reaction. There would be no difference for a zero-order reaction; consequently, the residence times would be identical for a CMFR and a PFR.

**Figure 6-13**

Plot of volume of CMFR divided by volume of PFR as function of percent removal.

**Figure 6-14**

Comparison of detention time required for CMFR as compared to PFR: (a) for one CMFR, (b) for two CMFRs in series, and (c) for multiple CMFRs in series.

As shown on Fig. 6-14b, the hydraulic detention time and reactor volume are reduced for two CMFRs in series. The use of multiple CMFRs in series can approach the efficiency of a PFR, as shown on Fig. 6-14c.

The notation for determining chemical conversion in reactors with recycle is shown on Fig. 6-15. A portion of the throughput  $Q$  is diverted from the reactor effluent and recycled to the influent at a rate  $q$ . A portion of the solids may also be wasted from the recycle stream using a separation device such as a clarifier.

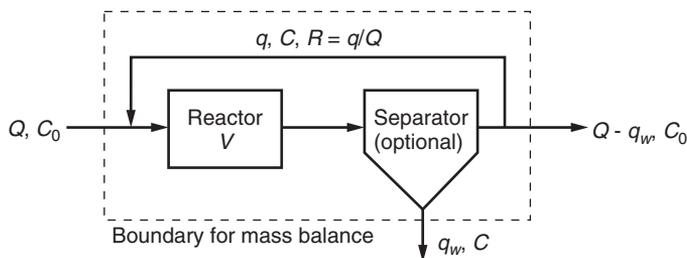

## Reactors with Recycle

### COMPLETELY MIXED FLOW REACTORS WITH RECYCLE

A steady-state materials balance around the CMFR of volume  $V$  (see Fig. 6-15) yields

$$QC_0 - [(Q - q_w)C + q_w C] - kCV = 0 \quad (6-70)$$

where  $Q$  = flow rate, L/s  
 $C_0$  = influent concentration, mg/L  
 $q_w$  = waste flow rate, L/s  
 $C$  = effluent concentration, mg/L  
 $k$  = reaction rate constant,  $s^{-1}$   
 $V$  = reactor volume, L

**Figure 6-15**

Notation used for materials balance for reactor with recycle and solids separator.

The mass balance given by Eq. 6-70 may be simplified to the expression

$$\tau_{\text{CMFR}} = \frac{1}{k} \left( \frac{C_0}{C} - 1 \right) \quad (6-71)$$

where  $\tau_{\text{CMFR}}$  = residence time for CMFR, s  
 $k$  = reaction rate constant,  $\text{s}^{-1}$

Equation 6-71 is identical to Eq. 6-34 for a CMFR with first-order kinetics. However, the rate constant  $k$  for the heterogeneous reaction in Eq. 6-71 depends on the concentration of solids in the reactor; the reaction rate would be higher if some solids were recycled and they catalyzed the reaction.

### Plug Flow Reactors with Recycle

The steady-state materials balance for the PFR with recycle around the fluid element  $dV$  may be written as

$$(Q + q) dC = r dV \quad (6-72)$$

where  $q$  = recycle flow rate, L/s  
 $r$  = reaction rate,  $\text{mg/L} \cdot \text{s}$

Separating variables and integrating between the influent concentration with recycle  $C_I$  and  $C$ , the following equation for first-order kinetics is obtained:

$$\tau_{\text{reactor}} = \left( \frac{1 + R}{k} \right) \ln \left( \frac{C_I}{C} \right) \quad (6-73)$$

where  $\tau_{\text{reactor}}$  = residence time for PFR with recycle, s  
 $R$  = recycle ratio,  $q/Q$   
 $k$  = reaction rate constant,  $\text{s}^{-1}$   
 $C_I$  = influent concentration with recycle,  $\text{mg/L}$

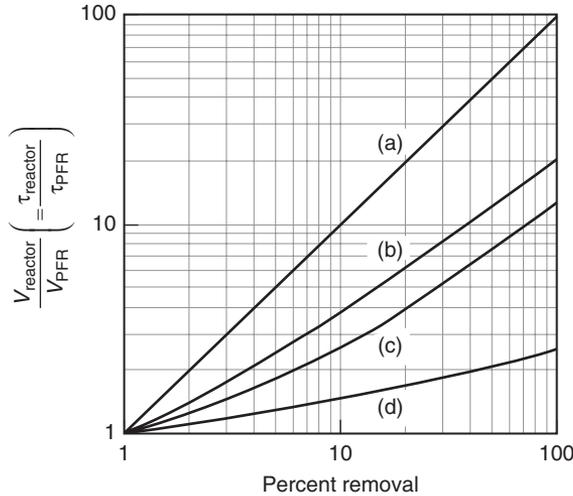

An expression for the influent concentration with recycle can be derived from the mass balance:

$$C_I = \frac{C_0 Q + qC}{Q + q} \quad (6-74)$$

The residence time for a PFR with recycle may be determined using the equation

$$\tau_{\text{reactor}} = \frac{1 + R}{k} \ln \left( \frac{C_0/C + R}{1 + R} \right) \quad (6-75)$$

With no recycle ( $R = 0$ ), the expected design equation for an ideal PFR is obtained. At the other extreme, with  $R \rightarrow \infty$ , the reactor approaches the CMFR model. The recycle reactor is thus a model of fluid behavior lying between the two extremes of complete mixing and no mixing. The residence time for a given reactor,  $\tau_{\text{reactor}}$ , is compared to  $\tau_{\text{PFR}}$  on Fig. 6-16. At the 95 percent conversion level (fraction of reactant remaining is 0.05), 100 percent recycle (PFR recycle  $R = 1$ ) increases the required reactor volume by a factor of approximately 4 ( $\tau_{\text{reactor}}/\tau_{\text{PFR}} \approx 4$ ). For the same

**Figure 6-16**

Impact of reaction order, reactor type, and required removal on reactor volume: (a) CMFR with second-order reaction, (b) CMFR with first-order reaction, (c) PFR with recycle  $R = 1$ , and first-order reaction, and (d) three CMFRs in series with first-order reaction.

95 percent conversion level, a CMFR would need to be approximately 6 times larger than a PFR for a first-order reaction and approximately 20 times larger than a PFR for a second-order reaction. As  $R$  decreases, a smaller reactor volume is required. Thus, a PFR recycle reactor should be designed with an efficient solids separator to ensure minimum recycle ratios that are consistent with the levels of solids required in the reactor. Complete process design also requires a mass balance on solids (Ferguson et al., 1973). As discussed for the CMFR with recycle, a PFR with solids recycle could have a smaller reactor volume if the recycled solids catalyzed the reaction.

## 6-6 Using Tracers to Characterize Hydraulic Performance of Nonideal Reactors

Water treatment facilities include the largest continuous-flow reactors in use today, and as the scale of continuous-flow reactors increases, their departure from the ideal flow behavior increases. The nonideality associated with large reactors has important implications for the treatment of drinking water because drinking water treatment plants include the largest engineered continuous-flow reactors in existence, far larger than most of the reactors of interest in chemical engineering. As a result, understanding nonideality is critical to the proper design of water treatment processes. There are two important ways in which real continuous-flow reactors behave differently than the ideal reactors discussed in the previous sections: (1) They exhibit nonideal flow behavior and tracer curves that deviate from the ideal curves shown on Fig. 6-4, and (2) the contents of nonideal reactors are not perfectly homogeneous, that is, they are not uniformly mixed to the molecular level.

Although much is known about the residence time distribution (RTD) behavior of flow through different reactor types, it is difficult to design a reactor and know the specific RTD that will result once flow passes through it at full scale. In the long term, computational fluid dynamics (CFD) promises to change this situation, but at the present time, if a reactor's application requires that its RTD be known, then tracer tests must be conducted in the full-scale reactor to measure the RTD directly. Tracer tests are also necessary to confirm the RTD of pilot-scale and demonstration-scale reactors and to develop data that can be used to predict the impact of design changes on performance. However, if the RTD is determined for a large-scale reactor, it may be possible to determine how to modify it to improve its performance by using baffles, turning vanes, and the like to make it perform closer to a PFR. Conducting and evaluating tracer tests are discussed in this section.

### Methodology for Tracer Testing

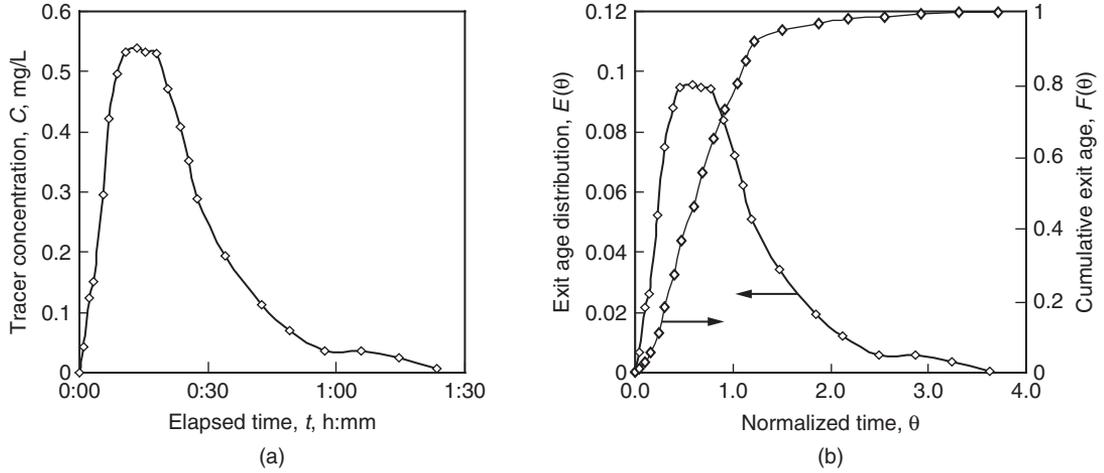

The basic technique used to conduct a tracer study is to introduce the tracer at the reactor inlet and measure the response at the outlet. A tracer is a conservative element, typically a dye or salt solution. The tracer concentration may be measured using a spectrophotometer if a dye is used, a conductivity meter, or specific ion measurements (e.g., fluoride or lithium) if salts are used. Application may be all at once (slug or pulse input) or pumped continuously (step input), resulting in different tracer output curves. When the tracer is applied through a step input, a second tracer curve may be obtained after the tracer input is stopped by recording the tracer disappearance, referred to as a step-down tracer study. Effluent samples can be collected manually as grab samples at specified time intervals or by using an autosampler coupled with a detection instrument for automated sampling. Sampling should be performed frequently enough so that the tracer response may be properly characterized.

### Analysis of Tracer Data

The tracer curve resulting from a step or pulse input, generally a plot of tracer concentration exiting the reactor as a function of time, is known as the  $C$  curve, as shown on Fig. 6-17a. To standardize the analysis of tracer curves, tracer data must be normalized in two ways: (1) with respect to the residence time and (2) with respect to the output concentration.

#### NORMALIZED TIME

The theoretical hydraulic residence time  $\tau$  in any reactor is equal to the reactor volume divided by the bulk flow rate. For a perfect tracer in an ideal reactor, the mean residence time  $\bar{t}$  is equal to  $\tau$  (Fogler, 1999; Trussell et al., 1979). However, reactors are not perfect, and as a result, the measured mean residence time is always less than  $\tau$ . The principal cause of this deviation is the presence of dead spaces in the reactor (spaces that do not mix well with the remainder of the contents) where the volume is not used. Thus, the effective volume of the reactor is smaller than the actual volume,

**Figure 6-17**

Results of tracer test from three CMFRs in series: (a) concentration  $C$  as function of time and (b) exit age distribution  $E$  and cumulative exit age distribution  $F$ .

and the mean residence time is smaller than  $\tau$ . When choosing a tracer, care must be taken that the tracer does not adsorb on the walls of the vessel because adsorption can cause the mean residence time to be less than  $\tau$ . It is important that  $\bar{t}$ , not  $\tau$ , be used in normalizing tracer curves. The mean residence time is determined from the results of the tracer study in the following manner:

$$\bar{t} = \frac{\int_0^{\infty} Ct \, dt}{\int_0^{\infty} C \, dt} \quad (6-76)$$

where  $\bar{t}$  = mean residence time of tracer in reactor, min or s

$C$  = concentration exiting reactor at time  $t$ , mg/L

$t$  = time since addition of tracer pulse to reactor's entrance, min or s

The denominator in Eq. 6-76 corresponds to the area under the concentration-versus-time curve. The normalized time is determined with the following expression:

$$\theta = \frac{t}{\bar{t}} \quad (6-77)$$

where  $\theta$  = normalized time, dimensionless

#### NORMALIZATION CONCENTRATION

The measured concentration must be normalized such that the possibility for all measurements is 1.0. To normalize the concentration, the measured

tracer concentration is divided by the total mass concentration.

$$C_N = \int_0^{\infty} C d(\theta) \quad (6-78)$$

$$1 = \int_0^{\infty} \frac{C}{C_N} d(\theta) \quad (6-79)$$

where  $C_N$  = total mass concentration of tracer recovered, mg/L

Just as  $\tau$  cannot be used in place of  $\bar{t}$  for normalization of the detention time, neither can the mass of tracer injected be used to normalize the concentration. The recovery of the tracer is always somewhat less than the mass injected, and the mass recovered in the measurements must be used for normalization. Nevertheless, a carefully conducted tracer study will normally account for more than 95 percent of the mass of the tracer applied, and when this is not the case, it is cause for reexamination of the entire study.

#### EXIT AGE DISTRIBUTION

The normalized curve for the pulse tracer study is referred to as the exit age distribution  $E(\theta)$ , and the normalized curve of the step input tracer study is referred to as the cumulative exit age distribution  $F(\theta)$ . It is also possible to do a continuous tracer study with a step down in concentration. In this case, the normalized curve is referred to as the cumulative internal age distribution  $I(\theta)$ . The exit age distribution is the most convenient form for performing reactor calculations and provides a distribution of the ages of the fluid elements that leave the reactor.

The exit age distribution is related to the cumulative exit age distribution and the cumulative internal age distribution by the equation

$$E(\theta) = \frac{dF(\theta)}{d\theta} = -\frac{dI(\theta)}{d\theta} \quad (6-80)$$

The exit age distribution curve has the the following important properties:

1. The integral  $\int_{\theta}^{\theta+\Delta\theta} E(\theta) d\theta$  equals the fraction of material leaving the reactor having ages between  $\theta$  and  $\theta + \Delta\theta$ .
2. The probability of having all possible ages is 1.0, that is,  $1.0 = \int_0^{\infty} E(\theta) d\theta$ .
3. The fraction older than a specified age,  $\theta_2$ , is  $\int_{\theta_2}^{\infty} E(\theta) d\theta$ .
4. The fraction younger than a specified age,  $\theta_2$ , is  $\int_0^{\theta_2} E(\theta) d\theta$ .

#### COMPUTATION OF EXIT AGE DISTRIBUTION CURVE

The exit age distribution for a CMFR is given by the expression

$$E(\theta) = \frac{C}{C_N} = \frac{C_0 e^{-\theta}}{\int_0^{\infty} C_0 e^{-\theta} d(\theta)} = e^{-\theta} \quad (6-81)$$

The exit age distribution and cumulative exit age for the tracer curve presented on Fig. 6-17a are shown on Fig. 6-17b. In principle, the exit age distribution for a PFR tracer study should show a very high concentration spike at the hydraulic detention time of the reactor, and the area under the exit age distribution  $E(\theta)$  must be 1. Accordingly, the exit age distribution for a PFR is given by the expression

$$E(\theta) = \delta(1 - \theta) \quad (6-82)$$

where  $\delta(1 - \theta) =$  Dirac delta function

The Dirac delta function  $\delta(x)$  has the following operational definition:

$$1 = \int_0^{\infty} \delta(1 - \theta) d\theta \quad \delta(1 - \theta) = 0 \quad \text{for } \theta \neq 1$$

and

$$\delta(1 - \theta) = \delta(0) = \infty \quad \text{for } \theta = 1 \quad (6-83)$$

Conceptually, the Dirac delta function has an infinite height, infinitesimally small base, and an area of 1.0. The Dirac delta function is commonly used in calculus and is defined as

$$\int_0^{\infty} y(x)\delta(x_0) d\theta = y(x_0) \quad (6-84)$$

where  $x, x_0 =$  independent variables

The term  $\delta(x)$  is not evaluated except when it is used in an integral. Use of the delta function is similar to the use of imaginary numbers such as  $\sqrt{-1}$  because the products of imaginary numbers are always evaluated and the mathematical representation of the numbers is needed before they are multiplied with one another.

Because not all of the tracer will be recovered, the following steps are followed to obtain the exit age distribution from a pulse tracer study:

1. Determine the mean detention time using Eq. 6-76.
2. Compare the mean detention time with the hydraulic detention time and determine if there is any short circuiting. If there is short circuiting, evaluate whether modification to the reactor can eliminate this and improve performance.
3. Determine the normalization concentration using the equation

$$C_N = \int_0^{\infty} Cd\left(\frac{t}{\bar{t}}\right) = \frac{\int_0^{\infty} C dt}{\bar{t}} \quad (6-85)$$

4. Replot the tracer study as  $E(\theta) = C/C_N$  versus  $\theta = t/\bar{t}$ .

**COMPUTATION OF VARIANCE**

The variance  $\sigma_t^2$ , the second moment about the mean of the data, is used to determine the spread of the tracer curve using the following equation:

$$\sigma_t^2 = \frac{\int_0^{\infty} (t - \bar{t})^2 C dt}{\int_0^{\infty} C dt} \quad (6-86)$$

where  $\sigma_t^2 =$  variance with respect to  $t$ ,  $\text{min}^2$

The variance can also be calculated from the exit age distribution as follows:

$$\sigma_\theta^2 = \int_0^{\infty} E(\theta) (\theta - 1)^2 d\theta = \frac{\sigma_t^2}{\bar{t}^2} \quad (6-87)$$

where  $\sigma_\theta^2 =$  variance with respect to  $\theta$ , dimensionless

### Example 6-4 Calculation of exit age distribution for pulse tracer study

A pulse study on an open-channel reactor (PFR) was conducted and the results are reported in the table below. Plot the tracer curve and normalized RTD curve and determine the variance of the tracer data.

Time, min	C, mg/L	Time, min	C, mg/L	Time, min	C, mg/L
0	0	64	34	90	31
10	0	65	38	95	21
20	1	66	46	100	15
30	2	68	58	105	10
40	4	70	62	110	6
50	9	71	63	120	3
55	15	72	63	130	1
60	24	75	64	140	0
62	28	80	58		
63	30	85	45		

**Solution**

1. The tracer curve is shown on panel (a) of the figure in step 2e below.
2. Construct a plot of the normalized RTD curve.
  - a. Set up a computation table to determine the mean detention time (used for normalizing time data) using Eq. 6-76:

$$\bar{t} = \frac{\int_0^{\infty} Ct \, dt}{\int_0^{\infty} C \, dt} \approx \frac{\sum \bar{C}t \Delta t}{\sum \bar{C} \Delta t}$$

The summation is shown in the table given below.

$t$ , min	$C$ , mg/L	$\left(\frac{C_{i-1}+C_i}{2}\right) \Delta t$	$\left(\frac{C_{i-1}t_{i-1}+C_it_i}{2}\right) \Delta t$	$t$ , min	$C$ , mg/L	$\left(\frac{C_{i-1}+C_i}{2}\right) \Delta t$	$\left(\frac{C_{i-1}t_{i-1}+C_it_i}{2}\right) \Delta t$
0	0	—	—	70	62	120	8,284
10	0	0	0	71	63	62.5	4,407
20	1	5	100	72	63	63	4,505
30	2	15	400	75	64	190.5	14,004
40	4	30	1,100	80	58	305	23,600
50	9	65	3,050	85	45	257.5	21,163
55	15	60	3,188	90	31	190	16,538
60	24	97.5	5,663	95	21	130	11,963
62	28	52	3,176	100	15	90	8,738
63	30	29	1,813	105	10	62.5	6,375
64	34	32	2,033	110	6	40	4,275
65	38	36	2,323	120	3	45	5,100
66	46	42	2,753	130	1	20	2,450
68	58	104	6,980	140	0	5	650
Total						2,148.5	164,627

$$\bar{t} \approx \frac{\sum \bar{C}t \Delta t}{\sum \bar{C} \Delta t} = \frac{164,627}{2148.5} = 76.6 \text{ min}$$

- b. Determine the value to be used for normalization of the tracer concentration  $C_N$  using Eq. 6-85:

$$C_N = \frac{\int_0^{\infty} C \, dt}{\int_0^{\infty} C d\left(\frac{t}{\bar{t}}\right)} = \frac{\int_0^{\infty} C \, dt}{\bar{t}} \approx \frac{\sum \bar{C} \Delta t}{\bar{t}} = \frac{2148.5}{76.6} = 28 \text{ mg/L}$$

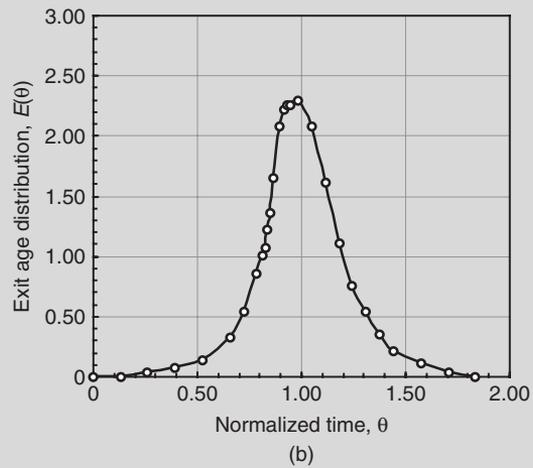

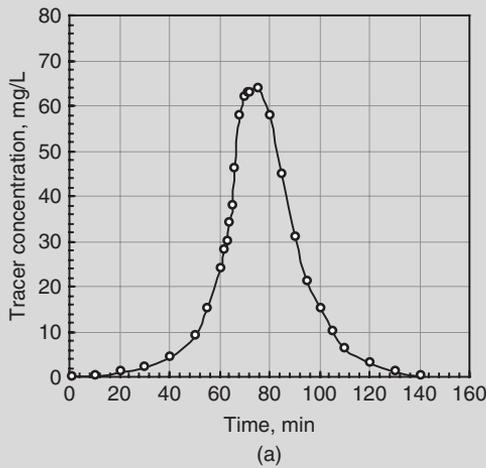

- c. Use  $\bar{t}$  and  $C_N$  to normalize the original tracer study data:

$$\theta = \frac{t}{\bar{t}} = \frac{t}{76.6} \quad \text{and} \quad E(\theta) = \frac{C}{C_N} = \frac{C}{28}$$

- d. Set up a computation table to determine the values to be used for plotting the RTD curve.

t, min	C, mg/L	$\theta$	$E(\theta)$	t, min	C, mg/L	$\theta$	$E(\theta)$
0	0	0.00	0.00	70	62	0.91	2.21
10	0	0.13	0.00	71	63	0.93	2.25
20	1	0.26	0.04	72	63	0.94	2.25
30	2	0.39	0.07	75	64	0.98	2.28
40	4	0.52	0.14	80	58	1.04	2.07
50	9	0.65	0.32	85	45	1.11	1.61
55	15	0.72	0.54	90	31	1.17	1.11
60	24	0.78	0.86	95	21	1.24	0.75
62	28	0.81	1.00	100	15	1.30	0.54
63	30	0.82	1.07	105	10	1.37	0.36
64	34	0.83	1.21	110	6	1.43	0.21
65	38	0.85	1.36	120	3	1.56	0.11
66	46	0.86	1.64	130	1	1.69	0.04
68	58	0.89	2.07	140	0	1.83	0.00

e. The final exit age distribution is shown in panel (b) below.

3. Compute the variance using Eqs. 6-86 and 6-87:

$$\sigma_t^2 = \frac{\int_0^\infty (t - \bar{t})^2 C dt}{\int_0^\infty C dt} \approx \frac{\sum (t - \bar{t})^2 C \Delta t}{\sum \bar{C} \Delta t}$$

$$\sigma_\theta^2 = \frac{\sigma_t^2}{\bar{t}^2}$$

Set up a computation table to compute the terms needed to determine the variance.

t, min	C, mg/L	$\bar{C} \Delta t^a$	Term <sup>b</sup>	t, min	C, mg/L	$\bar{C} \Delta t^a$	Term <sup>b</sup>
0	0	—	—	70	62	120	7,176.5
10	0	0	0.0	71	63	62.5	2,416.4
20	1	5	16,075.5	72	63	63	1,720.4
30	2	15	37,886.0	75	64	190.5	2,367.1
40	4	30	48,750.9	80	58	305	2,040.7
50	9	65	59,024.7	85	45	257.5	9,324.2
55	15	60	33,703.4	90	31	190	21,452.2
60	24	97.5	34,398.2	95	21	130	31,283.7
62	28	52	12,746.8	100	15	90	37,933.6
63	30	29	5,842.1	105	10	62.5	40,375.0
64	34	32	5,558.8	110	6	40	36,651.3
65	38	36	5,344.4	120	3	45	61,384.2
66	46	42	5,235.8	130	1	20	42,324.6
68	58	104	9,660.1	140	0	5	14,203.5
						2,148.5	584,880.0

$${}^a \bar{C} \Delta t = \left( \frac{C_{i-1} + C_i}{2} \right) \Delta t.$$

$${}^b \left\{ [(t_{i-1} - \bar{t})^2 C_{i-1} + (t_i - \bar{t})^2 C_i] / 2 \right\} \Delta t.$$

$$\sigma_t^2 = \frac{\sum (t - \bar{t})^2 \bar{C} \Delta t}{\sum \bar{C} \Delta t} = \frac{584,880}{2,148.5} = 272.2 \text{ min}^2$$

$$\sigma_t = 16.50 \text{ min}$$

$$\sigma_\theta^2 = \frac{\sigma_t^2}{\bar{t}^2} = \frac{272.2 \text{ min}^2}{(76.6 \text{ min})^2} = 0.0464$$

$$\sigma_\theta = 0.221$$

### Comment

The numerical integration in this example was carried out using the trapezoidal rule. It should be noted that other methods of integration, including the rectangular, Simpson, and Durand rules as well as more complex methods, may be used.

### Parameters Used to Characterize Tracer Results

For some time, the environmental engineering community has understood that the RTD of a reactor, particularly a disinfection contactor, is important. As a result, tracer curves have been used to characterize these reactors and aid in understanding their performance. As this understanding has grown more sophisticated, a number of indices have been used to characterize reactors and their tracer results. Some of the most commonly used terms are summarized in Table 6-5. By far the most commonly used term to characterize reactors is the hydraulic detention time  $\tau$ , and it is clear that

**Table 6-5**

Terms used to characterize tracer curves

Term	Definition
$d$	Dispersion number. Measures dispersion in reactor. For an ideal PFR, $d = 0$ . For an ideal CMFR, $d = \infty$
Pe	Peclet number; $Pe = 1/d$
$\tau$	Theoretical hydraulic residence time ( $\tau = V/Q$ )
$t_i$	Time at which tracer first appears
$\theta$	Normalized detention time ( $t/\bar{t} \approx t/\tau$ )
$t_p, t_{\text{modal}}$	Time at which peak concentration of tracer is observed (mode)
$\bar{t}$	Mean residence time, centroid of pulse tracer curve
$t_{10}, t_{50}, t_{90}$	Time at which 10, 50, and 90% of tracer has passed through reactor or when 10, 50, and 90% of the fluid has passed through the reactor
$t_{90}/t_{10}$	Morrill dispersion index (MDI)
$t_i/\tau$	Index of short circuiting. In an ideal PFR, the ratio is 1 and approaches zero with increased short circuiting
$t_p/\tau$	Index of modal retention time. Ratio is 1 in an ideal PFR and zero in an ideal CMFR. For values of the ratio greater than or less than 1.0, the flow distribution in the reactor is not uniform
$\bar{t}/\tau$	Index of average retention time; reflects the volume of the reactor that is not used as the fluid passes through the reactor. This volume is sometime called dead volume. If the ratio is 1.0, there is no dead volume in the reactor
$t_{50}/\tau$	Index of mean retention time. The ratio $t_{50}/\tau$ is a measure of the skew of the $E(\theta)$ curve. A value of $t_{50}/\tau$ of less than 1.0 corresponds to an $E(\theta)$ curve that is skewed to the left. Similarly, for values greater than 1.0 the $E(\theta)$ curve is skewed to the right
$n$	Equivalent number of tanks in series in TIS model

$\tau$  has great significance. Of the remaining indices, the most important are probably the dispersion number  $d$ ; the Peclet number  $Pe$ ; the equivalent number of tanks in series (TIS),  $n$ ; and  $t_{10}$ . The dispersion number, the Peclet number, and the equivalent number of tanks in series are important because these can be used in the single-parameter models as a comprehensive measure of dispersion, as discussed in Sec. 6-7. The time for 10 percent of the tracer to pass through the reactor,  $t_{10}$ , is important because the U.S. EPA uses that measurement for regulating the performance of disinfection reactors for drinking water.

## 6-7 Modeling Hydraulic Performance of Nonideal Reactors

---

As described in Sec. 6-6, the flow in real reactors is not ideal and RTD curves are used to characterize the nonideal flow. In nonideal reactors, the mixing conditions are complex and flow behavior often deviates substantially from the assumptions of ideal flow. The nonideal reactor analysis in this section includes (1) the factors that cause nonideal flow; (2) distinction between molecular diffusion, turbulent diffusion, and dispersion; and (3) models used for characterizing nonideal flow and predicting nonideal reactor performance.

Mixing at two scales dramatically affects reactor efficiency. At the microscale ( $< \sim 500 \mu\text{m}$ ), there is concern about mixing reactants in the influent such that there is a uniform concentration of the reactants entering the reactor. At the macroscale, there is concern about how long different fluid elements (which are presumed uniform in concentration at the microscale) reside in the reactor. There are three principal types of nonideal fluid behavior at the macroscale in processing equipment: (1) inadequate initial blending, (2) short circuiting, and (3) diffusion and dispersion. Ultimately, nonideal flow can cause decreased removal efficiencies or the formation of undesirable by-products.

### Causes of Nonideal Flow

#### INADEQUATE INITIAL BLENDING

Nonideal flow in reactors may be caused by inadequate initial blending of reacting components as they enter the reactor. As blending of miscible fluids and soluble components will occur, the initial mixing issue becomes a question of whether the blending is accomplished fast enough relative to the speed of the reactions taking place. Blending is addressed in greater depth in Sec. 6-10.

#### SHORT CIRCUITING

Short circuiting is characterized by a segment of the fluid stream having a residence time considerably shorter than the mean hydraulic residence

time. Short circuiting is a common design issue in CMFRs, rectangular basins, and packed columns or towers, and it is particularly important in processes where a high level of removal is required, such as disinfection (e.g., 99.99 percent inactivation). The impact of short circuiting on processes with low versus high removal requirements is compared in Sec. 13-4. Short circuiting may develop within the reactor due to poor fluid mechanical design of (1) internal packing material, (2) inlet and outlet structures, and (3) the aspect ratio of the reactor itself (length as compared to depth and width with a larger aspect ratio being most desirable). Short circuiting also occurs when circulation patterns develop due to wind or density differences due to temperature or the concentration of dissolved or suspended materials. For example, when the flow entering the reactor is warmer than the flow in the reactor, a portion of flow can travel to the outlet across the top of the reactor. Short circuiting also occurs in sedimentation basins due to the greater bulk density of the sludge with respect to the bulk water above it. In shallow reactors, wind can transport a portion of the incoming flow to the outlet, resulting in an observed detention time that is shorter than the theoretical residence time of the reactor. Wind can also cause backmixing. However, as discussed later, velocity gradients and short circuiting can be overcome by using baffles, increasing the aspect ratio of the reactor, and proper orientation of basins relative to the prevailing winds or covering them.

#### **DIFFUSION AND DISPERSION**

In addition to improper initial blending and short circuiting, diffusion and dispersion can contribute to the nonideal flow observed in reactors. In general, diffusion involves the movement of a constituent from a higher concentration to a lower concentration as a result of collisions with fluid molecules that move by Brownian motion. Dispersion is the mixing brought about by physical processes such as turbulence and velocity gradients.

##### *Diffusion*

Molecular diffusion occurs when dissolved constituents or very small particles move randomly within the water matrix as a result of collisions with water molecules that move randomly. This random motion is generally referred to as Brownian motion. Because molecular diffusion does not depend on any bulk movement of the water, it can occur both under laminar and turbulent flow conditions. Molecular diffusion is irreversible and is different for different constituents. Mass transfer brought about by molecular diffusion is described by Fick's law, which is considered in Chap. 7.

##### *Dispersion*

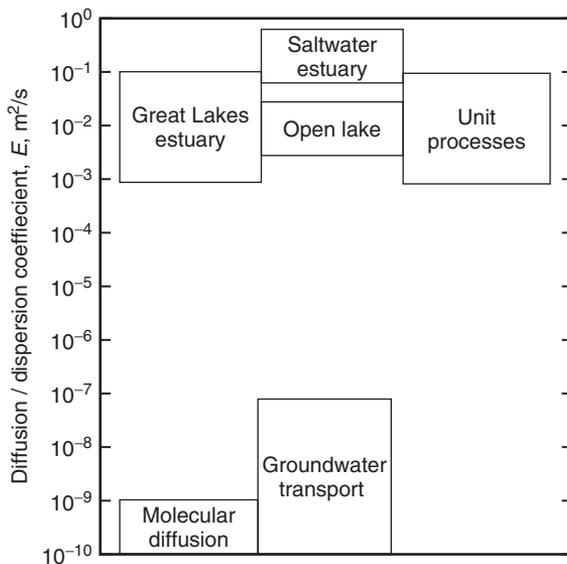

The mixing process whereby a constituent is transported from a higher concentration to a lower concentration, by eddies formed by turbulent

flow or shearing forces between fluid layers is known as dispersion. Eddies can vary in size from microscale to macroscale to large circulation patterns in the ocean. Microscale mass transport is only by molecular diffusion, whereas in the macroscale mass transport can be by both molecular and dispersion, with the latter predominating. Kolmogorov (1941a,b,c), as discussed in Sec. 6-10, identified the dividing line between the microscale and macroscale and suggested a method for determining the size of the smallest eddy that could be generated as a function of the amount of energy dissipated. Dispersion is considered further in Sec. 6-10.

The constituent mixing that results from the shearing forces between fluid layers and by the random fluid motion of turbulence is also known as dispersion. The parabolic distribution of flow velocities that occurs in pipe flow is a classic example of the shearing that occurs between fluid layers and is known as Taylor dispersion. Dispersion occurs mainly in tanks, channels, pipes, or columns and is characterized by longitudinal mixing, which distorts the flat velocity profile (perpendicular to the direction of flow) that is assumed for an ideal PFR. Because dispersion coefficients are dominated by the character of turbulence at the macroscale, they are identical for all constituents, and tracer studies can be conducted using a dye or salt solution. Typical values of some observed dispersion coefficients  $E$  are illustrated on Fig. 6-18. Representative values for molecular diffusion are shown in the lower left on Fig. 6-18.

When an engineer designs a large reactor for water treatment, nonideal flow is almost always a design issue. To ensure that the reactor will perform as intended, it is important that the design engineer consider impacts that

### Models Used to Describe Nonideal Flow

**Figure 6-18**  
Observed coefficients of dispersion and molecular diffusion.

nonideal flow might have on reactor performance. Considering nonideal effects on reactors occurs through two important steps: (1) understanding the impact of reactor design on nonideal flow and (2) understanding the impact of nonideal flow on reactor performance. Neither of these tasks is accomplished easily, but understanding the impact of reactor design on nonideal flow presents a particular challenge. Usually, the approach taken is to (1) construct a model of the RTD in the reactor as a way of understanding its nonideal behavior and then (2) use the RTD model to predict the impact on reactor performance. Two single-parameter models are typically used to model RTD: (1) the dispersion model or dispersed-flow model (DFM) and (2) the tanks-in-series (TIS) model. Once a reactor has been built, it is common to conduct a tracer study to determine the actual RTD of the reactor and then to see how well that RTD can be fit to one of these single-parameter models. The DFM and the TIS model are introduced in the following discussion.

#### DISPERSED-FLOW MODEL

If longitudinal dispersion is the main cause for deviation from ideal flow in a conduit reactor (i.e., a tube, pipe, or channel), then the following mass balance may be established, assuming a constant cross-sectional area and no short circuiting in the reactor:

$$\left( QC|_{z,t} - E \cdot a \left. \frac{\partial C}{\partial z} \right|_{z,t} \right) \Delta t - \left( QC|_{z+\Delta z,t} - E \cdot a \left. \frac{\partial C}{\partial z} \right|_{z+\Delta z,t} \right) \Delta t + r \cdot a \cdot \Delta z \Delta t = a \cdot \Delta z [C|_{t+\Delta t,z} - C|_{t,z}] \quad (6-88)$$

where

$Q$  = flow rate, L/s

$\Delta t$  = elapsed time on interval  $t \rightarrow t + \Delta t$ , s

$C|_{z,t}$  = average concentration in reactor evaluated at  $z$  for interval  $t \rightarrow t + \Delta t$ , mg/L

$C|_{z+\Delta z,t}$  = average concentration in reactor evaluated at  $z + \Delta z$  for interval  $t \rightarrow t + \Delta t$ , mg/L

$E$  = dispersion coefficient,  $m^2/s$

$a$  = cross-sectional area of reactor,  $m^2$

$\left. \frac{\partial C}{\partial z} \right|_{z,t}$  = change in concentration with position in reactor evaluated at  $z$  for the interval  $t \rightarrow t + \Delta t$ ,  $mg/L \cdot m$

$\left. \frac{\partial C}{\partial z} \right|_{z+\Delta z,t}$  = change in concentration with position in reactor evaluated at  $z + \Delta z$  for interval  $t \rightarrow t + \Delta t$ ,  $mg/L \cdot m$

$r$  = average reaction rate on interval  $t \rightarrow t + \Delta t$  in element,  $mg/L \cdot s$

$\Delta z$  = length of element, m

$C|_{t+\Delta t,z}$  = average concentration in element evaluated at  $t + \Delta t$ , mg/L

$C|_{t,z}$  = average concentration in element evaluated at  $t$ , mg/L

In Eq. 6-88, there are values of the dependent variable that are equal to the mean value over the intervals  $(t, t + \Delta t)$  or  $(z, z + \Delta z)$ , which can be inferred from the mean-value theorem. For this reason, the dependent values are evaluated somewhere located in the intervals  $(t, t + \Delta t)$  and  $(z, z + \Delta z)$ . When taking the limit as  $\Delta t$  and  $\Delta z$  approach zero, they are evaluated at  $t$  and  $z$  because they were contained on the intervals. Dividing by  $a \Delta z$  and  $\Delta t$ , multiplying by  $\tau$ , taking the limit as  $\Delta z \rightarrow 0$ ,  $\Delta t \rightarrow 0$ , and rearranging, the following expression is obtained:

$$-\frac{\partial C}{\partial(z/L)} + \left(\frac{E}{vL}\right) \frac{\partial^2 C}{\partial(z/L)^2} + r\tau = \frac{\partial C}{\partial(t/\tau)} \quad (6-89)$$

where  $L$  = length of reactor, m  
 $v$  = average fluid velocity ( $Q/a$ ), m/s  
 $\tau$  = hydraulic detention time, s

To evaluate the RTD, it is assumed that the tracer does not participate in any reactions (i.e., a conservative tracer). Thus, Eq. 6-89 can be rearranged to the following:

$$-\frac{\partial C}{\partial \bar{z}} + \frac{1}{\text{Pe}} \frac{\partial^2 C}{\partial \bar{z}^2} = \frac{\partial C}{\partial(t/\tau)} \quad (6-90)$$

where  $\text{Pe}$  = Peclet number =  $vL/E$ , dimensionless  
 $\bar{z}$  = dimensionless length ( $\bar{z} = z/L$ )

The Peclet number is the “single parameter” of the DFM. Specifying the Peclet number is concomitant with specifying the entire RTD. Conceptually, the Peclet number is the ratio between mass transport by advection to dispersion:

$$\text{Pe} = \frac{vL}{E} = \frac{\text{rate of transport by advection}}{\text{rate of transport by dispersion}} \quad (6-91)$$

High Peclet numbers result when advection controls mass transport within the reactor because dispersion and advection act in parallel. As the Peclet number approaches infinity, transport is only by advection; no axial dispersion occurs and the reactor performance approaches that of a PFR. Conversely, for a Peclet number approaching zero, there is no transport by advection; only axial dispersion occurs and the reactor performance approaches that of a CMFR.

Often the dispersion number  $d$  is used in place of the Peclet number. The relationship between the dispersion number and the Peclet number is as follows:

$$d = \frac{1}{\text{Pe}} \quad (6-92)$$

where  $d$  = dispersion number, dimensionless

The Peclet number and dispersion number are both used in environmental literature, and, therefore, it is important to understand the relationship between these two parameters. The dispersion number and DFM are also

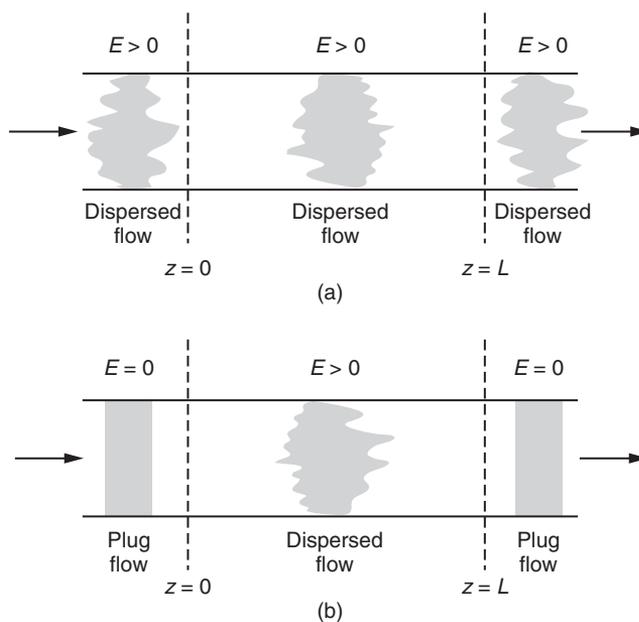

used in Chaps. 8 and 13. To solve Eq. 6-90, one initial condition and two boundary conditions are needed (Fogler, 1999). The boundary conditions, which apply to either steady-state or unsteady-state conditions, are discussed below.

*Open and closed systems and the DFM model*

There are two well-known approaches to the boundary conditions for the DFM model, the closed-system approach and the open-system approach. The differences between the open and closed models are shown on Fig. 6-19. For the closed-system model, it is assumed that plug flow occurs in and out of the reactor and dispersed flow occurs within the reactor. For the open-system model, it is assumed that dispersed-flow conditions are present throughout; that is, the reactor is essentially a segment of flow with characteristics common to the flow preceding and following it. Most unit operations used in environmental engineering are better approximated by the closed-system assumptions, although, as will be shown later, the differences between these models are not very significant when the Peclet number is greater than approximately 40 (when the dispersion number is below approximately 0.025), and most engineered PFRs exceed this performance.

*Solving DFM for a closed-flow system*

For a closed reactor it is assumed that plug flow conditions exist before the entrance (advection only) and dispersed-flow conditions exist after the

**Figure 6-19**  
Illustration of boundary conditions for dispersion model: (a) open system and (b) closed system.

entrance (advection and dispersion). Thus, the following mass balance can be written at the entrance to the reactor:

$$QC|_{z=0^-} = QC|_{z=0^+} - E \cdot a \left. \frac{\partial C}{\partial z} \right|_{z=0^+} \quad (6-93)$$

where  $QC|_{z=0^-}$  = mass of tracer that enters reactor, or  $QC_0$ , mg/s  
 $QC|_{z=0^+}$  = advective transport of tracer evaluated at  $z = 0^+$ ,  
 mg/s  
 $z = 0^-, 0^+$  = location just before and just after entrance of reactor

Recognizing that the velocity  $v$  is equal to flow divided by the cross-sectional area,  $Q/a$ , Eq. 6-93 may be rewritten as

$$\left. \frac{\partial C}{\partial z} \right|_{z=0^+} = \frac{v}{E} (C|_{z=0^+} - C|_{z=0^-}) \quad (6-94)$$

The final form of the boundary condition is given by the expression

$$\left. \frac{\partial C}{\partial (z/L)} \right|_{z=0^+} = \frac{vL}{E} (C|_{z=0^+} - C_0) = \text{Pe} (C|_{z=0^+} - C_0) \quad (6-95)$$

As shown in Eq. 6-95, there is a discontinuity in the concentration at the entrance of the reactor. Also for a closed system, it is assumed that dispersed-flow conditions exist before the exit (advection and dispersion) and plug flow conditions exist after the exit (advection only). Thus, a mass balance on the exit of a closed reactor yields

$$QC|_{z=L^-} - (E \cdot a) \left. \frac{\partial C}{\partial z} \right|_{z=L^-} = QC|_{z=L^+} \quad (6-96)$$

where  $QC|_{z=L^-}$  = advective transport of tracer evaluated at  $z = L^-$ ,  
 mg/s  
 $QC|_{z=L^+}$  = mass of tracer that leaves reactor, mg/s  
 $C$  = effluent concentration, mg/L  
 $z = L^-, L^+$  = locations just before and just after exit of reactor

Unlike the entrance of the reactor, there cannot be a discontinuity in concentration at the exit, and therefore the final form of the boundary condition is given by the following expressions:

$$\left. \frac{\partial C}{\partial z} \right|_{z=L} = 0 \quad (6-97)$$

$$C|_{L^-} = C|_{L^+} \quad (6-98)$$

Thomas and McKee (1944) developed a solution for a closed reactor for a conservative or nonreacting tracer, which has been modified in terms of the Peclet number:

$$\frac{C}{C_0} = 2 \sum_{i=1}^{\infty} b \left[ \frac{a \sin b + b \cos b}{a^2 + 2a + b^2} \right] \exp \left[ a - \frac{(a^2 + b^2) \theta}{2a} \right] \quad (6-99)$$

where  $C$  = effluent concentration of nonreactive tracer, mg/L  
 $C_0$  = initial concentration of tracer in reactor, mg/L  
 $b = \cot^{-1} \left[ \frac{(b/a) - (a/b)}{2} \right]$   
 $a = Pe/2 = \frac{1}{2}d$   
 $Pe$  = Peclet number, dimensionless (see Eq. 6-91)  
 $\theta$  = normalized detention time,  $t/\bar{t}$

To fit the closed-system DFM to an existing reactor, a pulse tracer study is conducted to obtain the exit age distribution. In turn, the tracer data can be fit with Eq. 6-99 to determine  $Pe$ . For a corresponding set of  $C/C_0$  and  $\theta$  values, a  $Pe$  is assumed and Eq. 6-99 is solved by successive numerical approximation. The process is repeated until a value of  $Pe$  is found such that Eq. 6-99 closely approximates the tracer curve.

Because of the difficulty in solving Eq. 6-99 and because it is easier to determine the variance of the tracer curve, the dispersion may be estimated using the following expression, which relates the  $Pe$  to  $\sigma_\theta^2$  (Fogler, 1999):

$$\sigma_\theta^2 = \frac{\sigma_t^2}{\bar{t}^2} = \left( \frac{2}{Pe} \right) - \left[ 2 \left( \frac{1}{Pe} \right)^2 (1 - e^{-Pe}) \right] \quad (6-100)$$

where  $\sigma_\theta^2$  = variance with respect to  $\theta$   
 $\sigma_t^2$  = variance with respect to  $t$

Consequently, a determination from variance is often used in spite of the inaccuracies that can result from determining  $\sigma_\theta^2$  from experimental data. For example, small concentrations far from the centroid can have a large impact on the value of  $\sigma_\theta^2$ . Thus, for accurate estimates of reaction performance, Eq. 6-99 should be fit to the data to determine the  $Pe$ .

#### *Solving DFM for an open-flow system*

For an open system it is assumed that dispersed-flow conditions exist before and after the entrance (advection and dispersion). Thus, the following mass balance can be written at the entrance to the reactor:

$$QC|_{z=0^-} - E \cdot a \left. \frac{\partial C}{\partial z} \right|_{z=0^-} = QC|_{z=0^+} - E \cdot a \left. \frac{\partial C}{\partial z} \right|_{z=0^+} \quad (6-101)$$

The final form of the boundary condition at the entrance to the reactor is given by

$$C|_{z=0^-} - \frac{1}{Pe} \left. \frac{\partial C}{\partial (z/L)} \right|_{z=0^-} = C|_{z=0^+} - \frac{1}{Pe} \left. \frac{\partial C}{\partial (z/L)} \right|_{z=0^+} \quad C|_{z=0^-} = C|_{z=0^+} \quad (6-102)$$

Similarly, a mass balance at the exit of an open reactor yields the final form of the boundary condition:

$$C|_{z=L^-} - \frac{1}{Pe} \left. \frac{\partial C}{\partial (z/L)} \right|_{z=L^-} = C|_{z=L^+} - \frac{1}{Pe} \left. \frac{\partial C}{\partial (z/L)} \right|_{z=L^+} \quad C|_{z=L^-} = C|_{z=L^+} \quad (6-103)$$

It is important to realize that  $C|_{z=0^-}$  and  $C|_{z=0^+}$  are not equal to the influent concentration into the reactor because dispersion transports the substance upstream and downstream.

If Eq. 6-90 is solved for a nonreactive tracer ( $r = 0$ ) in an open reactor, the following expression for  $E(\theta)$  is obtained (Levenspiel and Smith, 1957):

$$E(\theta) = \frac{1}{\sqrt{4\pi\theta(1/\text{Pe})}} e^{-\text{Pe}(1-\theta)^2/4\theta} \quad (6-104)$$

For low dispersion (high Pe), Eq. 6-104 simplifies to the following:

$$E(\theta) = \frac{1}{\sqrt{4\pi(1/\text{Pe})}} e^{-\text{Pe}(1-\theta)^2/4} \quad (6-105)$$

The mean detention time  $\bar{t}$  for an open reactor is longer than the theoretical hydraulic detention time  $\tau$  because some of the tracer can migrate upstream of the reactor. The mean detention time can be determined using the expression

$$\bar{t} = \left[ 1 + \left( \frac{2}{\text{Pe}} \right) \right] \tau \quad (6-106)$$

where  $\bar{t}$  = centroid of tracer curve =  $\int_0^\infty Ct dt / \int_0^\infty C dt$   
 $\tau$  = hydraulic detention time =  $V/Q$

It has been shown that the following relationship between the Pe and  $\sigma_\theta^2$  applies to open systems (Fogler, 1999):

$$\sigma_\theta^2 = \frac{\sigma_t^2}{\bar{t}^2} = \frac{2}{\text{Pe}} + 8 \left( \frac{1}{\text{Pe}} \right)^2 \quad (6-107)$$

To fit the open-system DFM to an existing reactor, a pulse tracer study is conducted to obtain the exit age distribution. The Peclet number may be estimated in two ways: from the variance of tracer data using Eq. 6-107 or by directly fitting the tracer data to Eq. 6-104. As discussed for the closed reactor system, the latter approach usually results in a superior fit and should be used to determine the Peclet number whenever possible.

#### TANK-IN-SERIES MODELS

The analysis summarized in Eq. 6-21 can be used to show that the exit age distribution for a cascade of  $n$  CMFRs in series is given by the following expression (Levenspiel, 1998):

$$E(\theta)_n = \frac{n(n\theta)^{n-1}}{(n-1)!} e^{-n\theta} \quad (6-108)$$

where  $E(\theta)_n$  = exit age distribution for  $n$  tanks in series  
 $\theta$  = relative residence time =  $t/\bar{t}$ , dimensionless

The variance can be determined using the expression

$$\sigma_\theta^2 = \frac{1}{n-1} \quad (6-109)$$

where  $\sigma_\theta^2$  = variance with respect to  $\theta$

To fit the TIS model to an existing reactor, a pulse tracer study is conducted to obtain the exit age distribution. The tracer data can be fit with Eq. 6-108 to determine  $n$ . Once the value of  $n$  has been estimated using this method, Eq. 6-108 can be used to construct a curve of  $E(\theta)$  as a function of  $\theta$ . Again, under conditions of low dispersion (high  $n$ ), the results of the TIS model approach those of the DFM. Under these conditions, the following relationship may be used:

$$n = \frac{1}{2}Pe + 1 \approx \frac{1}{2}Pe \quad (6-110)$$

For Pe numbers of 5, 10, and 25,  $n$  is equal to 3.5, 6.0, and 13.5, respectively. The results obtained using the TIS and DFM methods are similar; however, it is much easier to use the TIS method as compared to the DFM method. Fortunately, the equivalence can be drawn between the number of tanks for the TIS model and the Pe number used in the closed-flow DFM method (see Eq. 6-100), as shown in Eqs. 6-111 and 6-112 for a large Pe:

$$\sigma_0^2 \approx \frac{1}{n} \approx \left\{ \left( \frac{2}{Pe} \right) - \left[ 2 \left( \frac{1}{Pe} \right)^2 (1 - e^{-Pe}) \right] \right\} \quad (6-111)$$

$$n \approx \frac{1}{(2/Pe) - 2(1/Pe)^2(1 - e^{-Pe})} \approx \frac{Pe}{2} \quad (6-112)$$

The result shown in Eqs. 6-110 and 6-112 can be used to develop an appreciation for the magnitude of the Pe number. For example, a Pe of 20, 50, or 100 would correspond to 10, 20, or 50 tanks in series, respectively.

### Example 6-5 Determination of single-parameter fit to RTD

Using the tracer data analysis shown in Example 6-4, estimate the Peclet number and dispersion number for the open-flow DFM by fitting the model to Eq. 6-104 and also the number of tanks in series by fitting the data to Eq. 6-108. Plot the resulting exit age curves and compare them to the original data.

#### Solution

1. Determine the Peclet number for the open-flow DFM by fitting Eq. 6-104 to the  $E(\theta)$  curve shown in Example 6-4.
2. Determine the number of tanks in series for the tanks-in-series model by fitting Eq. 6-108 to the  $E(\theta)$  curve shown in Example 6-4.

Both fits are accomplished by setting up the data and the equation on a spreadsheet and finding the value of Pe (Eq. 6-104) or  $n$  (Eq. 6-108) that minimizes the sum of squares of the differences

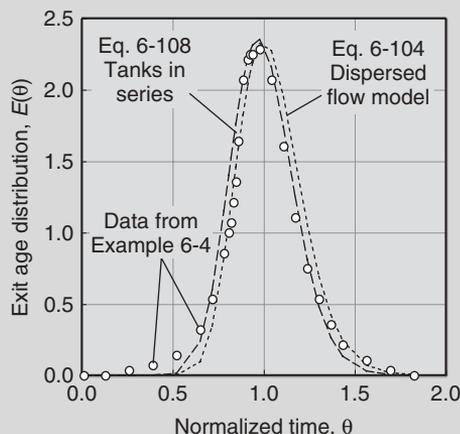

between the model and the data. The results of these calculations are shown in the table below.

$\theta$	$E(\theta)$	Eq. 6-104	[col. 2 – col. 3] <sup>2</sup>	Eq. 6-108	[col. 2 – col. 5] <sup>2</sup>

3. Determine the dispersion number from the Peclet number using Eq. 6-92:

$$d = \frac{1}{Pe} = \frac{1}{67} = 0.0149$$

4. A plot comparing the exit age data with the results of the two models is illustrated below.

### Comment

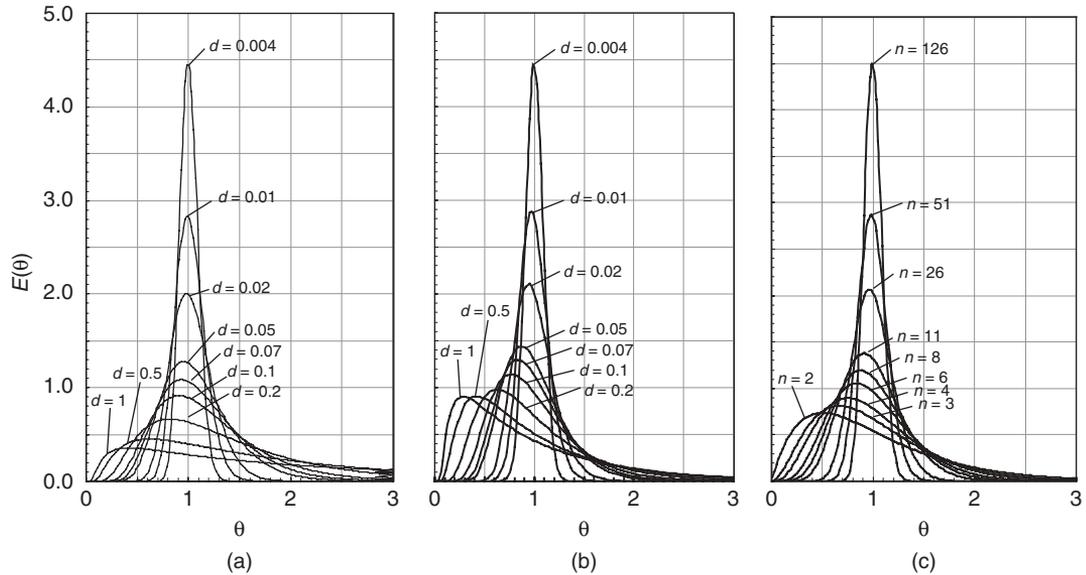

Both the TIS and DFM models fit the data well, except for the data for small exit ages. The fluid that exits the reactor with small residence times can have a large influence on reactor performance.

### Application of RTDs and $t_{10}$ Concept

The RTDs for the three models, closed-flow DFM, open-flow DFM, and TIS model, are displayed on Fig. 6-20. Under conditions where dispersion is high (high  $d$  for the DFM or low  $n$  for the TIS model), these three models produce significantly different RTDs, as shown on Fig. 6-20. Under conditions where dispersion is low (low  $d$  for the DFM or high  $n$  for the TIS model), these models produce RTDs that are nearly identical.

In subsequent sections it will be shown that the entire RTD is useful in evaluating the expected performance of a given reactor design. However, RTDs are complicated, and their use in evaluating reactor performance, while the best available technology, is also somewhat more complicated than just assuming that an actual reactor performs similar to a PFR with a certain residence time that is determined by a tracer study. As a result, regulatory authorities often regulate reactor design using certain simplified performance criteria. For example, in disinfection practice (see Chap. 13), it is assumed that the effective contact time corresponds to the length of time it takes for the first 10 percent ( $\theta_{10}$ ) of a tracer to pass through the reactor. This approach is conservative because credit is only received for  $\theta_{10}$  and not  $\theta_{50}$ , which corresponds to the actual residence time.

Each RTD model discussed was examined to assess the impact of reactor dispersion on  $\theta_{10}$ , the fraction of the reactor's theoretical detention time

**Figure 6-20**

Comparison of  $E(\theta)$  curves for (a) DFM open system, (b) DFM closed system, and (c) TIS model.

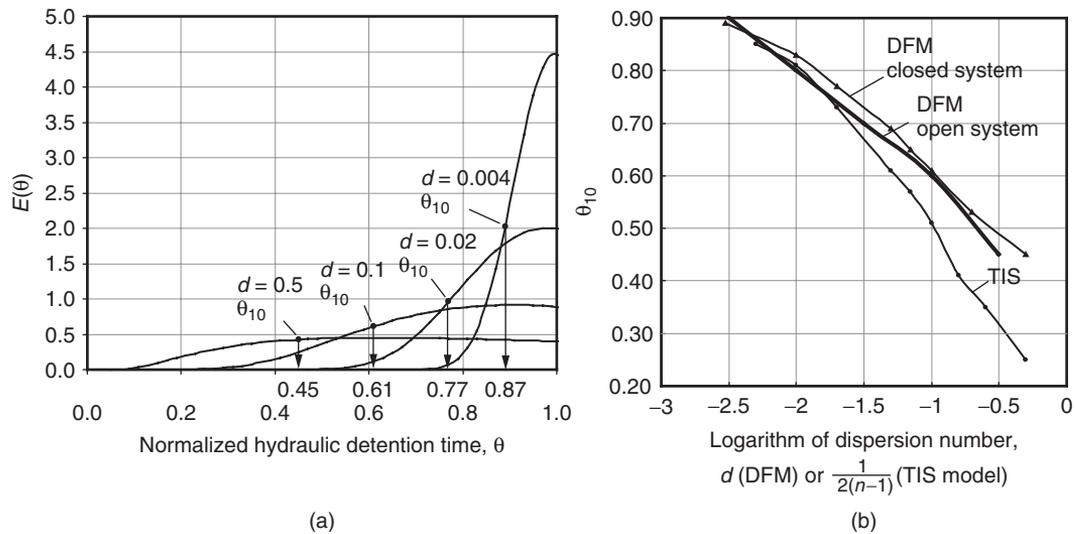

that would be allowed as credit by the U.S. EPA rules (see example for open-system DFM on Fig. 6-21a). A plot of  $\theta_{10}$  ( $t_{10}/\bar{t}$ ) as a function of increasing dispersion for all three RTD models is displayed on Fig. 6-21b. Note that the TIS model does not allow for direct application of the dispersion or Peclet numbers, so an approximate transformation represented by Eq. 6-110 was used for comparison purposes. As expected, the  $\theta_{10}$  value drops consistently as dispersion increases. For example, credit would be received for more than 80 percent of the residence time of the reactor for low dispersion ( $d < 0.01$ ,  $Pe > 100$ ,  $n > 50$ ) to as low as 25 to 50 percent of the residence time for reactors with high dispersion ( $d > 0.3$ ,  $Pe < 3$ ,  $n < 2$  or 3). A credit of 80 percent or more would correspond to a well-designed reactor.

Extensive studies have been conducted to determine the dispersion in open-channel flow. The dispersion in an existing reactor can be determined using a tracer study; however, when designing facilities, it is useful to be able to predict the dispersion. Davies (1972) proposed the following relationship for flow in an open channel and a high Reynolds number, which can be used to estimate the dispersion coefficient:

$$E = 1.01\nu(\text{Re})^{0.875} \quad (6-113)$$

where  $E$  = coefficient of dispersion,  $\text{m}^2/\text{s}$   
 $\nu$  = kinematic viscosity,  $\text{m}^2/\text{s}$   
 $\text{Re}$  = Reynolds number =  $4\nu R_h/\nu$ , dimensionless  
 $v$  = velocity in open channel,  $\text{m}/\text{s}$   
 $R_h$  = hydraulic radius = sectional area/wetted perimeter,  $\text{m}$

**Predicting  
Dispersion in  
a Channel**

**Figure 6-21**

Dispersion and  $\theta_{10}$ . (a) Analyzing effect of dispersion on  $\theta_{10}$  using DFM model for open system. (b) Relationship between increasing dispersion and  $\theta_{10}$  for three models: DFM closed system, DMF open system, and TIS model.

Other models developed for the dispersion coefficient are based on the Taylor equation and are discussed in Chap. 13.

### Example 6-6 Estimate of dispersion in open channel

For an open-channel PFR with a water flow rate of  $4320 \text{ m}^3/\text{d}$ , estimate the dispersion number and  $t_{10}$ . Assume that  $\bar{t} \cong \tau$  and that the channel has a length of 40 m, a width of 3 m, and a water depth of 3 m. Use a kinematic viscosity of  $1.003 \times 10^{-6} \text{ m}^2/\text{s}$  for the water. Assume the dispersion in the channel can be estimated accurately using Eq. 6-113 and that the RTD in the channel can be predicted using the open-flow DFM model (Eq. 6-104).

#### Solution

1. Estimate the dispersion number.
  - a. To apply Eq. 6-113, compute the Reynolds number  $Re$ :

$$\begin{aligned} \text{Average water velocity } v &= \frac{(4320 \text{ m}^3/\text{d})(1 \text{ d}/86,400 \text{ s})}{3 \text{ m} \times 3 \text{ m}} \\ &= 0.0056 \text{ m/s} \end{aligned}$$

$$\text{Hydraulic radius } R_h = \frac{3 \text{ m} \times 3 \text{ m}}{3 \text{ m} + 3 \text{ m} + 3 \text{ m}} = 1 \text{ m}$$

$$\begin{aligned} \text{Reynolds number } Re &= \frac{4vR_h}{\nu} = \frac{(4)(0.0056 \text{ m/s})(1 \text{ m})}{1.003 \times 10^{-6} \text{ m}^2/\text{s}} \\ &= 22,156 \end{aligned}$$

- b. Compute the coefficient of dispersion  $E$ :

$$\begin{aligned} E &= 1.01\nu(Re)^{0.875} = (1.01)(1.003 \times 10^{-6} \text{ m}^2/\text{s})(22,156)^{0.875} \\ &= 0.00643 \text{ m}^2/\text{s} \end{aligned}$$

- c. Compute the dispersion number using Eqs. 6-91 and 6-92:

$$d = \frac{E}{vL} = \frac{0.00643 \text{ m}^2/\text{s}}{(0.0056 \text{ m/s})(40 \text{ m})} = 0.0289$$

2. Estimate  $t_{10}$ .

- a. Determine the Peclet number from the dispersion number using Eq. 6-92:

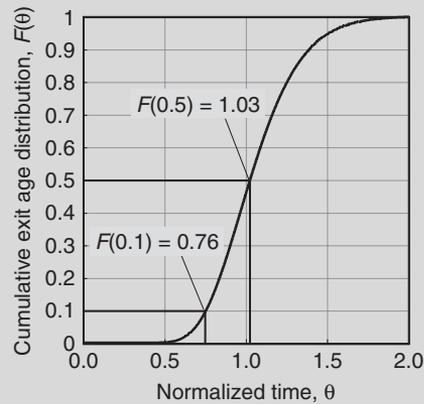

$$Pe = \frac{1}{d} = \frac{1}{0.0289} = 34.5$$

- b. Set up a table to compute the cumulative exit age distribution  $F(\theta)$  using Eq. 6-104 to find  $E(\theta)$  from  $\theta$  and Eq. 6-80 to convert  $E(\theta)$  to  $F(\theta)$ :

$\theta$	$E(\theta)$	$\bar{E}(\theta)$	$\bar{E}(\theta)\Delta\theta^a$	$F(\theta)$	$\theta$	$E(\theta)$	$\bar{E}(\theta)$	$\bar{E}(\theta)\Delta\theta^a$	$F(\theta)$

<sup>a</sup> $\Delta\theta = 0.1$ .

- c. Plot the cumulative exit age distribution and estimate the value of  $\theta$  at  $F(\theta) = 0.10$ . As shown in the plot below, the value of  $\theta$  at  $F(\theta) = 0.10$  is 0.76.

- d. Determine the hydraulic detention time for the basin.

$$\tau = \frac{V}{Q} = \frac{360 \text{ m}^3}{3 \text{ m}^3/\text{min}} = 120 \text{ min}$$

- e. Determine the mean residence time. The mean residence time is equal to the hydraulic detention time as given in the problem statement. Because there is no short circuiting, Eq. 6-106 should be used to estimate  $\bar{t}$ , but the open-flow DFM model was used to simulate a closed-flow DFM model because it is simpler to use and yields similar results at high Pe values.

$$\bar{t} = \tau \quad \text{and} \quad \bar{t} = 120 \text{ min.}$$

- f. Estimate  $t_{10}$ .

From the above plot,  $F(0.10) = 0.76$

Therefore, by EPA's definition  $t = t_{10}$  when  $\theta_{10} = 0.76$ .

Substituting into to Eq. 6-77 and rearranging,

$$t_{10} = \bar{t} \times \theta_{10} \quad \text{or} \quad t_{10} = 120 \times 0.76 = 91 \text{ min}$$

The influence of the aspect ratio can be determined by examining Eq. 6-113. If it is assumed that the Reynolds number is raised to the power of 1.0, the following expressions can be derived:

$$\text{Pe}_{R_h} = \frac{vR_h}{E} = 0.25 \quad (6-114)$$

$$\text{Pe}_L = \text{Pe}_{R_h} \frac{L}{R_h} \quad (6-115)$$

where  $\text{Pe}_{R_h}$  = Peclet number based on hydraulic radius

As shown in Eq. 6-115, the Pe number increases as the  $L/R_h$  increases. Thus, if the  $L/R_h$  is 400, which corresponds to a long conveyance channel, the Pe number would be 100, which corresponds to a  $\theta_{10}$  of 0.8.

When designing reactors for water treatment, there are generally two types of reactors: (1) a well-mixed reactor in which mixing is mechanically forced for a number of reasons (e.g., to blend chemicals, as discussed in Sec. 6-10, to strip volatile compounds, or to prevent particle settling) and (2) a reactor mixed by the flow through the process equipment (e.g., channels, ditches, or pipes).

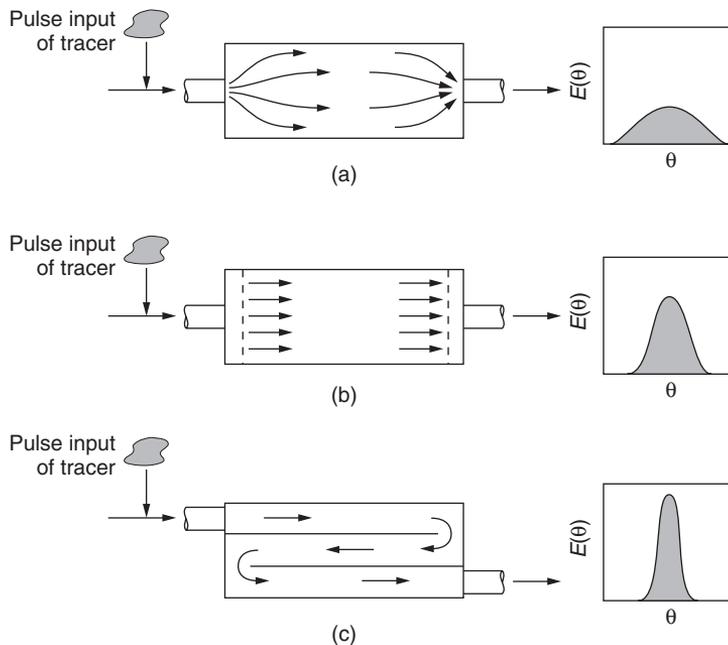

## Improving Reactor Performance

### IMPROVING CMFR PERFORMANCE

Generally, the performance of well-mixed reactors can be improved by inserting baffles in the reactor and converting the reactor from one CMFR to multiple CMFRs. The improvement in reactor performance expected after dividing a CMFR into multiple CMFRs may be estimated with the TIS model described previously. Procedures used to obtain adequate mixing are discussed in Sec. 6-10.

### IMPROVING PFR PERFORMANCE

The methods used to improve the performance of a PFR are different than those described for the CMFR. If the fluid velocity is low or the inlet and outlet hydraulics are poor, as shown on Fig. 6-22a, dead volume and

**Figure 6-22**

Improvement of reactor performance of a basin: (a) original basin with poor inlet hydraulics, (b) basin with improved inlet and outlet hydraulics, and (c) basin with insertion of baffles to increase aspect ratio.

short circuiting can occur. The solution to improving process performance is to distribute the flow uniformly at the inlet and outlet, such as with diffuser baffles, as shown on Fig. 6-22b. For nonsedimentation processes, reactor performance can be improved by installing baffles in the basin so that the flow serpentine through the basin, as shown on Fig. 6-22c. Increasing velocity by inserting baffles that are shown on Fig. 6-22c is not recommended for sedimentation processes, and is discussed in Chap. 10, because sedimentation processes need quiescent conditions. Tracer studies and nonideal flow models can be used to evaluate such improvements. Baffle installation as shown on Fig. 6-22c increases the reactor length-to-depth or length-to-width ratio and the impact of the aspect ratio can then be evaluated.

Turning vanes, hammer heads, filets, and submerged baffles after each turn can be used to minimize short circuiting and improve reactor performance. These features and other techniques are discussed in Chap. 13 because of the importance of minimizing dispersion in disinfection contactors. Chapter 13 also discusses approaches to design to achieve a specific level of dispersion.

## 6-8 Modeling Reactions in Nonideal Reactors

The modeling of chemical reactions occurring in ideal reactors was introduced in Secs. 6-4 and 6-5. However, the nonideal nature of the hydraulics of real reactors, as described in Secs. 6-6 and 6-7, affects the actual performance. Therefore, it is necessary to describe the performance of reactors in terms of the nonideal nature of reactor hydraulics. When a tracer curve is not available, the DFM and TIS model, introduced in Sec. 6-7, may be used with appropriate kinetic expressions to model reactor performance, as described below.

### Dispersed-Flow Model Applied to a Reactive System

The dispersed-flow model, presented in Sec. 6-7, can be used with appropriate reaction kinetics to predict reactor performance. Steady state can only exist for a constant influent concentration, and at steady state, Eq. 6-89 becomes

$$\left(\frac{1}{Pe}\right) \frac{d^2 C}{d\bar{z}^2} - \frac{dC}{d\bar{z}} - k\tau C^n = 0 \quad (6-116)$$

where  $Pe$  = Peclet number, dimensionless

$C$  = effluent concentration, mg/L

$\bar{z}$  = dimensionless length =  $z/L$ , dimensionless

$L$  = length of reactor, m

$k$  = rate constant,  $(\text{mg/L})^{-n+1}/\text{s}$

$\tau$  = hydraulic detention time, s

$n$  = reaction order

If the dimensionless normalized concentration  $\bar{C}$  is introduced into Eq. 6-116, the following expression is obtained:

$$\left(\frac{1}{\text{Pe}}\right) \frac{d^2 \bar{C}}{d\bar{z}^2} - \frac{d\bar{C}}{d\bar{z}} + k\tau C_0^{n-1} \bar{C}^n = 0 \quad (6-117)$$

where  $\bar{C}$  = normalized concentration =  $C/C_0$ , dimensionless  
 $C_0$  = initial concentration, mg/L

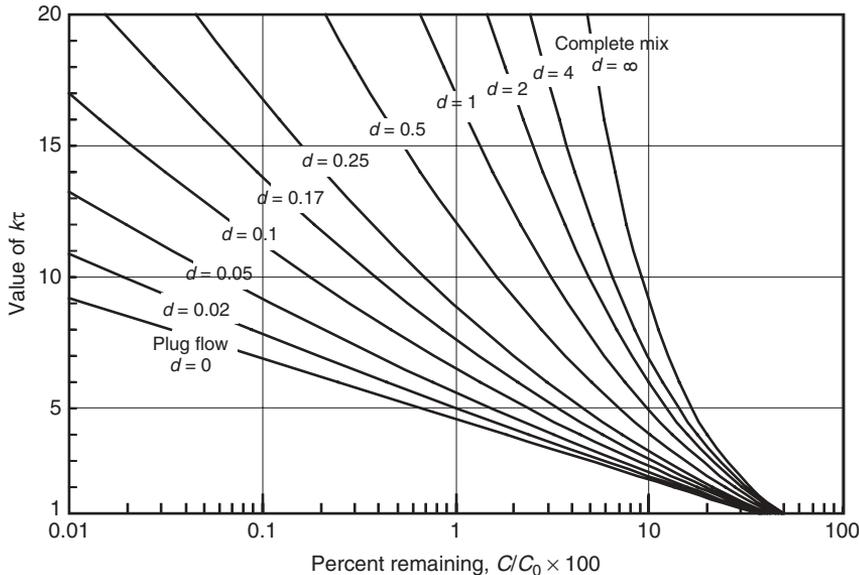

In Eq. 6-117, the effluent concentration is governed by three dimensionless groups: the Damköhler number ( $k\tau C_0^{n-1}$ ), the Peclet number (Pe), and the reaction order ( $n$ ).

Equation 6-117 has been solved analytically by Danckwerts (1953) and Wehner and Wilhelm (1958) for a first-order reaction. For reactors that are either open or closed, the solution is

$$\frac{C}{C_0} = \frac{4a \exp(\text{Pe}/2)}{[(1+a)^2 \exp(a \text{Pe}/2)] - [(1-a)^2 \exp(-a \text{Pe}/2)]} \quad (6-118)$$

where  $a = \sqrt{1 + 4k\tau(1/\text{Pe})}$

A generalized plot of Eq. 6-118 is presented on Fig. 6-23 for values of the Damköhler number ( $k\tau$ ) and dispersion number of interest in water treatment. The design engineer can control the product  $k\tau$  by adjusting the design hydraulic detention time  $\tau$ . The Peclet number can also be controlled to some extent by the details of the design of the reactor itself (e.g., baffling, aspect ratio). For example, if the value of  $k\tau$  is equal to 4, then the best performance that could be achieved with a PFR would be

**Figure 6-23**  
 Reactor performance as function of Damköhler number and dispersion number (inverse of Peclet number) for first-order reaction.

### Example 6-7 DFM calculation for first-order reaction

Using the DFM for a closed reactor and exit age distribution shown in Example 6-5, compare the reactor removal efficiency for a PFR and a CMFR. Use the following values for the calculations:

$$C_0 = 200 \text{ mg/L} \quad k = 0.0746 \text{ min}^{-1} \quad -r = kC$$

$$\bar{t} = 76.6 \text{ min (calculated in Example 6-4)}$$

#### Solution

1. Compute the reactor removal efficiency. For a first-order reaction, the Damköhler number is

$$k\tau \simeq k\bar{t} = (0.0746)(76.6) = 5.72$$

Use Eq. 6-118 to solve for  $C/C_0$  ( $Pe = 67$  from Example 6-5):

$$a = \sqrt{1 + 4k\tau \left(\frac{1}{Pe}\right)} = \sqrt{1 + 4(0.0746)(76.6) \left(\frac{1}{67}\right)} = 1.16$$

$$\begin{aligned} \frac{C}{C_0} &= \frac{4a \exp(Pe/2)}{[(1+a)^2 \exp(a Pe/2)] - [(1-a)^2 \exp(-a Pe/2)]} \\ &= \frac{4(1.16) \exp(67/2)}{[(1+1.16)^2 \exp(1.16 \times 67/2)] - [(1-1.16)^2 \exp(-1.16 \times 67/2)]} \\ &= 0.0050 \end{aligned}$$

$$C = 1.0 \text{ mg/L}$$

Alternatively,  $C/C_0$  may be estimated using Fig. 6-23; however, because the dispersion number is low, the use of Fig. 6-23 is limited.

2. Compare the reactor removal efficiency with a PFR and a CMFR.
  - a. The effluent concentration for a PFR with a mean detention time equal to the hydraulic detention time is determined using Eq. 6-65:

$$\frac{C}{C_0} = e^{-k\bar{t}} = e^{-(0.0746)(76.6)} = 0.00330 \quad \text{or} \quad C = 0.66 \text{ mg/L}$$

The ratio  $C/C_0$  may also be determined using Fig. 6-23;  $C/C_0 \simeq 0.0035$  for a PFR when  $d$  approaches zero ( $Pe = \infty$ ).

- b. The effluent concentration for a CMFR with a mean detention time equal to the hydraulic detention time is determined by

rearranging Eq. 6-37:

$$\frac{C}{C_0} = \frac{1}{1 + k\bar{t}} = 0.149 \quad \text{or} \quad C = 29.8 \text{ mg/L}$$

Here,  $C/C_0$  may also be determined using Fig. 6-23;  $C/C_0 \simeq 0.14$  for a CMFR when  $d$  approaches infinity ( $Pe = 0$ ).

### Comment

In this example, a  $Pe$  value of 67 (which corresponds to 33 reactors in series in the TIS model) yields an effluent concentration that is double that of an ideal PFR. For disinfection where reductions of 99.99 percent or greater may be required, reactors with very high  $Pe$  or low dispersion numbers must be used (see Chap. 13).

98 percent (2 percent remaining), and if the reactor Peclet number was equal to 2 (dispersion number equals 0.5), the best performance that could be achieved is 90 percent (10 percent remaining). Also, as shown on Fig. 6-23, when removal requirements are modest (less than 50 percent), the Peclet number for the reactor does not make a great deal of difference. On the other hand, when removal requirements are more stringent, maintaining a high  $Pe$  (low dispersion) is a critical design requirement.

For second-order reactions, Eq. 6-115 can only be solved numerically. The corresponding results for the DFM for a second-order reaction are displayed on Fig. 6-24.

The reactor performance for the TIS model can be estimated from mass balances for a number of tanks in series. For a first-order reaction, the following expression is obtained:

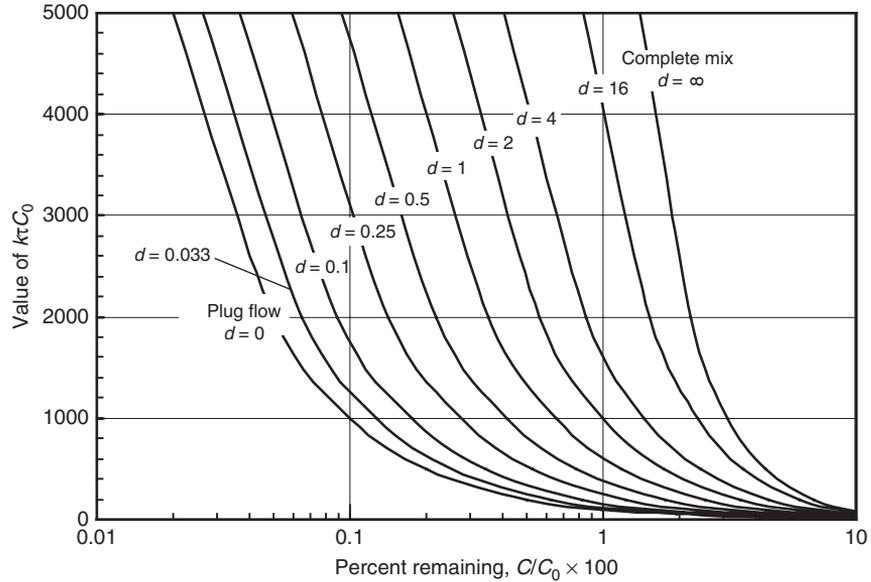

$$\frac{C}{C_0} = \frac{1}{(1 + k\tau/n)^n} \quad (6-119)$$

For a second-order reaction, the following equation can be used for  $n$  tanks by calculating the effluent concentration from tank  $i$  from the previous tank:

$$\frac{C_i}{C_{i-1}} = \frac{-1 + \sqrt{1 + 4k\tau C_{i-1}/n}}{2k\tau C_{i-1}/n} \quad (6-120)$$

where  $i$  = intermediate tank in series of  $n$  tanks  
 $C_i$  = concentration exiting tank  $i$ , mg/L  
 $C_{i-1}$  = initial concentration entering tank  $i$ , mg/L

### Tanks-in-Series Model Applied to a Reactive System

**Figure 6-24**  
Reactor performance as function of Damköhler number and dispersion number (inverse of Peclet number) for second-order reaction. (Adapted from Levenspiel and Bischoff, 1959.)

### Example 6-8 Tank-in-series model calculation

Calculate the performance for the reactor evaluated in Example 6-7 for a first-order reaction using the TIS model and compare to the results from the DFM. Estimate the reactor performance for a PFR and a CMFR with the identical hydraulic detention times.

#### Solution

1. Determine the reactor removal efficiency for a TIS model with  $n = 33$  tanks (see Example 6-5) using Eq. 6-119 for the TIS model:

$$\frac{C}{C_0} = \frac{1}{(1 + k\tau/n)^n} = \frac{1}{(1 + 5.72/33)^{33}} = 0.00512$$

$$C = 1.02 \text{ mg/L}$$

2. The results from TIS and DFM analysis and the estimated performance of a reactor for a PFR and a CMFR with the identical hydraulic detention time are compared in the following table:

	TIS	DFM	PFR	CMFR
C, mg/L	1.02	1.00	0.66	29.8

**Comment**

As summarized in the table above, the reactor performance predicted using the TIS and DFM models is similar. In addition, the performance is closer to that of a PFR than to a CMFR because the  $Pe$  and number of tanks in series is large.

## 6-9 Using Tracer Curves to Model Reactions in Reactors

---

The DFM and TIS models presented in the previous sections are useful for generating RTD curves when actual tracer response data are not available. The DFM and TIS model can also be used for modeling reactions, where it is assumed that homogeneous conditions exist on the molecular scale (microscale). However, when a tracer curve obtained from a reactor study or CFD calculation is available, the segregated-flow model (SFM) may be used to model reactions. The SFM, limitations of the SFM, and comparison of the SFM and various nonideal flow models are presented in this section.

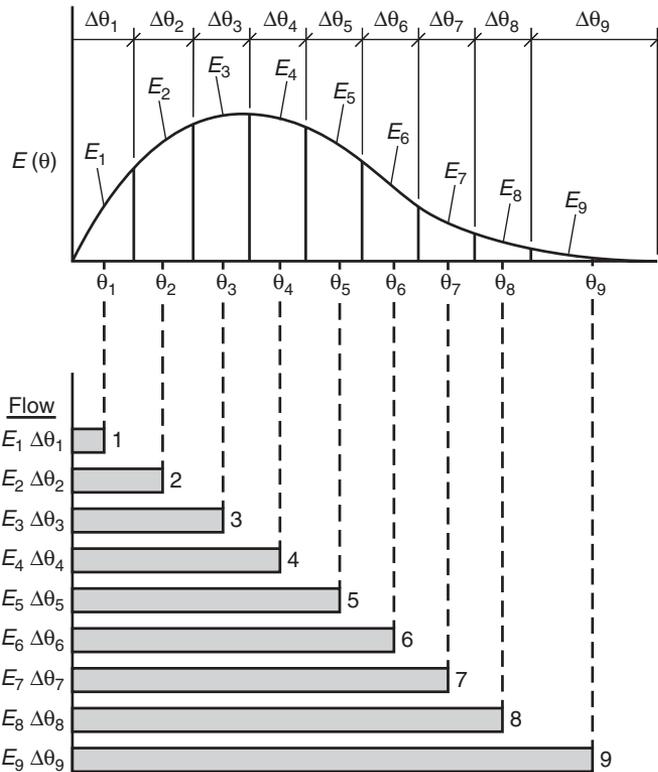

The assumption in the SFM is that all fluid elements are segregated, meaning they do not mix or interact with each other. Consequently, the performance of a real reactor can be determined by estimating the amount of reaction that would take place for each fluid element and then mixing the elements at the end of the reactor. For an exit age distribution as shown on Fig. 6-25, the SFM is obtained by approximating the real reactor as numerous batch or plug flow reactors that have different residence times and exit age characteristics. The normalized curve for the pulse tracer study,  $E(\theta)$ , is used to determine the amount of fluid that has a particular age.

For development of the SFM, performance for a real reactor is estimated in terms of  $C/C_0$ . The contribution for fluid element 9 (see Fig. 6-25) is given by the expression

$$\left( \begin{array}{l} C/C_0 \text{ from CMBR or PFR} \\ \text{with detention time } \theta_9 \end{array} \right) \times \left( \begin{array}{l} \text{fraction of exit stream} \\ \text{that has age } \theta_9 \end{array} \right) = R(\theta_9) E_9 \Delta\theta_9 \quad (6-121)$$

where  $\theta_9$  = exit age for fluid element 9  
 $R(\theta_9)$  = dimensionless effluent concentration for fluid element 9, which equals effluent concentration divided by influent concentration leaving ideal PFR or CMBR with hydraulic detention time that corresponds to  $\theta_9$   
 $E_9$  = exit age distribution for fluid element 9  
 $E_9 \Delta\theta_9$  = fraction of exit stream that has age  $\theta_9$

### Segregated-Flow Model

**Figure 6-25**

Definition sketch for SFM. Flow at each average  $\theta$  corresponds to flow in ideal plug flow or batch reactor.

To determine the reactor performance, sum the contribution of each PFR as follows:

$$\frac{\bar{C}}{C_0} = R(\theta_1)E_1 \Delta\theta_1 + R(\theta_2)E_2 \Delta\theta_2 + \cdots + R(\theta_9)E_9 \Delta\theta_9 \quad (6-122)$$

where  $\bar{C}$  = average effluent concentration, mg/L

In theory, an infinite number of small PFRs is needed, and taking the limit  $N \rightarrow \infty$ , the following expression is obtained:

$$\frac{\bar{C}}{C_0} = \sum_{i=1}^N R(\theta_i)E(\theta_i) \Delta\theta_i = \int_0^{\infty} R(\theta)E(\theta) d\theta \quad (6-123)$$

The parameter  $R(\theta)$  can be obtained by substitution of  $\theta\bar{t}$  for  $\tau$  in the following general expression for any order kinetics. The expressions given

previously in Table 6-3 can also be used.

$$\tau = - \int_{C_0}^C \frac{dC}{-r} \quad (6-124)$$

For example, the following expressions are obtained for first- and second-order reactions:

$$R(\theta) = \begin{cases} e^{-k\theta\bar{t}} & \text{(first order)} \\ \frac{1}{1 + k\bar{t}C_0\theta} & \text{(second order)} \end{cases} \quad (6-125)$$

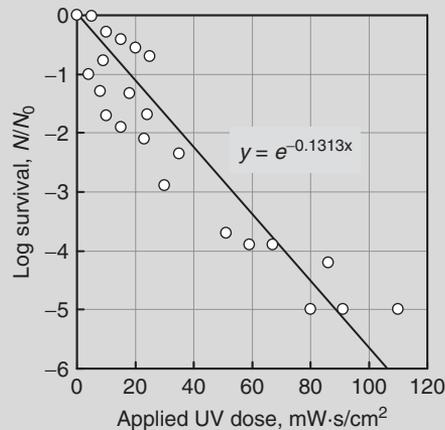

The SFM can be used when  $E(\theta)$  and  $R(\theta)$  are known. For example, SFM applies when there is batch rate data because  $R(\theta)$  is identical to the result that would be expected from a batch reactor. To convert  $C/C_0$  versus time to  $C/C_0$  versus  $\theta$ , divide the elapsed time in the batch reactor study by  $\bar{t}$ . The SFM can also be used for sedimentation basins with  $R(\theta)$  determined from settling column tests, where the settling column has a depth equal to the settling zone in the sedimentation basin.

### Example 6-9 Evaluation of UV disinfection process using SFM

A UV disinfection process takes place in a pipe that contains UV lamps. The pipe is 1 m long with a diameter of 0.3 m. The process flow rate is 1000 m<sup>3</sup>/d and the average UV intensity in the reactor is 15 mW/cm<sup>2</sup>. The results of a tracer study conducted on the UV disinfection reactor are shown in the following table:

Time, s	Normalized Time, $\theta$	$E(\theta)$	Time, s	Normalized Time, $\theta$	$E(\theta)$
0.0	0.000	0.000	9.0	1.400	0.466
0.6	0.100	0.000	9.7	1.500	0.309
1.3	0.200	0.001	10.3	1.600	0.196
1.9	0.300	0.017	11.0	1.700	0.120
2.6	0.400	0.101	11.6	1.800	0.071
3.2	0.500	0.314	12.3	1.900	0.040
3.9	0.600	0.647	12.9	2.000	0.022
4.5	0.700	1.006	13.6	2.100	0.012
5.2	0.800	1.273	14.2	2.200	0.006
5.8	0.900	1.376	14.8	2.300	0.003
6.5	1.000	1.313	15.5	2.400	0.002
7.1	1.100	1.134	16.1	2.500	0.001
7.7	1.200	0.901	16.8	2.600	0.000
8.4	1.300	0.668			

The UV dose–response curve for a certain microorganism has been determined and the results are shown in the following plot:

The average concentration of the microorganism in the influent to the UV reactor,  $N_0$ , is  $0.1 \text{ L}^{-1}$ . Estimate the concentration of the microorganism in the effluent from the UV disinfection process using the SFM.

### Solution

1. Set up a table to compute the number of organisms surviving the disinfection process.
  - a. Compute the unit exit age distribution  $E(\theta) \Delta\theta$  with a  $\Delta\theta$  value of 0.1. For the time step  $t = 2.6$ ,

$$E(\theta) \Delta\theta = (0.101)(0.1) = 0.0101$$

- b. Estimate the applied dose. The applied dose is determined by multiplying the average UV intensity in the reactor by the corresponding time step. For the time step  $t = 2.6$ ,

$$\text{Applied dose} = (15 \text{ mW/cm}^2)(2.6 \text{ s}) = 39.0 \text{ mW} \cdot \text{s/cm}^2$$

- c. Estimate the fraction of organisms surviving at the applied dose,  $R(\theta)$ . The fraction of organisms surviving is a function of the applied dose, and the relationship is given in the problem statement. Use the curve fit to determine the survival. For the time step  $t = 2.6$ ,

$$\text{Estimated survival, } N/N_0 = e^{(-0.1313 \times 39.0 \text{ mW} \cdot \text{s/cm}^2)} = 0.0060$$

- d. Compute the number of organisms surviving. The number of organisms surviving may be determined by multiplying the fractional survival  $N/N_0$  at each time step by the average influent concentration and the unit exit age distribution. For the time step  $t = 2.6$ ,

$$\begin{aligned}\text{Microorganisms surviving} &= (0.0101)(0.0060)(0.1 \text{ L}^{-1}) \\ &= 6.03 \times 10^{-6} \text{ L}^{-1}\end{aligned}$$

- e. Summarize the computations in a table.

Time, s	Normalized Time, $\theta$	$E(\theta)$	$E(\theta) \Delta\theta$	Applied Dose, $\text{mW} \cdot \text{s}/\text{cm}^2$	Estimated Survival, $R(\theta), N/N_0$	Effluent Microorganism Concentration, $\text{L}^{-1}$

16.1	2.500	0.001	$8.548 \times 10^{-5}$	242.0	0.0000	0.000000
16.8	2.600	0.000	$4.212 \times 10^{-5}$	251.7	0.0000	0.000000
			1			0.000214

- Estimate the concentration of microorganisms in the process effluent. Summing the values of effluent microorganism concentration for all time steps results in a value of  $0.000214 \text{ L}^{-1}$ . For a flow rate of  $1000 \text{ m}^3/\text{d}$ , the total number of organisms that can pass through the reactor without being inactivated in one day is

$$\begin{aligned}\text{Microorganism concentration 1 d flow} &= (0.000214 \text{ L}^{-1})(10^6 \text{ L/d}) \\ &= 214 \text{ d}^{-1}\end{aligned}$$

### Comment

Because of the nonideal hydraulics in the reactor, it is possible for some of the water to pass through before the detention time required for adequate treatment. Because some microorganisms can cause illness even at low dosages, reactor performance is critical to ensure safe water.

### Limitations of SFM Application

The SFM is valid for any shape of reactor and has the following limitations:

- The SFM can be used to obtain an exact solution for a first-order reaction.
- For a zero-order reaction, the effluent concentration is identical for both PFRs and CMFRs. Mixing has no impact on the reactor performance and maximum performance can be obtained as long as  $\bar{t} = \tau$ .
- For reaction orders greater than 1.0, the effluent concentration calculated using the SFM is less than the actual effluent concentration and represents the lower bound of the effluent concentration (the best possible performance).
- For reaction orders less than 1.0, the effluent concentration calculated by the SFM is greater than the actual effluent concentration and represents the upper bound of the effluent concentration (the worst possible performance).

A comparison of the differences between the actual and calculated effluent concentration for a CMFR when using the SFM for reaction orders greater than 1 and less than 1 are presented in the following discussion.

#### REACTION ORDERS GREATER THAN 1

For a second-order reaction in a CMFR, the effluent concentration from a CMFR is given by the expression

$$\frac{C}{C_0} = \frac{-1 + \sqrt{1 + 4k\tau C_0}}{2k\tau C_0} \quad (6-127)$$

where  $k$  = reaction rate, L/mg · s  
 $\tau$  = hydraulic detention time, s

For  $k\tau C_0 = 1$ , the resulting value of  $C/C_0$  is 0.618, as computed using Eq. 6-125. The terms that appear in the SFM approximation of a CMFR are

$$R(\theta) = \frac{1}{1 + k\tau C_0 \theta} \quad (6-128)$$

$$E(\theta) = e^{-\theta} \quad (6-129)$$

The SFM approximation for a CMFR with  $k\tau C_0 = 1.0$  results in the expression

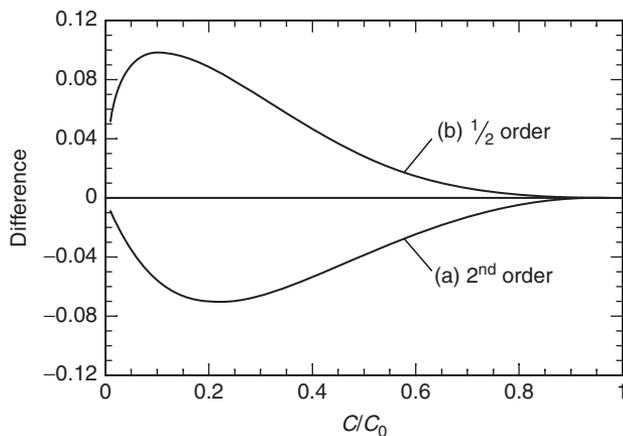

$$\frac{\bar{C}}{C_0} = \int_0^\infty \left[ \left( \frac{1}{1 + k\tau C_0 \theta} \right) e^{-\theta} \right] d\theta = 0.596 \quad (6-130)$$

Thus, for a second-order reaction, the SFM method predicts a lower concentration than a mass balance on a CMFR. The difference between Eqs. 6-130 and 6-127 is shown as line (a) on Fig. 6-26. As shown, the concentration predicted by the SFM is consistently lower than the result for a CMFR. The reason the SFM predicts a lower concentration for a second-order reaction is because less backmixing occurs as the performance approaches ideal plug flow. Under ideal conditions, the results from the SFM analysis will be identical to the analytical solution for a PFR.

#### ORDERS LESS THAN 1

For reaction orders less than 1.0, such as  $n = 0.5$ , the following relationship for  $R(\theta)$  is obtained from a PFR mass balance:

$$R(\theta) = \left( 1 - \frac{k\tau\theta}{2C_0^{0.5}} \right)^2 \quad (6-131)$$

**Figure 6-26**

Difference between the actual effluent concentration for a CMFR and the SFM for: (a) a second-order reaction rate and (b) a half-order reaction rate.

The SFM approximation to a CMFR is given by the expression

$$\frac{\bar{C}}{C_0} = \int_0^{\infty} \left[ \left( 1 - \frac{k\tau\theta}{2C_0^{0.5}} \right)^2 e^{-\theta} \right] d\theta \quad (6-132)$$

However, a reasonable result of Eq. 6-130 cannot be obtained using the range of integration from zero to infinity because the value of  $k\tau\theta/(2C_0^{0.5})$  needs to be between zero and unity (otherwise the effluent concentration is negative). Therefore, the SFM approximation for a CMFR with a reaction order of 0.5 is modified to

$$\frac{\bar{C}}{C_0} = \int_0^{(1/L)} [(1 - L\theta)^2 e^{-\theta}] d\theta \quad (6-133)$$

where  $L = k\tau/(2C_0^{0.5})$

For  $L = 0.5$  the resulting value of  $\bar{C}/C_0$  is 0.432, as computed using Eq. 6-133.

For a CMFR using a conventional mass balance approach, the following expressions are obtained:

$$\tau = \frac{V}{Q} = \frac{C_0 - C}{kC^{0.5}} \quad (6-134)$$

$$\frac{C}{C_0} = \frac{1}{2} \left[ 2 + \frac{\tau^2 k^2}{C_0} - \sqrt{\left( 2 + \frac{\tau^2 k^2}{C_0} \right)^2 - 4} \right] \quad (6-135)$$

For  $k\tau/2C_0^{0.5} = 0.5$  (equal to  $\tau^2 k^2/C_0 = 1$ ), the resulting value of  $C/C_0$  is 0.382, as computed using Eq. 6-135.

Thus, for a half-order reaction, the SFM method predicts a higher concentration than a mass balance on a CMFR. The difference between Eq. 6-133 and 6-135 is shown as line (b) on Fig 6-26. As shown on Fig. 6-26, the SFM consistently predicts a larger concentration than a mass balance on a CMFR. This difference is the maximum difference that can be expected using the SFM for a half-order reaction.

As shown in the analysis presented above, the differences for 0.5 and second orders represent the maximum difference between the SFM and a given reactor's actual performance, respectively. The SFM predicts an exact answer for any reaction order when used to simulate a PFR [ $E(\theta) = \delta(1)$ ]. Accordingly, the SFM would predict reactor performance that is closer to the observed reactor performance as the reactor backmixing decreased to that of a PFR (no backmixing).

## 6-10 Mixing Theory and Practice

Mixing is a central part of water treatment. In some unit operations, mixing has a profound impact on the course of the reactions of interest. In other unit operations, understanding mixing is an important adjunct to

process control. In still others, mixing energy actually contributes to the rate of the reaction (e.g., flocculation). In the early days, the design and implementation of mixing facilities was a haphazard processes. Even today, there is a great deal of art in designing mixing facilities. Nevertheless, as discussed below, scientific tools are available that can be used to improve the design of these facilities.

Two types of mixing are applied in water treatment: (1) agitation and (2) blending. Each is considered separately in the following discussion.

## Types of Mixing

### AGITATION (FLUID)

*Agitation* is the term used to describe the motion induced in a fluid to promote processes such as flocculation, to maintain particles in suspension, and for mass transfer such as aeration. In flocculation, the water is agitated to bring about contact between particles, after the chemistry (coagulation) has been used to neutralize their natural repulsion to each other. To design mixing facilities for flocculation it is important to know (1) the particle size distribution of the particles to be flocculated and (2) the degree of agitation necessary to bring about particle contact. The subject of flocculation is considered in greater detail in Chap. 10. Agitation is also used to prevent particles from settling in equalization and related facilities (also covered in Chap. 10). Mass transfer reactions are enhanced by agitation such as occurs as water falls over a cascade of stairs or when air is bubbled through water for the addition of oxygen or to remove supersaturated gases from solution. Mass transfer reactions are discussed further in Chap. 7.

### BLENDING

The process of combining two or more liquid streams to achieve a specified level of uniformity is known as *blending*. To design mixing facilities, for the purposes of blending, it is important to (1) understand how to estimate the thoroughness of the blending required so that process sampling, analysis, and control can be accomplished (e.g., chlorination, pH control, or fluoridation) and (2) identify those situations where the speed and thoroughness of blending both have important impacts on process efficiency and effectiveness (e.g., coagulation with  $\text{Al}^{3+}$  or  $\text{Fe}^{3+}$  or disinfection of secondary effluent with chlorine). Significant differences in approach result from these different design objectives.

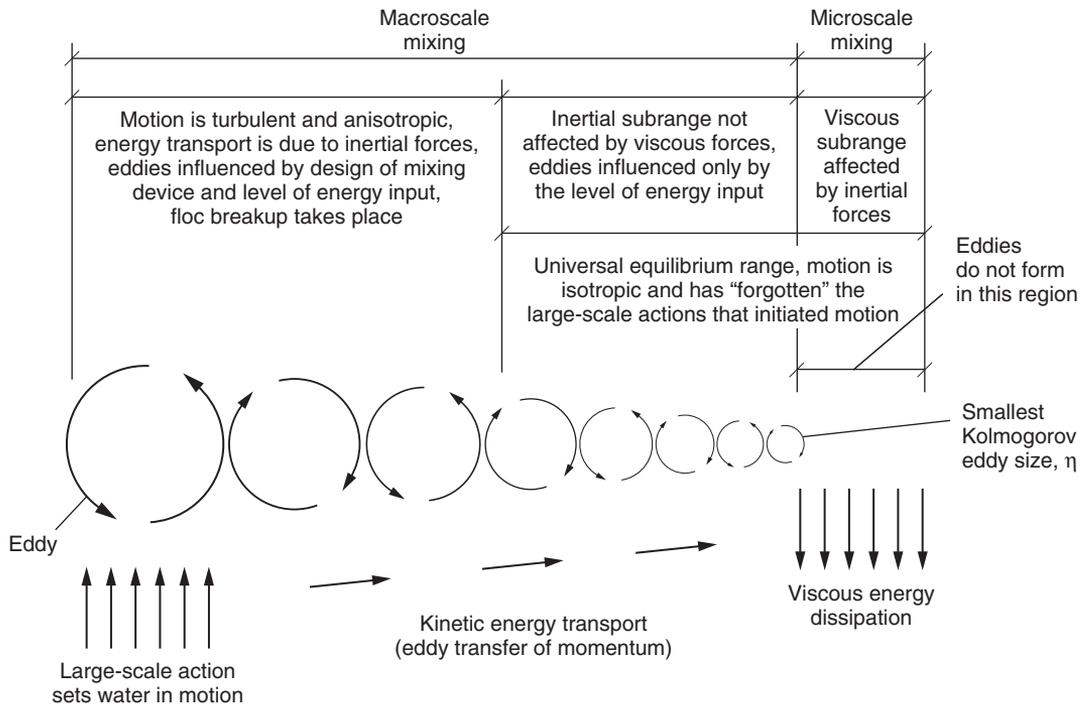

Because of their large size, virtually all water treatment processes take place in turbulent flow. As a result, to better understand mixing in water treatment, it is helpful to gain a conceptual understanding of turbulence. Thus, before discussing mixing for agitation and blending, the nature of turbulence is explored briefly below.

## Some Fundamentals of Mixing

**INTRODUCTION TO TURBULENCE**

It is helpful to think of turbulent flow as consisting of a cascade of eddies—more specifically a cascade of energy from large eddies to small eddies. Kinetic energy imparted to the water through physical action (a pump, a mixer, falling over a weir, etc.) imparts momentum to large segments of water, creating the large eddies moving in a direction consistent with the motive force; however, the structure of water is such that, as these large eddies move around, their energy is immediately transferred to smaller eddies. Once the eddies become small enough, inertial forces are overcome by the viscous nature of water and they can get no smaller. This cascade of eddies and the significance of the different zones of turbulent flow are illustrated on Fig. 6-27.

The immediate turbulence resulting from the motion-inducing device is anisotropic (energy of motion is in one direction or another), but once the energy from this source has been relayed down to smaller eddies, the turbulence becomes isotropic (energy of motion is equal in all directions). The velocity gradients necessary for flocculation (see Sec. 9-6) are present under both anisotropic and isotropic turbulence, but the large-scale shear forces responsible for floc breakup are mostly found in anisotropic flow.

**Figure 6-27**

Overview of turbulence as it relates to mixing. (Adapted from Stanley and Smith, 1995.)

The design of the mixing equipment for flocculation involves a trade-off between flocculation and floc breakup.

#### MIXING AND SCALE OF TURBULENCE

The largest eddies start out approximately one-half to one-third the dimension of the mixing device, and the size of the smallest eddies is determined by the boundary between turbulent and viscous flow. The size of the smallest eddy is considered the dividing line between the microscale and macroscale. In the macroscale, mass transfer takes place both by turbulent diffusion and molecular diffusion, but turbulent diffusion is dominant. In the microscale, mass transfer takes place only by molecular diffusion. As more energy is input to the system, the dividing line between the microscale and the macroscale becomes increasingly smaller; that is, the smallest eddies get even smaller. A Russian mathematician named Kolmogorov recognized this dividing line and suggested that the diameter of the smallest eddy,  $\eta$ , could be estimated from the amount of energy being dissipated in the system (Kolmogorov 1941a,b,c):

$$\eta = \left( \frac{\nu^3}{\varepsilon} \right)^{1/4} \quad (6-136)$$

where  $\eta$  = diameter of smallest eddy, m  
 $\nu$  = kinematic viscosity,  $\text{m}^2/\text{s}$   
 $\varepsilon$  = energy dissipation rate at point of interest,  $\text{J}/\text{kg} \cdot \text{s}$

The energy dissipation rate in a mixing vessel,  $\varepsilon$ , is not uniform throughout the vessel, but because energy must be dissipated at the same rate at which it is input to the system, the overall average rate of energy dissipation,  $\bar{\varepsilon}$ , is equal to the power input:

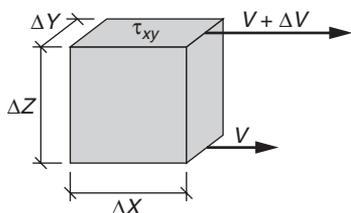

$$\bar{\varepsilon} = \frac{P}{M} \quad (6-137)$$

where  $\bar{\varepsilon}$  = average energy dissipation per unit mass for vessel,  $\text{J}/\text{kg} \cdot \text{s}$   
 $P$  = power of mixing input to entire mixing vessel,  $\text{J}/\text{s}$   
 $M$  = mass of water in mixing vessel,  $\text{kg}$

#### CAMP-STEIN ROOT-MEAN-SQUARE VELOCITY GRADIENT

About the same time as Kolmogorov did his work, Camp and Stein (1943) proposed a similar parameter, the root-mean-square (RMS) velocity gradient  $\bar{G}$ . Camp and Stein proposed that  $\bar{G}$  could be used as a design parameter for flocculation facilities and that the speed of flocculation is directly proportional to the velocity gradient. In subsequent studies it was demonstrated that the direct proportionality that Camp and Stein hypothesized occurred with both metal ion coagulants (Harris et al., 1966) and polymers (Birkner and Morgan, 1968) at both bench and pilot scale (Harris et al., 1966).

Camp and Stein (1943) developed a simple equation for  $\bar{G}$  by equating the velocity gradient to the power dissipated per unit volume ( $P/V$ ).

**Figure 6-28**  
Schematic of forces acting on fluid element in flocculator.

Consider the fluid element illustrated on Fig. 6-28 and the forces acting on it. The shear stress in the  $x$ - $y$  plane,  $\tau_{xy}$ , is due to the velocity gradient in the  $z$  direction, and the force exerted on it is given by the expression

$$\text{Force} = \tau_{xy} \Delta x \Delta y = \mu \frac{dv}{dz} \Delta x \Delta y \quad (6-138)$$

where  $\mu$  = dynamic viscosity of water,  $N \cdot s/m^2$  and  $\Delta x$ ,  $\Delta y$ ,  $\Delta z$  are fluid element dimensions on Fig. 6-28. The product of force and velocity is power, so, using the velocity increment due to the shear stress in the fluid element, the power per unit volume can be written as

$$\frac{P}{V} = \frac{\text{Force} \times \text{velocity}}{\Delta x \Delta y \Delta z} = \frac{[\mu (dv/dz) \Delta x \Delta y] [(dv/dz) \Delta z]}{\Delta x \Delta y \Delta z} = \mu \left( \frac{dv}{dz} \right)^2 \quad (6-139)$$

where  $P/V$  = power dissipated in selected fluid element,  $J/m^3 \cdot s$

Under turbulent-flow conditions, the velocity gradient is not well defined and varies both in time and space throughout the flocculation vessel. Camp and Stein proposed that the velocity gradient, averaged over the volume of the entire vessel, could be used as a design parameter for flocculation. They named the parameter the RMS velocity gradient. Rearranging Eq. 6-139 and defining the RMS velocity gradient  $dv/dz$  as  $\bar{G}$ ,

$$\bar{G} = \sqrt{\frac{P}{\mu V}} \quad (6-140)$$

where  $\bar{G}$  = global RMS velocity gradient (energy input rate),  $s^{-1}$

$P$  = power of mixing input to vessel,  $J/s$  (same as  $P$  in Eq. 6-137)

$V$  = volume of mixing vessel,  $m^3$

The Camp–Stein RMS velocity gradient  $\bar{G}$  has since become a widely adopted standard used by engineers for assessing energy input in all kinds of mixing processes, particularly flocculation, and  $\bar{G}$  is the parameter that will be used to characterize mixing energy throughout this book.

### Example 6-10 Determination of relationship between smallest eddy size $\eta$ and $\bar{G}$ for water at $10^\circ C$

Find the relationship between  $\eta$  and  $\bar{G}$  and then produce a semilog plot of this relationship for water at  $10^\circ C$  and for  $\bar{G}$  values between 1 and  $1000 s^{-1}$ . At  $10^\circ C$  the kinematic viscosity of water is  $1.31 \times 10^{-6} m^2/s$ . Assume that all the energy is dissipated uniformly throughout the vessel (e.g.,  $\epsilon \cong \bar{\epsilon}$ ).

**Solution**

1. Develop a relationship between  $\eta$  and  $\bar{G}$ .
- a. Solving Eq. 6-137 and Eq. 6-140 for  $P$  and setting them equal to each other yields

$$M\bar{\varepsilon} = \bar{G}^2 \mu V$$

- b. Rearranging gives

$$\bar{\varepsilon} = v\bar{G}^2$$

where

$$v = \frac{\mu}{\rho} = \frac{\mu V}{M}$$

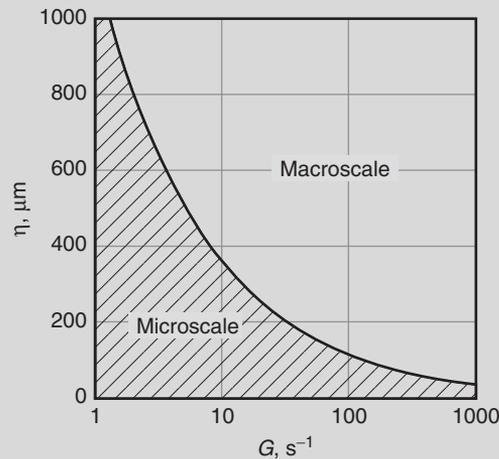

- c. Rearrange Eq. 6-136 to yield

$$\varepsilon = \frac{v^3}{\eta^4}$$

- d. Assuming  $\varepsilon \cong \bar{\varepsilon}$ , equating the equations from steps b and c yields

$$\begin{aligned} \eta &= \left( \frac{v}{\bar{G}} \right)^{1/2} \\ &= \left[ \frac{(1.31 \times 10^{-6} \text{ m}^2/\text{s})}{\bar{G}, \text{ s}^{-1}} \right]^{1/2} \end{aligned}$$

2. Substitute values for  $\bar{G}$  between 1 and 1000  $\text{s}^{-1}$  in the expression developed above and plot the results. The required plot is given below.

### Uniformity and Time Scales in Mixing

One of the principal objectives of mixing, as noted previously, is the blending of two flows, usually the blending of a small flow of chemical solution with the much larger flow of the water to be treated. The greater the difference in the flow of the water to be treated and the flow of the chemical being blended, the more difficult the blending is to accomplish. There are two ways that the degree of blending can be assessed: (1) the uniformity of the concentration of components in solution with time (both in time and in space) and (2) the time it takes to accomplish a specified level of uniformity. The uniformity of blending with time and/or space is generally addressed by specifying an objective for the variation of the concentration of the chemical to be blended.

In water treatment there are two principal circumstances when blending is important: (1) blending must be achieved before samples can be taken for the analysis that confirms that the quality of the blend meets the goals (e.g., before chlorine residual analysis) and (2) rapid blending must be achieved with water treatment chemicals that involve irreversible competitive consecutive reactions (e.g., coagulation with alum or ferric chloride or the breakpoint reactions between chlorine and ammonia described in Chap. 13).

#### UNIFORMITY OF BLENDING

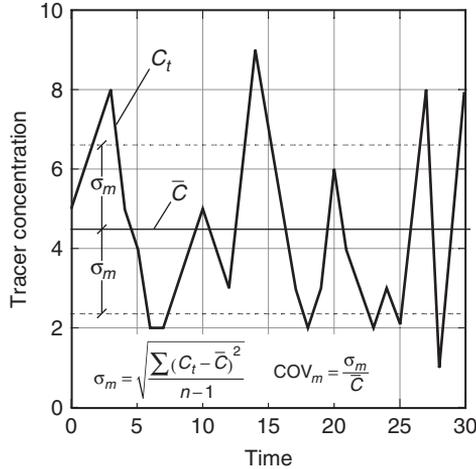

When a chemical is to be added to a water stream and blending is required, there are two tasks that must be addressed: (a) specifying the uniformity of the blend produced and (b) specifying the magnitude of the task that the mixer must accomplish. Assessing the uniformity of the blend can be determined with respect to variations in time and/or space, but it is most often determined in the context of variation in time. Important variations in the concentration with time are identified on Fig. 6-29. The standard deviation is

$$\sigma = \sqrt{\frac{\sum_{t=1}^n (C_t - \bar{C})^2}{n - 1}} \quad (6-141)$$

where  $C_t$  = instantaneous concentration at time  $t$ , mg/L  
 $\bar{C}$  = average concentration mg/L, and  
 $\sigma$  = standard deviation of the concentration in the stream  
 $n$  = number of samples of concentration

When the uniformity of the blend is specified, the standard deviation is usually normalized to the average concentration. This normalized standard deviation is usually identified as the coefficient of variation (COV):

$$\text{COV} = \left( \frac{\sigma}{\bar{C}} \right) \times 100\% \quad (6-142)$$

**Figure 6-29**  
Illustration of typical concentration variation immediately downstream of tracer addition point.

where COV = coefficient of variation with time

$\sigma$  = standard deviation of concentration, mg/L

$\bar{C}$  = average concentration over time, mg/L

An analogous exercise can be used to estimate the quality of a blend in space, for example, samples taken across the cross section of flow a specified distance downstream of the point of chemical addition.

The magnitude of the blending that must be accomplished is determined by the COV that is sought in the design and the segregation of the unmixed streams. Danckwerts (1952) defined the term *intensity of segregation*  $I_s$  as given by Eq. 6-143 to characterize the state of blending:

$$I_s = \left( \frac{\sigma_m}{\sigma_u} \right)^2 \quad (6-143)$$

where  $I_s$  = Danckwerts' intensity of segregation

$\sigma_m$  = standard deviation of concentration in blended stream

$\sigma_u$  = standard deviation between two streams in unblended condition

Danckwerts' intensity of segregation  $I_s$  is a description of the degree to which the two streams have been blended. The general description of how completely the streams are blended can be put in the following way:

When  $I_s = 0$ , the two streams are blended completely.

When  $I_s = 1$ , the two streams are completely unblended.

The term  $I_s$  can also be used to specify what a mixing device must accomplish. The value of  $I_s$  for a mixer can be determined from Eq. 6-143 if  $\sigma_u$  is known and a decision is made on the  $\sigma_m$  to be specified.

The standard deviation between the two unblended streams,  $\sigma_u$ , can be estimated on the basis of their relative flow rates. When chemical A is being added to a stream of water, the volume fraction of the chemical solution being added to the original water stream can be estimated as follows:

$$\bar{X}_A = \frac{Q_A}{Q_w + Q_A} \quad (6-144)$$

By definition,

$$\bar{X}_w = 1 - \bar{X}_A \quad (6-145)$$

where  $\bar{X}_A$  = volume fraction of stream containing chemical A in unblended condition

$Q_A$  = flow rate of solution stream of chemical A, m<sup>3</sup>/s

$Q_w$  = flow rate of water stream being treated, m<sup>3</sup>/s

$\bar{X}_w$  = volume fraction of water in unblended condition

and if it is assumed that a large number of random samples are taken from the two streams, it can be shown that

$$\sigma_{u(\text{vol})} \cong \sqrt{\bar{X}_A (1 - \bar{X}_A)} \quad (6-146)$$

where  $\sigma_{u(\text{vol})}$  = standard deviation of concentrations before blending (expressed as volume fraction)

When designing systems to dose chemicals in a water treatment plant, concentration data are often more readily available than flow rate data. A mass balance can be used to relate the flows and concentrations:

$$Q_A C_A = Q_w C_{\text{dose}} \quad (6-147)$$

or

$$\frac{Q_A}{Q_w} = \frac{C_{\text{dose}}}{C_A} \quad (6-148)$$

where  $Q_A$  = flow rate of feed stream for chemical A, m<sup>3</sup>/s

$Q_w$  = flow rate of water stream being treated, m<sup>3</sup>/s

$C_A$  = concentration of chemical A in feed stream, kg/m<sup>3</sup>

$C_{\text{dose}}$  = dose of chemical A to be applied to water stream, kg/m<sup>3</sup>

The volume fraction can then be found by substituting Eq. 6-148 into Eq. 6-144:

$$\bar{X}_A = \frac{C_{\text{dose}}}{C_A + C_{\text{dose}}} \quad (6-149)$$

The application of the above equations is illustrated in Example 6-11.

#### TIME REQUIRED TO ACCOMPLISH BLENDING

The uniformity of the blend is important, but the time required to accomplish blending is equally important. There are two circumstances where the time required to meet a blending goal,  $t_b$ , is important: (1) when blending must be complete for purposes of analysis and control and (2) when blending must be completed rapidly to prevent adverse outcomes.

### Example 6-11 Estimating value of $I_s$

A water treatment plant must dose the water with 30 mg/L of alum so that the coefficient of variation of the blend is 5 percent or less ( $COV \leq 5$  percent). Estimate the  $I_s$  that characterizes the magnitude of the blending job (the mixer's specification). It may be assumed that the alum solution has a strength of 651 g/L. *Hint:* Both  $\sigma_u$  and  $\sigma_m$  must be on the same basis. Because  $\sigma_u$  is estimated as a volume fraction ( $\sigma_{u(vol)}$ ),  $\sigma_m$  must also be expressed as a volume fraction ( $\sigma_{m(vol)}$ ) for  $I_s$  to be properly determined.

#### Solution

1. Determine the volume fraction using Eq. 6-149:

$$\bar{X}_A = \frac{C_{dose}}{C_A + C_{dose}}$$

As  $C_A \gg C_{dose}$ ,

$$\bar{X}_A \cong \frac{C_{dose}}{C_A} = \frac{30 \text{ mg/L}}{651,000 \text{ mg/L}} = 4.61 \times 10^{-5}$$

2. Estimate the standard deviation of the concentration using Eq. 6-142: (Eq. 6-142 is equally valid whether concentration or volume fraction is used).

$$COV = 5\% = \frac{\sigma_{m(vol)}}{\bar{X}_A} \times 100\%$$

$$\sigma_{m(vol)} = 0.05 \times 4.61 \times 10^{-5} = 2.30 \times 10^{-6}$$

3. Determine the uniformity of the unblended streams. Substituting  $4.61 \times 10^{-5}$  into Eq. 6-146 results in the unblended uniformity on a volume fraction basis ( $\sigma_{u(vol)}$ ):

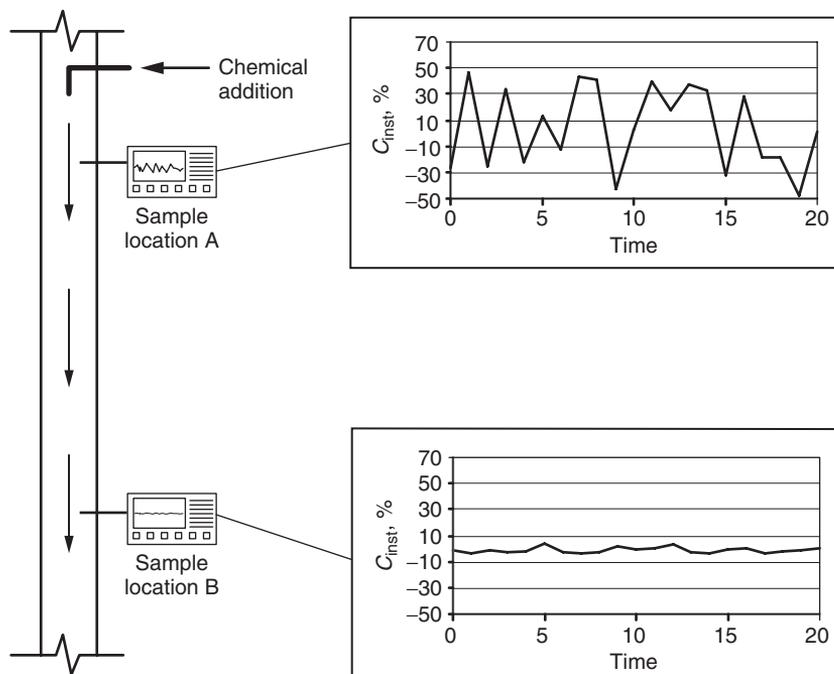

$$\sigma_{u(vol)} = \sqrt{4.61 \times 10^{-5} (1 - 4.61 \times 10^{-5})} = 0.00679$$

4. Determine the intensity of segregation using Eq. 6-143:

$$I_s = \left( \frac{2.30 \times 10^{-6}}{0.00679} \right)^2 = (3.39 \times 10^{-4})^2 = 1.15 \times 10^{-7}$$

#### *Blending time and control*

A situation where blending must be complete for purposes of analysis and control is illustrated on Fig. 6-30. As shown, a simple point discharge is introduced into a conduit, and the variation of concentration is observed

**Figure 6-30**

To achieve reliable monitoring for control, the downstream sampling point must be beyond the point where uniform blending is achieved.

at two sampling points downstream. Sampling at point A, the signal that is generated would make control very difficult. Sampling at point B solves this problem, but at the expense of time. Sampling at point B introduces another control problem, the travel time from point A to point B. When a chemical feed is simply discharged into turbulent flow in a pipe or channel, a travel distance of as much as 100 conduit diameters in length may be required before acceptable blending is achieved. When such travel distances are not acceptable, a special mixing or blending device is required. The design engineer needs to know where the blend will be sufficiently uniform and what may be done if uniformity is not achieved soon enough.

#### *Rapid blending*

When irreversible competitive consecutive reactions are involved, it is often important to accomplish blending rapidly to avoid adverse outcomes. It is also important that blending be accomplished in a manner that prevents backmixing (recirculation) so that components already formed do not gain access to the chemical being added a second time. Put another way, the two components must be rapidly blended across the flow cross section. A relatively simple model for characterizing situations where rapid mixing is important was proposed by Toor (1969). Toor proposed that reactions

be broken into three classes:

$$\frac{t_k}{t_b} \gg 1 \text{ (slow reaction)} \quad (6-150)$$

$$\frac{t_k}{t_b} \approx 1 \text{ (moderate reaction)} \quad (6-151)$$

$$\frac{t_k}{t_b} \ll 1 \text{ (fast reaction)} \quad (6-152)$$

where  $t_k$  = time characteristic of reaction of interest, e.g., reaction half-life, s

$t_b$  = time characteristic of blending, e.g., time required to achieve COV < 5 percent, s

For slow reactions ( $t_k \gg t_b$ ), blending is generally accomplished at the molecular level before the reaction of interest makes significant progress. With moderate reactions ( $t_k \sim t_b$ ), the reaction occurs at the same pace as blending, and with fast reactions ( $t_k \ll t_b$ ) the state of the reaction at any moment in time is limited by the remaining segregation, that is, the degree to which the blending is not yet complete. To make deliberate decisions about rapid blending, information must be available on both the time characteristic of the reaction  $t_k$  and the time characteristic of mixing  $t_b$ .

Toor recognized that comparing  $t_k$  and  $t_b$  alone is not enough to make sound decisions about the importance of rapid blending. For example, when a simple, reversible reaction with no competitive side reactions is being considered, the outcome will be the same no matter how fast is the blending. The outcome of fast, competitive, consecutive, poorly reversible reactions can be markedly influenced by the time of blending. Consider the following competitive, consecutive model reactions (Toor, 1969):

Consider the case where a concentrate of chemical A is being added to a dilute solution of chemical B and the objective is to produce product R, that is, S is considered an undesirable by-product. When mixing is slow ( $t_b \gg t_k$ ), B is soon depleted in the A-rich zones of the mixture and the formation of S is favored. When blending is fast ( $t_b \ll t_k$ ), the formation of R is favored unless too much A is added.

The time characteristic of blending  $t_b$  increases with the scale of the water stream being treated. For example, in a 0.007- to 0.03-ML/d pilot plant,  $t_b$  ranges from 0.1 to 1 s. Whereas in treatment plants with capacities of 10, 100, and 1000 ML/d, with efficient blending,  $t_b$  is on the order of 3, 10, and 30 s, respectively. When rapid blending is expected to be important, large-scale testing is important.

**Table 6-6**

Blending assessment of some typical reactions

Example Reactions	Blending Time, s	Is Rapid Initial blending Important?	Comments
Coagulation with Fe <sup>3+</sup> or Al <sup>3+</sup>	<0.3	Yes	Fast, poorly reversible, competitive, consecutive
pH adjustment	≪1	No	Fast, easily reversible
CaCO <sub>3</sub> nucleation	~20	Perhaps	Somewhat fast, poorly reversible
HOCl/NOM to DBPs	~90,000	No	Very slow, not reversible, competitive, consecutive
Chlorine hydrolysis	0.06	Yes	Fast, easily reversible, Cl <sub>2</sub> has low solubility
Chlorine/ammonia (high Cl <sub>2</sub> /N)	<0.1–2000	Yes	Fast in early stages, poorly reversible, competitive, consecutive
Chlorine/ammonia (low Cl <sub>2</sub> /N)	10,000–1,000,000	No	Extremely slow, poorly reversible, competitive, consecutive
HOCl/coliform	~10	No	Fast, persistent residual kill
HOCl/ <i>Giardia</i>	~200	No	Slow, persistent residual kill
HOCl/ <i>Cryptosporidium</i>	~90,000	No	Slow, persistent residual kill

Several reactions commonly encountered in the treatment of drinking water are summarized in Table 6-6. Three reactions are discussed further below: (1) the addition of sulfuric acid to reduce the pH, (2) the reaction of chlorine with NOM, and (3) the reaction of chlorine with ammonia to form chloramines:

1. *pH adjustment with H<sub>2</sub>SO<sub>4</sub>*. This reaction is extremely fast ( $t_k \ll t_b$ ). The reaction is also reversible. The time of blending will control the apparent rate of the reaction, but the outcome will be the same for any reasonable mixing time. Thus, it is only important that blending be complete before the water is sampled and analyzed for pH or before another reaction is introduced, which depends on the pH goal being sought.
2. *Chlorination of NOM to form DBPs*. Though hardly simple, the reaction of chlorine with NOM is generally regarded as slow. The time for completion is generally 10 to 20 h or more. The time of blending is rarely more than a few minutes. Thus,  $t_k \gg t_b$ , and this is a slow

reaction where the speed of initial blending would not be of great importance.

3. *Reaction of chlorine with ammonia to form chloramines.* These reactions are discussed further in Chaps. 8 and 13. They consist of a series of competitive, consecutive reactions some of which are very fast and many of which are poorly reversible (Saunier and Selleck, 1979; Wei and Morris, 1974). Consequently, blending can and does have a great impact on the outcomes achieved.

All the discussion so far has been concerned with managing the dispersion created by the turbulence at the macroscale (turbulent diffusion) to accomplish a specified level of blending. When rapid blending is being pursued for the purposes of facilitating chemical reactions, blending must be accomplished to the molecular level. Consequently, diffusion must be responsible for transport of the treatment chemical within the microscale. The time scale that is required for this transport into the smallest eddies can be estimated by using the following expression (Crank, 1979):

$$t_d = \frac{3R^2}{4D_l} \quad (6-155)$$

where  $t_d$  = time for molecules to diffuse in or out of eddy, s

$R$  = radius of eddy, m

$D_l$  = liquid diffusivity of chemical molecule ( $\sim 10^{-9}$  m<sup>2</sup>/s)

Earlier in this section it was shown that eddy size is influenced by the energy input and that the eddy diameter is equal to the Kolmogorov microscale  $\eta$ , introduced previously in the earlier subsection on mixing and the scale of turbulence (Logan, 1999). Hence the radius of the smallest eddy is equal to half of  $\eta$ :

$$R_{\text{avg}} = \frac{1}{2}\eta \quad (6-156)$$

where  $R_{\text{avg}}$  = radius of smallest eddy, m

Expressing energy input in terms of the Camp–Stein  $\overline{G}$  and combining Eqs. 6-136, 6-137, 6-140, and 6-155, it can be demonstrated that the product  $\overline{G}t_d$  that must be sustained to ensure that mixing occurs throughout the microscale can be calculated as shown below for 10°C:

$$\overline{G}t_d = \frac{3\nu}{16D_l} \cong \frac{3 \times 1.31 \times 10^{-6} \text{ m}^2/\text{s}}{16 \times 10^{-9} \text{ m}^2/\text{s}} = 246 \quad (6-157)$$

Obtaining the engineering data necessary for the design of a mixing device using intensity of segregation  $I_s$  is not very easy for the following reasons:

(1) most of the work on specification of blending has been done in the

### Blending below Microscale

### Mixing Devices Used for Blending

chemical engineering field, (2) even in that field the important blending problems are in laminar flow in liquids and turbulent-flow studies are largely limited to combustion, and (3) the mixing devices used in chemical engineering are designed to handle much smaller flows.

As a result, environmental engineers more commonly rely on mixing devices that are designed to achieve a certain intensity of mixing ( $\bar{G}$ ) rather than mixing devices designed to produce a specified quality of mix (COV < 5 percent) (Kawamura, 2000). Several of the devices that are commonly used are described in Table 6-7 and illustrated on Fig. 6-31. The advantages and disadvantages of the various devices are also noted in Table 6-7.

Nevertheless, design data for the intensity of segregation approach are available for some devices. In the remainder of this chapter, the limited design data available are used to highlight some key design issues.

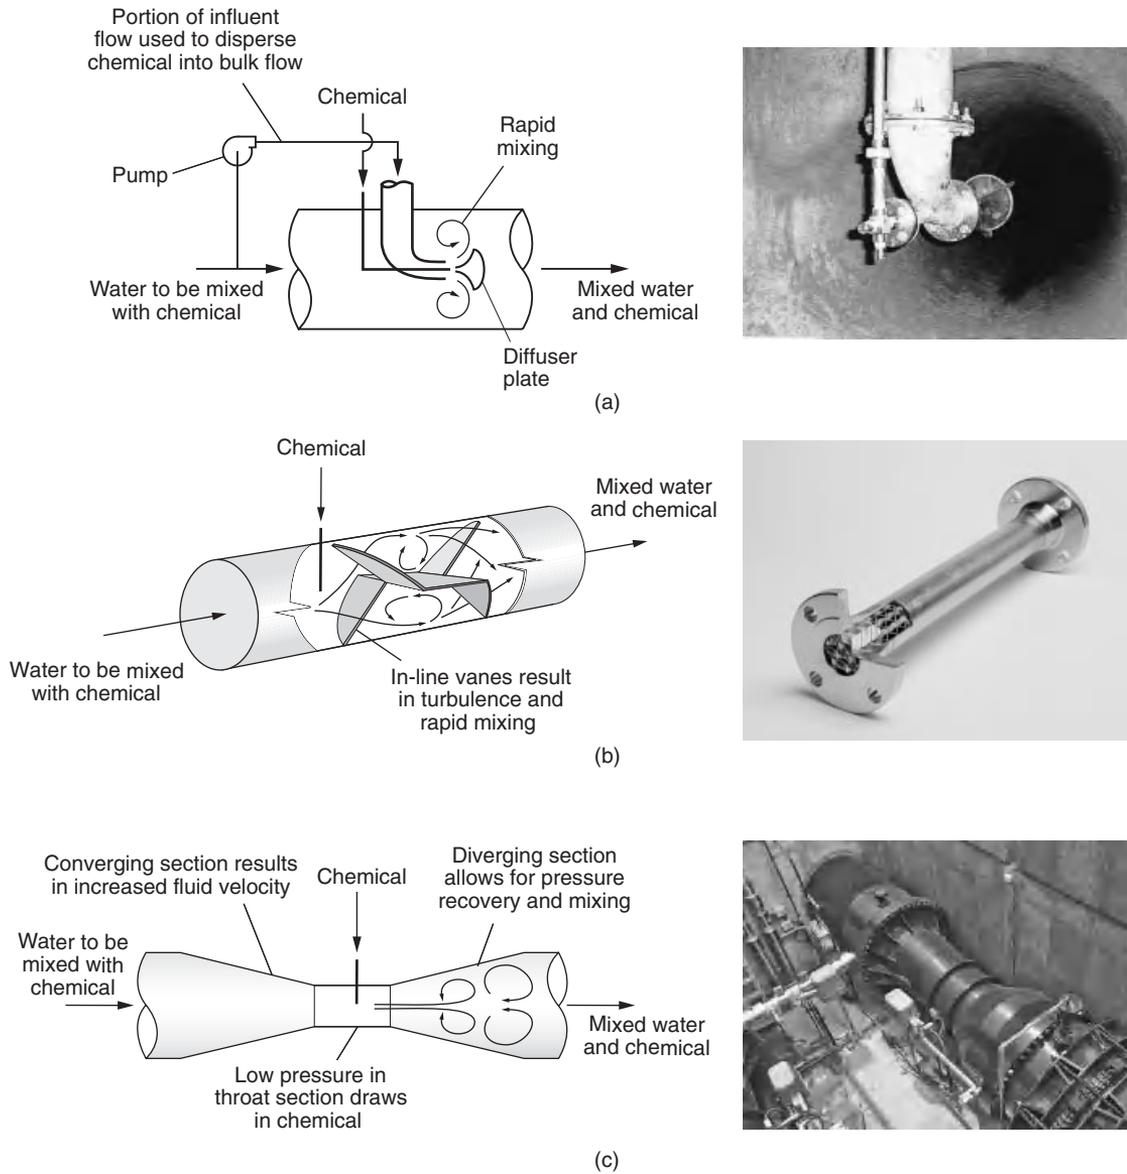

### Design of Mixers to Achieve a Specified Blend

The design of mixers to achieve a specified blend is discussed briefly below. The design is based on the principles described earlier and published statistics on four mixing devices that are useful for blending for control or rapid mixing in small facilities. Unfortunately, design information is not available for devices used for the rapid mixing of flow streams, which

**Table 6-7**  
Rapid mixing devices that avoid or minimize backmixing

Mixing Device	Advantages	Disadvantages	Upper Flow Limit, ML/d <sup>a</sup>
Centerline diffuser	Simple, reliable, inexpensive, data for Eq. 6-158 available	Turbulence is essential	5
Venturi injector	Simple, reliable	Data for Eq. 6-158 not available, subject to clogging	30
Static mixer	Simple, reliable, data for Eq. 6-158 available	Expensive, subject to clogging	100
Axial pumped jets	Can be simple, reliable	Data for Eq. 6-158 not available, subject to clogging, some backmixing	100
Lateral pumped jets	Can be simple, reliable	Data for Eq. 6-158 not available, subject to clogging	150
Conventional stirred tanks	Familiar, can be effective at blending	Expensive to maintain, high energy costs, extensive backmixing	150

<sup>a</sup>Approximate upper limit for efficient mixing in reasonable time. Above these limits, multiple units in parallel are recommended.

**Figure 6-31**

Illustrations of blending approaches used in water treatment: (a) pumped flash mixer, (b) in-line static mixer, and (c) in-line Venturi mixer.

are the size of those found in the larger full-scale water treatment plants. For these designs, empirical rules are generally used, although there is increasing interest in applying computational fluid dynamics (DuCoste and Oritz, 2003). Despite these limitations, the illustrative calculations are given here because they demonstrate important features regarding the scalability of rapid mixing.

Godfrey (1985) proposed the following related rules for modeling a variety of mixers that operate in the centerline of pipe flow: (1) a centerline discharge, (2) a Kenics static mixer, (3) a Koch static mixer, and (4) a pipe with trapezoidal baffles:

$$\left(\frac{\sigma_b}{\sigma_u}\right)_{AR=L/D} = \left(\frac{\sigma_b}{\sigma_u}\right)_{AR=1}^{L/D} \quad (6-158)$$

where  $(\sigma_b/\sigma_u)_{AR=L/D} = \sigma_b/\sigma_u$  achieved by mixer with length-to-width ratio (aspect ratio, AR) equal to  $L/D$

$(\sigma_b/\sigma_u)_{AR=1} = \sigma_b/\sigma_u$  achieved by mixer with aspect ratio of unity

$L$  = length of mixer, m

$D$  = diameter of mixer, m

$$(N_{VH})_{AR=L/D} = \frac{L}{D} (N_{VH})_{AR=1} \quad (6-159)$$

where  $(N_{VH})_{AR=L/D}$  = number of velocity heads lost through mixer with aspect ratio equal to  $L/D$

$(N_{VH})_{AR=1}$  = number of velocity heads lost through mixer with aspect ratio of unity

Godfrey (1985) reported values for  $(\sigma_b/\sigma_u)_{AR=1}$  and  $(N_{VH})_{AR=1}$  for four mixing devices as shown in Table 6-8.

Equation 6-159 can be used to estimate the  $L/D$  of the mixing device required to meet a specified level of uniformity,  $(\sigma_b/\sigma_u)_{AR=L/D}$ , and Eq. 6-158 can be used to estimate the head loss that will occur through the device. The mixing time required to meet the specified level of uniformity,  $t_b$ , is the time it takes for the water to pass through the mixer and is determined from the velocity of flow and the length of the mixer.

**Table 6-8**

Performance and design parameters for mixing devices

Mixing Device	$(\sigma_b/\sigma_u)_{AR=1}$	$(N_{VH})_{AR=1}$
Pipeline	0.95	0.02
Koch static mixer	0.21	3.8
Kenics static mixer	0.63	2.0
Trapezoidal baffles	0.38	6.6

### Example 6-12 Design of static mixer to achieve specified degree of blending

A pilot plant is to be designed to add 30 mg/L of alum to a design flow of 5 L/min. The blend specification is that  $COV \leq 5$  percent. Estimate the length of a static mixer required for this degree of blending. Use a design velocity of  $\leq 2$  m/s. Assume that the mixing device inserts come in units 1.5 diameters in length and are available in diameters of 12.5 and 20 mm. Use a whole number of inserts to achieve a reasonable safety factor. Finally, estimate the length of time required for the water to achieve the required degree of blending and the head loss through the mixer.

#### Solution

1. Determine the mixer diameter using a design velocity  $\leq 2$  m/s:
  - a. The area of the pipe is

$$A_{\text{pipe}} = \frac{Q}{V}$$

$$= \frac{(5 \text{ L/min}) (1 \text{ m}^3/1000 \text{ L})}{(2 \text{ m/s}) (60 \text{ s/min})} = 4.17 \times 10^{-5} \text{ m}^2$$

- b. The corresponding pipe diameter is

$$d_{\text{pipe}} = \sqrt{\frac{4A_{\text{pipe}}}{\pi}} = \sqrt{\frac{4 \times 4.17 \times 10^{-5} \text{ m}^2}{\pi}} = 0.0073 \text{ m} = 7.3 \text{ mm}$$

A pipe diameter of 12.5 mm (0.5 in.) is about the minimum practical size to use in a pilot plant. Choose  $D_{\text{mixer}} = 12.5$  mm.

2. Determine the number of mixer inserts:
  - a. From Example 6-11, the value of the intensity of segregation  $[I_s]_{\text{mixer}}$  is  $1.15 \times 10^{-7}$ . Thus, from Eq. 6-143,

$$\left(\frac{\sigma_b}{\sigma_u}\right)_{\text{mixer}} = \sqrt{1.15 \times 10^{-7}} = 3.39 \times 10^{-4}$$

Substituting into Eq. 6-158, yields

$$3.39 \times 10^{-4} = (0.21)^{L/D} \quad \text{and} \quad \frac{L}{D} = 5.12$$

- b. According to the problem statement, these mixing devices come with standard length inserts of  $L/D = 1.5$ . One mixer insert will provide  $L/D = 1.5$ . Four will provide  $L/D = 6$ . Use four inserts.
3. Estimate blending time  $t_m$  to meet the blend requirement:
- a. The total length of the mixer is  $4 \times 1.5 \times 0.0125 = 0.075$  m. The velocity  $v$  in the mixer will be

$$v = \frac{Q}{A} = \frac{(5 \text{ L/min}) \left( \frac{1 \text{ m}^3}{1000 \text{ L}} \right)}{\left[ \pi \times (0.0125 \text{ m})^2 / 4 \right] (60 \text{ s/min})} = 0.679 \text{ m/s}$$

- b. The blending time is

$$t_m = \frac{0.075 \text{ m}}{(0.679 \text{ m/s})} = 0.11 \text{ s}$$

4. Determine the total head loss:
- a. The velocity head is

$$\text{Velocity head} = \frac{v^2}{2g} = \frac{(0.679 \text{ m/s})^2}{2(9.8 \text{ m/s}^2)} = 0.0235 \text{ m}$$

- b. From Gray's data,

$$[N_{VH}]_{AR=1} = 3.8$$

The total head loss is

$$\Delta H_L = 0.0235 \times 3.8 \times 6 = 0.54 \text{ m}$$

### Comment

It seems practical to meet this blending specification with  $t_b \sim 0.1$  s at the small scale of this pilot plant. Further analysis will show that using the same static mixer takes much more time and head loss at full scale.

### Design of Blending for Process Control

Equation 6-158 along with the  $(\sigma_b/\sigma_u)_{AR=1}$  value for flow in a straight pipe or channel can be used to estimate the blending requirements for process control. However, the value of  $(\sigma_b/\sigma_u)_{AR=1}$  given above is an approximation, and field measurement can often provide a more accurate estimate. Likewise, field measurements of the blending being achieved in a channel can be used to evaluate alternatives for remediating control problems.

### Example 6-13 Blending to achieve process control

In a large water treatment plant with a flow of 200 ML/d, hydrofluosilicic acid is added to the product water. The acid is added, with mixing, at the beginning of a 100-m (328-ft) channel and the fluoride residual is monitored 23 m (75 ft) downstream of the point of addition. Unfortunately, the COV of the fluoride signal at the monitoring point is unacceptably high for control purposes (25 percent). Estimate how far down the channel the sample point would have to be moved to meet a COV criterion of 5 percent. Also estimate the water travel time between the point of fluoride addition and the point of fluoride analysis. The hydrofluosilicic acid solution has a fluoride concentration of 220 g/L. *Hint:* It is possible to estimate  $[I_s]_{\text{mixer}}$  by assuming that segregation will decline as the water flows down the channel as it would in a pipe. The channel has a depth of 3 m. The depth should be used as  $D$  in Eqs. 6-157 and 6-158. The width of the channel is also 3 m.

#### Solution

- Using Eq. 6-142, the COV downstream of the old monitor ( $\text{COV}_{\text{old monitor}}$ ) and the COV downstream of the new monitor ( $\text{COV}_{\text{new monitor}}$ ) can be used to relate the standard deviation downstream of the old monitor ( $\sigma_{\text{old monitor}}$ ) to the standard deviation downstream of the new monitor ( $\sigma_{\text{new monitor}}$ ):

$$\frac{\text{COV}_{\text{new monitor}}}{\text{COV}_{\text{old monitor}}} = \frac{(\sigma_{\text{new monitor}}/\bar{C}) \times 100\%}{(\sigma_{\text{old monitor}}/\bar{C}) \times 100\%} = \frac{\sigma_{\text{new monitor}}}{\sigma_{\text{old monitor}}}$$

Thus

$$\frac{\sigma_{\text{new monitor}}}{\sigma_{\text{old monitor}}} = \frac{\text{COV}_{\text{new monitor}}}{\text{COV}_{\text{old monitor}}} = \frac{5\%}{25\%} = 0.2$$

- Estimate the required length  $L$ :
  - Estimate the  $L/D$  value using Eq. 6-158:

$$\left(\frac{\sigma_b}{\sigma_u}\right)_{\text{AR}=L/D} = \left(\frac{\sigma_b}{\sigma_u}\right)_{\text{AR}=1}^{L/D}$$

$$\left(\frac{\sigma_b}{\sigma_u}\right)_{\text{AR}=L/D} = \frac{\sigma_{\text{new monitor}}}{\sigma_{\text{old monitor}}} = 0.2$$

$$0.2 = \left(\frac{\sigma_b}{\sigma_u}\right)_{\text{AR}=1} = 0.95^{L/D}$$

Taking the logarithm of both sides and rearranging,

$$\frac{L}{D} = \frac{-0.699}{-0.0223} = 31.4$$

b. The required length  $L$  is

$$L = 31.4 \times 3 = 94 \text{ m}$$

Thus, the sampling point will have to be moved 71 m (94 – 23) downstream from the current monitoring point.

3. Estimate the water travel time,  $t_b$ :

a. Estimate the velocity in the channel:

$$v = \frac{Q}{A} = \frac{(200 \text{ ML/d}) \left(1 \text{ m}^3/1000 \text{ L}\right) \left(10^6 \text{ L/1 ML}\right)}{3 \text{ m} \times 3 \text{ m}}$$

$$= 2.2 \times 10^4 \text{ m/d} = 15.4 \text{ m/min}$$

b. The blending time is

$$t_b = \frac{L}{v} = \frac{0.94 \text{ m}}{15.4 \text{ m/min}} = 6.1 \text{ min}$$

## Problems and Discussion Topics

- 6-1 Derive the solution to mass balance equations for the second- and  $n$ th-order reactions occurring in a CMBR.
- 6-2 A second-order irreversible elementary reaction  $2A \rightarrow \text{products}$  is carried out in a batch reactor. For a certain set of conditions, it is found that it took 20 min for a reaction to reach 60 percent completion. What would be the time required to reach the same degree of completion if (a) the initial concentration of A were doubled and (b) the reaction rate constant were doubled?
- 6-3 A first-order reaction  $A \rightarrow \text{products}$  is to be carried out in a CMFR. The reaction rate constant was determined to be  $1.0 \text{ h}^{-1}$ . What is the residence time required for 90 percent conversion of the reactant provided there are no changes in temperature and density of the system?
- 6-4 A given reactant decomposes in water with a second-order rate constant of  $k = 0.43 \text{ L/mol} \cdot \text{s}$ . If a feed stream with an initial concentration of  $1.0 \text{ mol/L}$  is passed through a CMFR at the rate of  $0.1 \text{ m}^3/\text{s}$ , what will be the reactor volume required for 90 percent decomposition of the reactant?

- 6-5 If two CMFRs in series each having one-half the volume calculated in Problem 6-4 were used, what would be the resulting percent decomposition of the reactant?
- 6-6 Derive and solve the differential equation that can be used to describe the effluent concentration leaving a CMFR for a first-order reaction. Assume  $C_0^* = C_0$ .
- 6-7 Rearrange the solution obtained in Problem 6-6 and solve for the time (expressed as multiples of the hydraulic detention time) required after startup such that the effluent concentration is within 1 percent of the steady-state value  $C_\infty$ :

$$\frac{C - C_\infty}{C_0} \leq 0.01$$

Plot the time required to achieve the above criteria versus the ratio of the steady-state concentration to the influent concentration. Is there a maximum time?

- 6-8 A reaction follows the rate expression of  $r = -kC^{1.5}$ . The feed concentration is 1 mol/L and the reaction rate constant  $k$  was determined to be 1.0 (L/mol)<sup>1/2</sup>/h. For a flow rate of 100 L/h, compute the volume requirement for a CMBR at 95 percent conversion if the down time for the CMBR is 1 h between batches? What is the volume requirement for a CMFR at 95 percent conversion? What is the volume requirement for a PFR at 95 percent conversion?
- 6-9 If  $A \rightarrow$  products follows a second-order reaction mechanism, what is the volume requirement for a CMFR as compared to a PFR for 95 percent conversion of A? How could the volume efficiency be improved?
- 6-10 Because of the ease of construction and operation of a CMFR, its use is sometimes preferred over a PFR. For the following conditions, indicate the preferred reactor (PFR or CMFR), where an additional CMFR volume requirement of 25 percent is acceptable. Justify each answer by computing the volume requirements for the CMFR and PFR under each condition presented in the table below.

Reaction Order	Degree of Completion of Reaction, %	PFR	CMFR
2	99		
1	99		
0	99		
0	10		
1	10		

Reaction Order	Degree of Completion of Reaction, %	PFR	CMFR
2	10		
0	40		
1	40		
2	40		
$\frac{1}{3}$	40		

- 6-11 Explain graphically using a plot of  $-1/r$  versus concentration of reactants as a function of time why the PFR is more efficient in terms of volume requirements than the CMFR when the order of the reaction is greater than zero. Also show graphically why a large number of equal-volume CMFRs connected in series can achieve the same volume efficiency as a PFR.
- 6-12 The following kinetic data were obtained to determine the order of reaction with respect to one reactant. Determine the reaction order that yields the best fit and estimate the rate constant for the reaction.

Time, min	Concentration, mg/L
0	40.00
1	31.50
2	21.50
3	17.85
4	12.16
5	10.08
6	6.84
7	5.25
8	4.30
9	2.95
10	2.42

- 6-13 The reaction  $A \rightarrow B$  is autocatalytic (i.e., the product itself is also participating in the reaction), yielding a rate expression of the form

$$r_A (\text{mol/L} \cdot \text{min}) = -kC_A C_B \quad k = 0.05 \text{ L/mol} \cdot \text{min}$$

- Calculate the residence time required in a CMFR at steady state to achieve 80 percent conversion of A when the feed concentration of A and B are 2 mol/L and 0.05 mol/L.
- Because the reaction follows second-order kinetics, a PFR should in theory yield a lower residence time and thus require a smaller reactor volume than a CMFR. Is a PFR preferred over a CMFR for the case of an autocatalytic reaction? State clearly the reasons for either recommending or not recommending a PFR, based

- on a plot of  $-1/r_A$  versus concentration. What combination of reactors will result in the smallest volume?
- 6-14 Derive the exit age distribution for  $n$  reactors (tanks) in series.
- 6-15 Calculate the effluent concentration  $C$  using the DFM for a second-order reaction in the case of a closed reactor. Assume  $Pe = 0.4$ ,  $\tau = 10$  min,  $k = 0.05$  L/mg  $\cdot$  min, and  $C_0 = 2000$  mg/L.
- 6-16 Consider a PFR in which the conversion (extent of reaction) is 99.5 percent for a first-order reaction.
- What would be the conversion in a completely mixed flow reactor of the same volume?
  - What would be the conversion in that reactor if the dispersion number  $E/vL = 1$ ?
  - What would the conversion be if the length was doubled but the residence time remained the same? (Assume  $E$  is the same as the original.)
  - What would the conversion be if the length was halved and the residence time remained the same? (Assume  $E$  is the same as the original reactor.)
  - Suppose it is desired to obtain 95 percent conversion in this nonideal reactor system with  $E/vL = 1$ . How many times larger than the volume of a PFR would be needed in the real reactor?
- 6-17 Rework Problem 6-16 for second-order kinetics.
- 6-18 Derive the expression to obtain the effluent concentration for  $n$  reactors (tanks) in series for a second-order reaction.
- 6-19 The following concentration data expressed in mg/L were obtained from tracer studies conducted on five different reactors. For a given reactor (to be selected by the instructor), plot the tracer curve, the normalized RTD curve, and the cumulative RTD curve.

Time, min	Reactor 1	Reactor 2	Reactor 3	Reactor 4	Reactor 5
0	0	0	0	0	0
10	0	2	0	0	0
20	1	5.4	0	0	0
30	2	8.4	0.1	0	0
40	5.1	11.4	0.2	0	0
50	8.9	13	0.5	0	2
60	11.2	12.1	6.3	0	6.2
70	10.5	9.3	15.2	4.5	13
80	9.2	7.2	18.1	9	10.4
90	8	5.2	8.5	14.1	5.1
100	6.5	3.6	3.2	15.6	2.8
110	5	2.5	1.8	12.9	1.1
120	3.5	1.4	1.2	9.2	0.5

Time, min	Reactor 1	Reactor 2	Reactor 3	Reactor 4	Reactor 5
130	2	0.9	0.8	5.3	0.4
140	1.4	0.4	0.6	2.3	0.1
150	0.8	0.1	0.3	1.1	0
160	0.4	0	0.2	0.8	0
170	0.2	0	0.2	0.5	0
180	0	0	0.1	0.2	0
190	0	0	0	0.1	0
200	0	0	0	0	0

- 6-20 Using the data provided in Problem 6-19, compute the dispersion number, Peclet number, and equivalent number of tanks in series for the selected reactor (to be selected by the instructor). Plot the results of the single-parameter model and compare to the actual data.
- 6-21 Using the tracer data (to be selected by the instructor) provided in Problem 6-19, calculate the expected effluent concentration using the TIS model assuming a first-order reaction rate constant  $k = 0.2 \text{ min}^{-1}$ .
- 6-22 Using the tracer study results given in Problem 6-19 (reactor data to be selected by the instructor), determine the expected effluent concentration using the SFM. Assume a first-order reaction with the rate constant  $k = 0.2 \text{ min}^{-1}$ .
- 6-23 For a reaction  $A \rightarrow P$ ,  $C_0 = 100 \text{ mg/L}$ :
- Calculate the rate constants for first- and second-order kinetics assuming a PFR with the same detention time calculated in Problem 6-19 and an effluent concentration  $C = 0.5 \text{ mg/L}$ .
  - Using figures developed for the DFM, calculate the expected effluent concentrations for first- and second-order kinetics. Use the rate constants determined in (a) above and the Pe number determined in Problem 6-20.
  - Calculate the expected effluent concentration for first- and second-order kinetics using the TIS model. Use the rate constants determined in (a) above and the tank number determined in Problem 6-20.
  - Calculate the expected effluent concentration at steady state for the SFM using second-order kinetics and the rate constants in (a) above.
- 6-24 Consider an open channel with the following characteristics: (a) depth = width = 2 m, (b) depth = width = 2.5 m, and (c) depth = width = 3 m. The flow rate is  $4 \text{ m}^3/\text{s}$  and the detention time is 60 s. If a first-order irreversible reaction is occurring with a rate constant equal to  $0.1 \text{ s}^{-1}$ , determine the expected effluent concentration  $C/C_0$  for the various channel widths. Comment on the impact of

increasing the aspect ratio on reactor performance. Use Eq. 6-113 to estimate the dispersion factor. Assume the kinematic viscosity of water is  $1.003 \times 10^{-6} \text{ m}^2/\text{s}$ .

- 6-25 For a reactor with a length of 25 m, depth of 3.5 m, flow rate of  $2.5 \text{ m}^3/\text{min}$ , and width of 2, 3, 4, or 5 m (to be selected by the instructor), estimate the dispersion number, hydraulic detention time, and  $\theta_{10}$  value. Assume the kinematic viscosity of water is  $1.003 \times 10^{-6} \text{ m}^2/\text{s}$ .
- 6-26 Using the following dose–response data for a particular microorganism found in a water supply, apply the SFM to the reactor from Problem 6-19 (to be selected by the instructor) to estimate the effluent concentration:

Exposure Time, min	Number of Organisms Remaining, No./100 mL
0	100,000
10	10,000
20	1,000
30	100
40	10
50	1
60	0.1
70	0.01
80	0.001
90	0.0001

- 6-27 A treatment plant has been designed with the capability to add hydrofluosilicic acid. The mixer installed at the point of chemical addition is warranted to achieve a COV of  $\leq 5$  percent across the cross section of flow at the point where the automatic analyzer draws samples for analysis. In a performance test during plant startup (commissioning) samples were taken at nine representative points across the cross section and the results are reported below. Determine if the mixer is meeting its specification.

Sample Point	Fluoride, mg/L
1	1.02
2	1.20
3	0.95
4	0.90
5	1.10
6	0.85
7	0.95
8	0.98
9	0.95

- 6-28 A water treatment plant is to be designed to add 30 mg/L of alum that has a strength of 651 g/L to a design flow of 50 ML/min. The blend specification is for a COV value of  $\leq 5$  percent. Estimate the length of a Koch static mixer required for this application. Use a design velocity of 2 m/s. Assume that the mixer inserts come in units 1.5 diameters in length and are available in diameters of 12.5 and 20 mm. Use a whole number of inserts to achieve a reasonable safety factor. Finally, estimate the length of time required for the water to achieve the mixing and the head loss through the mixer.
- 6-29 Derive Eq. 6-146 for  $\sigma_u$ , the standard deviation of the volume fraction of two unmixed streams. *Hint 1:* Assume that 1000 samples are taken at random from the two streams and calculate the standard deviation of each. *Hint 2:* Samples drawn from  $Q_a$  will have a volume fraction equal to 1, whereas samples drawn from  $Q_w$  will have a volume fraction of  $Q_a$  equal to 0.

## Terminology for Mass Transfer

<b>Term</b>	<b>Definition</b>
Absorption	Process in which a solute is transferred from one bulk phase and is homogeneously spread throughout another bulk phase (as opposed to collecting at the interface between phases. See which is Adsorption).
Adsorbent	Solid phase onto which a solute accumulates during the process of adsorption.
Adsorption	Process in which a solute is transferred from one bulk phase and accumulates at the surface of another phase (such as a solid surface), resulting in an increased concentration of molecules in the immediate vicinity of the surface (in contrast to absorption).
Air stripping Batch system	Transfer of volatile components from water to air. System with no flow in or out during the mass transfer operation. Typically, two phases are brought together, mass transfer is allowed to proceed until nearly at equilibrium, and then the phases are separated.
Brownian motion	Random motion of solute molecules or particles caused by collisions with solvent molecules.
Co-current flow	Process in which two phases (e.g., liquid and gas, water and powdered activated carbon) contact each other with their mass flow in the same direction.

<b>Term</b>	<b>Definition</b>
Continuous contact operation	A process in which two phases are in continuous contact with each other from the inlet to the outlet of the system, with continuously changing concentrations in each phase as a function of position (e.g., a column filled with adsorbent, a countercurrent packed tower, etc.).
Countercurrent flow	Process in which two phases (e.g., water and air) contact each other with flow in opposite directions, with contact either in stages or continuously.
Cross flow	Process in which two phases (e.g., water and air) contact each other with flows perpendicular to each other.
Desorption	Mass transfer process involving the removal of substances from an adsorbent surface.
Diffusion	Mass transfer process in which solute molecules or small particles are transported from a region of high concentration to a region of lower concentration as a result of Brownian motion.
Diffusion coefficient	Parameter that relates proportionality of the flux of a solute in a solvent to the concentration gradient. Frequently used synonymously with diffusivity.
Diffusivity	Used as a synonym for diffusion coefficient.
Extracting phase	Phase to which compounds are transferred in water treatment (e.g., gas phase for stripping, liquid phase for absorption, solid phase for adsorption or ion exchange).
Flow-through system	System in which one or both phases flow continuously through it during the mass transfer operation.
Fluid–fluid process	Mass transfer process in which fluid is in contact with another fluid (e.g., air and water in a stripping tower).
Fluid–solid process	Mass transfer process in which fluid is in contact with a solid (e.g., packing), operated as fixed or fluidized beds.
Mass transfer	Transport of components (molecules, particles, etc.) from one location to another (typically from one phase to another).

Term	Definition
Staged operation	Mass transfer system in which two phases contact each other in discrete steps. Typically, the two phases are completely mixed with each other in each stage, and then separated before being sent to the next stage, where they are remixed (often with the two contacting phases traveling in different directions).
Solute	Dissolved substance.
Solvent	Liquid in which other compounds (solutes) are dissolved.
Sorption	General term for the many phenomena commonly included under the terms adsorption and absorption when the nature of the phenomenon involved is unknown or indefinite.
Stripping	Removal of a component from one phase by transfer to another (such as air stripping, see above)

---

Several water treatment processes involve the transfer of material from one phase to another (i.e., from liquid to gas, or liquid to solid). Aeration and air stripping (Chap. 14), adsorption, (Chap. 15), ion exchange (Chap. 16), and reverse osmosis (Chap. 17) are all processes that involve mass transfer between phases. In these processes, the contaminant removal efficiency, the rate of separation, and/or the size of the equipment can be governed by the rate of mass transfer.

Mass transfer, in the broadest possible definition, is the movement of matter from one location to another, and the rate at which this occurs can be the governing factor in treatment processes. Consider a contaminant removal process that relies on an instantaneous reaction at a surface. Since the reaction is instantaneous, the rate at which the contaminant is degraded is controlled not by the rate of the reaction but by the rate at which the reactants can be transported to the surface. Such a process is called *mass transfer limited*.

Mass transfer is a complex topic. Books have been written about the topic and the chemical engineering curriculum at many universities includes an entire course in mass transfer. This chapter focuses on key principles that are relevant to environmental engineering and water treatment processes. Topics discussed in this chapter include an introduction to mass transfer, molecular diffusion and diffusion coefficients, models and correlations for mass transfer coefficients, operating diagrams, and mass transfer across a gas–liquid interface with and without chemical reactions.

## 7-1 Introduction to Mass Transfer

---

To introduce the subject of mass transfer, the concept of flux and the fundamental equation for mass transfer are introduced in this section.

In mass transfer operations, the movement of matter is measured as flux. Mass flux is defined as the amount of material that flows through a unit area per unit time:

$$J_A = \frac{m}{At} \quad (7-1)$$

where  $J_A$  = mass flux of solute A across an interface, mg/m<sup>2</sup>·s  
 $m$  = mass of solute A, mg  
 $A$  = area perpendicular to the direction of flow, m<sup>2</sup>  
 $t$  = time, s

Because flux is defined per unit area, it is an intensive property (intensive properties, like concentration or temperature, do not depend on the size of the system). Thus, for two systems with the same mass flux, the system with the larger amount of area will have more mass transfer. Mass flow is the product of the flux and the area:

$$M_A = J_A A \quad (7-2)$$

where  $M_A$  = mass flow of solute A, mg/s

As will be seen later in this chapter, increasing the surface area is a key method for increasing the rate of mass transfer (and hence, increasing the efficiency of a separation process that relies on mass transfer).

In some cases (principally membrane processes), the material moving across the interface is measured in units of volume instead of mass, and the corresponding flux is called a volumetric flux instead of a mass flux. An example of units for a volumetric flux is L/m<sup>2</sup>·s. Other situations are best described with molar units, where the units of molar flux are mol/m<sup>2</sup>·s. Molar fluxes can be converted to mass fluxes by multiplying by the molecular weight.

Mass transfer occurs in response to a driving force. Forces that can move matter include gravity, magnetism, electrical potential, pressure, and others. In each case, the flux of material is proportional to the driving force.

In environmental engineering, the driving force of interest is a concentration gradient or, in more general terms, a gradient in chemical potential, or Gibbs energy. When a concentration gradient is present between two phases in contact with each other or between two locations within a single phase, matter will flow from the region of higher concentration to the

### Concept of Flux

### Fundamental Equation for Mass Transfer

region of lower concentration at a rate that is proportional to the difference between the two concentrations, as given by the following equation:

$$J_A = k_f (\Delta C_A) \quad (7-3)$$

where  $J_A$  = mass flux of component A, g/m<sup>2</sup>·s  
 $k_f$  = mass transfer coefficient, m/s  
 $\Delta C_A$  = difference in concentration of component A, mg/L

Equation 7-3 has only two components (the mass transfer coefficient and the concentration gradient), and while this equation seems simple, it has profound implications for many treatment processes. The bulk of the rest of this chapter is devoted to the examination of variations of this equation. The next four sections are devoted to development of the mass transfer coefficient and models that describe mass transfer. Following that, Sect. 7-6 will explore how operating diagrams can be used to describe the concentration gradient, and the last two sections describe mass transfer across a gas–liquid interface.

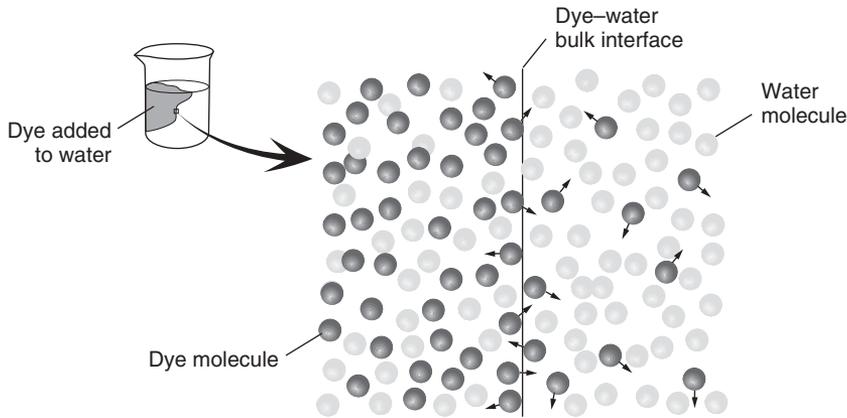

## 7-2 Molecular Diffusion

---

In the previous section, it was noted that mass flux is the product of a mass transfer coefficient and a driving force (see Eq. 7-3). A special case of mass transfer is *molecular diffusion*, in which solute molecules or particles flow from a region of higher concentration to a region of lower concentration solely due to kinetic energy of the solution molecules, that is, when no external forces are present to cause fluid movement. Molecular diffusion is a fundamental concept in many mass transfer problems. Although mass transfer coefficients are often determined using empirical correlations, the correlations are based on models of mass transfer that in turn depend on molecular diffusion at some level, and the diffusion coefficient will be a required parameter. As a result, an understanding of molecular diffusion is a necessary part of an understanding of mass transfer. Several important concepts related to molecular diffusion, including Brownian motion, Fick's first and second laws, and the Stokes–Einstein equation, are described in this section.

### Brownian Motion

Brownian motion is the random motion of a particle or solute molecule due to the internal energy of the molecules in the fluid. As a result of this internal thermal energy, all molecules are in constant motion. A solute molecule or small particle suspended in a gas or liquid phase will be bombarded on all sides by the movement of the surrounding gas or liquid molecules. The random collisions cause unequal forces that cause the solute molecule to move in random directions. The random motion

**Figure 7-1**  
Mechanism by which Brownian motion leads to diffusion. The left side has about 4 times as many dye molecules, consequently about 4 times as many pass the interface from left to right compared to the number passing in the other direction.

caused by these collisions is called Brownian motion after Robert Brown, who described it (Brown, 1827).

In a completely quiescent fluid, molecular diffusion by Brownian motion will cause matter to flow from regions of high concentration to regions of low concentration. If Brownian motion is strictly random, how does it result in the movement of matter in a specific direction defined by the concentration gradient? That question can be answered by considering the probability associated with the movement of groups of molecules. Consider a beaker containing water in which one drop of a blue dye has been placed. Molecules, both water molecules and dye molecules, are randomly moving in all directions. An imaginary boundary in the solution, as shown on Fig. 7-1, has a greater concentration of dye molecules on one side than the other. In response to completely random movement, the rate at which dye molecules cross the boundary in each direction is proportional to the number of dye molecules on each side; that is, the more dye molecules present, the more that can randomly cross the boundary from that direction. The net result is a bulk movement from concentrated regions to dilute ones. Net movement of dye molecules across any particular interface ceases when the concentration is the same on both sides. In this way, molecular diffusion stops (although Brownian motion continues) when the dye is uniformly distributed throughout the beaker; that is, the concentration is the same everywhere. When the concentration is the same everywhere, the solution in the beaker has reached equilibrium.

With Brownian motion as a foundation, molecular diffusion can be described by Fick's first law (Fick, 1855):

$$J_A = -D_{AB} \frac{dC_A}{dz} \quad (7-4)$$

### Fick's First Law

where  $J_A$  = mass flux of component A due to diffusion,  $\text{mg}/\text{m}^2 \cdot \text{s}$   
 $D_{AB}$  = diffusion coefficient of component A in solvent B,  $\text{m}^2/\text{s}$   
 $C_A$  = concentration of component A,  $\text{mg}/\text{L}$   
 $z$  = distance in direction of concentration gradient,  $\text{m}$

The term  $dC_A/dz$  is the concentration gradient, that is, the change in concentration per unit change in distance. The negative sign in Fick's first law arises because material flows from regions of high concentration to low concentration; thus, positive flux is in the direction of a negative concentration gradient.

The diffusion coefficient describes the proportionality between a measured concentration gradient and the measured flux of material. Typical values of diffusion coefficients for solutes in gases and liquids are as follows:

Liquids:  $\sim 10^{-10}$  to  $10^{-9}$   $\text{m}^2/\text{s}$  ( $10^{-6}$  to  $10^{-5}$   $\text{cm}^2/\text{s}$ ).

Gases:  $\sim 10^{-6}$  to  $10^{-5}$   $\text{m}^2/\text{s}$  ( $10^{-2}$  to  $10^{-1}$   $\text{cm}^2/\text{s}$ ).

### Diffusion in the Presence of Fluid Flow

Strictly speaking, Fick's first law describes the flux of component A with respect to the centroid of the diffusing mass of solute. In other words, Fick's first law describes the rate of diffusion from a relative point of view; if the fluid is moving, the mass transfer due to diffusion is superimposed on top of, or in addition to, mass transfer due to the movement of the fluid.

The mass flow of component A due strictly to advection (in the absence of diffusion) may be written as

$$M_A = QC_A \quad (7-5)$$

where  $M_A$  = mass flow of solute A due to advection,  $\text{mg}/\text{s}$   
 $Q$  = flow rate of fluid,  $\text{m}^3/\text{s}$

In terms of flux, the mass flow is divided by the perpendicular area:

$$J_A = \frac{QC_A}{A} = v(C_A) \quad (7-6)$$

where  $J_A$  = mass flux of component A due to advection,  $\text{mg}/\text{m}^2 \cdot \text{s}$   
 $A$  = cross-sectional area perpendicular to direction of flow,  $\text{m}^2$   
 $v$  = fluid velocity in direction of concentration gradient,  
 where  $v = Q/A$

Consequently, when matter is being transported by both fluid flow and diffusion, Eqs. 7-2, 7-4, 7-5, and 7-6 can be combined to define the net mass flow and mass flux as follows:

$$M_A = QC_A - D_{AB} \frac{dC_A}{dz} A \quad (7-7)$$

and

$$J_A = v(C_A) - D_{AB} \frac{dC_A}{dz} \quad (7-8)$$

The governing equations for unit processes are often developed by writing mass balance expressions around a control volume using a fixed point of view (stationary frame of reference). It is useful, therefore, to examine the difference between the mathematical expression for diffusion that is defined from a relative reference frame (flux =  $J$ ) and from a stationary reference frame (flux =  $N$ ). The expression for the molar flux of component A in solvent B can be written as a fraction of total molar flux, where the total molar flux is the sum of the fluxes of components A and B:

$$N_A = x_A N_{TOT} = x_A (N_A + N_B) \quad (7-9)$$

where  $N_A$  = molar flux of component A relative to stationary frame of reference, mol/m<sup>2</sup>·s

$N_B$  = molar flux of solvent B relative to stationary frame of reference, mol/m<sup>2</sup>·s

$N_{TOT}$  = total molar flux ( $N_A + N_B$ ), mol/m<sup>2</sup>·s

$x_A$  = mole fraction of A in solution, mol/mol

When matter is transported by both fluid flow and diffusion, the overall flux from a stationary reference frame is the sum of fluxes described in Eqs. 7-4 and 7-9:

$$N_A = x_A (N_A + N_B) - D_{AB} \frac{dC_A}{dz} \quad (7-10)$$

where  $D_{AB}$  = diffusion coefficient of component A in solvent B, m<sup>2</sup>/s

$C_A$  = molar concentration of component A, mol/L

$z$  = position in direction of flow and diffusion flux  
(or in direction of concentration gradient), m

In Eq. 7-10, the first term on the right side describes the molar flux of A due to the movement of the fluid, and the second term describes the molar flux of A due to diffusion, superimposed on the movement of the fluid.

For the case of no advective flow of the solvent ( $N_B = 0$ ), Eq. 7-10 can be algebraically rearranged to yield the expression

$$N_A = \frac{1}{1 - x_A} \left( -D_{AB} \frac{dC_A}{dz} \right) \quad (7-11)$$

where  $N_A$  = molar flux of component A relative to stationary frame of reference, mol/m<sup>2</sup>·s

An example of a situation where there is advective flow of the solution but no advective flow of the solvent is when a solute evaporates from a surface.

### Diffusion in Fixed and Relative Frames of Reference

The solute evaporates and moves away from the surface, and because the solute is moving and the solute is a component of the solution, the solution can be seen as moving. However, the solvent (in this case, the air) is not moving toward the surface.

For many environmental applications, particularly in aqueous solutions,  $x_A$  is very small. For example, the aqueous solubilities of chloroform and oxygen are about 9.3 g/L and 9.3 mg/L at 20°C, respectively; consequently, the largest mole fractions that can be found in water are 0.0014 and  $5.23 \times 10^{-6}$ , respectively. In these cases, the  $1/(1 - x_A)$  is negligible and  $J_A = N_A$ , that is, molar flux due to diffusion is the same regardless of whether a stationary or relative frame of reference is used. Fick's first law (Eq. 7-4) is also valid when the sum of the fluxes  $N_A$  and  $N_B$  are equal to zero, as in a case where the diffusion of species A is countered by the diffusion of B (equal molar counterdiffusion). For highly miscible solvents in water or VOCs in gases, however, it is advisable to examine whether the  $1/(1 - x_A)$  factor is important. These cases are rare, and for most applications throughout the remainder of the book, Fick's first law (Eq. 7-4) is applied directly even though a stationary frame of reference is being used.

### Fick's Second Law

Fick's first law describes diffusion when the concentration gradient is constant. Fick's second law describes the rate of change of concentration when the diffusion into a control volume is different from the diffusion leaving a control volume. Fick's second law can be derived by a mass balance on a differential element with volume  $a\Delta z$ , in which the only mass transport is due to diffusion:

$$[\text{accum}] = [\text{mass in}] - [\text{mass out}] \quad (7-12)$$

$$V \frac{dC}{dt} = J_{A,z} A - J_{A,z+\Delta z} A \quad (7-13)$$

where

$V = \text{volume, m}^3$

$C_A = \text{concentration of component A, mg/L}$

$t = \text{time, s}$

$J_{A,z} = \text{flux of component A entering the control volume, mg/m}^2 \cdot \text{s}$

$J_{A,z+\Delta z} = \text{flux of component A leaving the control volume, mg/m}^2 \cdot \text{s}$

$A = \text{cross-sectional area of control volume, m}^2$

Substituting Eq. 7-4 and replacing the volume of the control volume with the differential element volume  $A\Delta z$  results in

$$A\Delta z \frac{\partial C_A}{\partial t} = -D_{AB} \frac{\partial C_{A,z}}{\partial z} A + D_{AB} \frac{\partial C_{A,z+\Delta z}}{\partial z} A \quad (7-14)$$

where

$\Delta z = \text{length of differential element, m}$

$D_{AB} = \text{diffusion coefficient of component A in solvent B, m}^2/\text{s}$

The partial derivative arises because Eq. 7-14 contains derivatives in both time and distance. Dividing all terms by the area and rearranging yields

$$\frac{\partial C_A}{\partial t} = D_{AB} \left( \frac{\frac{\partial C_{A,z+\Delta z}}{\partial z} - \frac{\partial C_{A,z}}{\partial z}}{\Delta z} \right) \quad (7-15)$$

Taking the limit of the term in parentheses as  $\Delta z \rightarrow 0$  results in Fick's second law:

$$\frac{\partial C_A}{\partial t} = D_{AB} \frac{\partial^2 C_A}{\partial z^2} \quad (7-16)$$

Based on the principle that diffusion is caused by Brownian motion, and Brownian motion is caused by collisions with the solvent molecules, it ought to be possible to derive a theoretical value for the diffusion coefficient from the kinetic theory of matter. Albert Einstein derived this relationship in papers published in 1905 and 1908, and the derivation is explained in Laidler and Meiser (1999). As noted earlier, movement of a solute molecule or particle by Brownian motion is random in all directions, so net average distance over a period of time would be zero (movement in the  $x$  direction would be balanced by movement in the negative  $x$  direction). However, evaluating distance traveled by the molecule as the mean square displacement,  $\overline{x^2}$ , solves this problem. Relating the diffusion coefficient to kinetic energy involves two components; first, relating the mean square distance traveled by a molecule (or particle) during diffusion to the diffusion coefficient defined by Fick's laws, and second, determining the mean square distance traveled by a solute molecule as a result of collisions with solvent molecules. Equating the two relationships for mean square distance traveled provides a relationship between kinetic energy and the diffusion coefficient.

Einstein solved the first part of this relationship using arguments from statistical mechanics. The derivation is beyond the scope of this text, but the relationship established is

$$\overline{x^2} = 2Dt \quad (7-17)$$

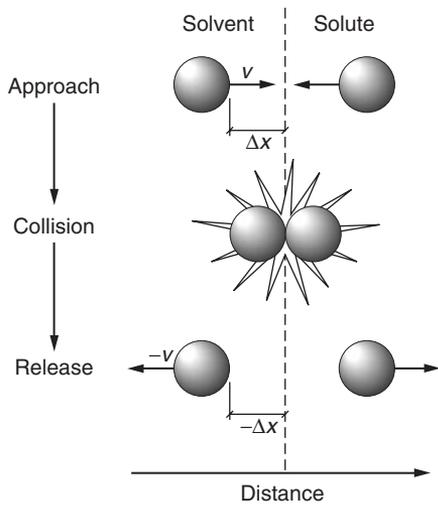

where  $\overline{x^2}$  = mean square displacement of solute molecule in  $x$  direction,  $\text{m}^2$

$D$  = diffusion coefficient,  $\text{m}^2/\text{s}$

$t$  = time, s

The second portion, relating distance traveled to kinetic energy, can be derived as follows. As shown on Fig. 7-2, for a perfect elastic collision, the solvent molecule hits the solute molecule and moves in the opposite

### Stokes–Einstein Equation

**Figure 7-2**  
Schematic of solvent molecule collision with solute molecule.

direction after the collision. For one dimension (in the direction of the concentration gradient), the average collision force exerted due to momentum change can be calculated using the following equation:

$$F_c = m \frac{v - (-v)}{t} = m \frac{2v}{t} \quad (7-18)$$

where  $F_c$  = average collision force exerted due to momentum change, N

$m$  = mass of solute molecule, kg

$v$  = average velocity of solvent molecule in one dimension, m/s

$t$  = time interval between collisions, s

The kinetic theory of gases states that the kinetic energy of gas molecules is

$$KE = \frac{3}{2} kT \quad (7-19)$$

where  $KE$  = average kinetic energy, N·m

$k$  = Boltzmann's constant,  $1.381 \times 10^{-23}$  J/K

$T$  = absolute temperature, K ( $273 + ^\circ\text{C}$ )

Kinetic energy is isotropic and can be partitioned equally in the three coordinate directions (i.e., kinetic energy in the  $x$ ,  $y$ , and  $z$  directions are each  $\frac{1}{2} kT$ ), so the kinetic energy in one direction is given by

$$KE = \frac{1}{2} mv^2 = \frac{1}{2} kT \quad (7-20)$$

Noting that  $v = x/t$ , Eq. 7-20 can be rearranged algebraically and substituted into Eq. 7-18 as follows:

$$mv = \frac{kT}{v} = \frac{kTt}{x} \quad (7-21)$$

$$F_c = \frac{2mv}{t} = \frac{2kT}{x} \quad (7-22)$$

After a collision, the solute molecule briefly accelerates due to unbalanced forces in the direction of the collision, but quickly reaches a steady-state velocity due to drag forces, which are a function of velocity. In 1851, Stokes deduced that the drag force of a solute molecule moving through a continuous fluid would be subjected to a drag force equal to

$$F_d = 3\pi\mu_l d_m v = 3\pi\mu_l d_m \frac{x}{t} \quad (7-23)$$

where  $F_d$  = drag force, N

$\mu_l$  = viscosity of liquid, kg/m·s

$d_m$  = solute molecule diameter, m

$x$  = average distance traveled by particle in time  $t$

(It should be noted that Eq. 7-23 is exactly the same as Eq. 10-4 when the drag coefficient  $C_d = 24/\text{Re}$ ). The velocity of a diffusing solute molecule or particle is constant when the collision forces equal the drag forces, and the average distance a molecule moves due to Brownian motion during a period of time can be determined by equating these equations. Equating the collision force (Eq. 7-22) and drag force (Eq. 7-23) and solving for the mean square distance traveled yields

$$\overline{x^2} = \frac{2kT}{3\pi\mu_l d_m} t \quad (7-24)$$

The mean square distance has now been related to the kinetic energy of molecules and the diffusion coefficient as defined in Fick's laws. Equating these two relationships (Eqs. 7-17 and 7-24) yields the Stokes–Einstein equation:

$$D_l = \frac{\overline{x^2}}{2t} = \frac{kT}{3\pi\mu_l d_m} \quad (7-25)$$

where  $D_l$  = liquid-phase diffusion coefficient,  $\text{m}^2/\text{s}$

Equation 7-25 was derived from the kinetic theory of gases and does not strictly apply to liquids. Nonetheless, Eq. 7-25 can be used to obtain a good prediction of the liquid diffusion coefficient for large molecules and particles. Furthermore, it predicts that diffusion increases with temperature and decreases with viscosity and molecular size, which have been observed experimentally.

For gases, the viscous force is not the same as it is for liquids because the fluid does not appear continuous for small particles or solutes. The size of a molecule or atom is on the order of 0.1 to 1 nm, and the average distance that a solute molecule travels before it collides with another molecule is on the order of 100 nm in a gas at 1 atm and room temperature. This effect is considered using the Cunningham correction factor, as shown in the following equation (Seinfeld and Pandis, 1998):

$$D_g = \frac{kTC_c}{3\pi\mu_g d_m} \quad (7-26)$$

where  $D_g$  = gas-phase diffusion coefficient,  $\text{m}^2/\text{s}$

$C_c$  = Cunningham correction factor

$\mu_g$  = viscosity of gas,  $\text{kg}/\text{m}\cdot\text{s}$

The Cunningham correction factor is determined from the expression

$$C_c = 1 + \frac{\lambda}{r} \left[ 1.257 + 0.4 \exp\left(-\frac{r}{\lambda}\right) \right] \quad (7-27)$$

where  $\lambda$  = mean free path, m

When  $\lambda/r$  is large, the following expression is obtained:

$$D_g = \frac{kT}{3\pi\mu_g d_m} \left(1 + \frac{\lambda}{r}\right) \quad (7-28)$$

The Cunningham correction factor gives rise to the collision function that appears in correlations for gas-phase diffusion coefficients.

The Brownian velocity is given by the following expression:

$$v_b = \frac{2D_l}{\bar{x}} \quad (7-29)$$

where  $v_b$  = Brownian velocity, m/s

The value of  $\bar{x}$  that can be used to calculate the Brownian velocity is approximately 0.5 nm for liquids and 100 nm for gases at room temperature and pressure. Equation 7-29 can be used to compare the distance a particle moves due to Brownian motion in comparison to other forces, such as settling due to gravity.

### 7-3 Sources for Diffusion Coefficients

---

The diffusion coefficient is an essential parameter for calculating the rate of mass transfer in a wide variety of situations. Diffusion coefficients can be obtained from:

1. Laboratory measurements
2. Reference books or published literature on previous laboratory measurements
3. Models and empirical correlations

Diffusion coefficients can be determined experimentally in the laboratory and procedures for doing so are available in the literature (Robinson and Stokes, 1959; Malik and Hayduk, 1968). When diffusion coefficients are needed for designing treatment systems or predicting process performance, however, it is more practical to obtain existing values or use correlations than to measure them. Measured diffusion coefficients of some common solutes found in water treatment are presented in Table 7-1. Diffusion coefficients for other constituents are available in the literature and reference books, such as Robinson and Stokes (1959), Marrero and Mason (1972), Poling et al. (2001), and CRC (2003).

For many compounds of interest, however, measured values of diffusion coefficients are not readily available. In addition, diffusion varies with temperature, and coefficients in reference books are often not at the temperature desired for the process application. In these cases, it is possible to estimate the diffusion coefficient based on chemical properties and

**Table 7-1**

Measured values of molecular diffusion coefficients in water (at 25°C, unless noted otherwise)

Constituent	$D_l, \text{m}^2/\text{s}$	Constituent	$D_l, \text{m}^2/\text{s}$
Neutral species		Strong electrolytes (0.001 M)

structure using various models and empirical correlations. For each class of compound, a variety of calculation methods are available (Lyman et al., 1990; Poling et al., 2001). Some of the most common correlations for diffusion coefficients are summarized in Table 7-2 and presented in more detail in the following sections. Because of the difficulty in finding measured values at the appropriate temperature, use of these correlations is the most common way of estimating diffusion coefficients for many applications.

The Stokes–Einstein equation (Eq. 7-25) relates the kinetic energy of molecules and the drag force of moving through a fluid to the diffusion coefficient. This equation can be used to calculate diffusion coefficients for large spherical molecules [molecular weight (MW) > 1000 Da] or particles in liquids, although values calculated with the Stokes–Einstein equation are slightly larger than measured values. Conversely, the Stokes–Einstein equation underestimates the diffusivity for small molecules with MW on the order of 100 Da. Substituting the parameters for water (at 20°C) into the Stokes–Einstein equation results in the expression

$$\begin{aligned}
 D_l &= \frac{kT}{3\pi\mu_l d_m} = \frac{(1.381 \times 10^{-23} \text{ N} \cdot \text{m}/\text{K})(293\text{K})}{3\pi(1.00 \times 10^{-3} \text{ N} \cdot \text{s}/\text{m}^2) d_m} \\
 &= \frac{4.29 \times 10^{-19} \text{ m}^3/\text{s}}{d_m}
 \end{aligned}
 \tag{7-30}$$

### Liquid-Phase Diffusion Coefficients for Large Molecules and Particles

**Table 7-2**

Models used for estimating molecular diffusion coefficients in liquids

Application	Model	Comments
Large spherical molecules or particles	Stokes–Einstein equation: $D_l = \frac{kT}{3\pi\mu_l d_m}$	Diffusion coefficients are slightly larger than measured values for large spherical molecules (MW > 1000 Da) or particles in liquids. Diffusivity for small molecules with MW on order of 100 Da is underestimated.
For nonelectrolytes and small molecules	Hayduk–Laudie correlation: $D_l = \frac{13.26 \times 10^{-9}}{(\mu_l)^{1.14} (V_b)^{0.589}}$	Hayduk and Laudie (1974); convert units for $\mu_l$ to cP and use Table 7-3 for $V_b$ (cm <sup>3</sup> /mol), $D_l$ is expressed in units of m <sup>2</sup> /s.
For electrolytes in absence of electric field	Nernst–Haskell equation: $D_{AB}^\circ = \frac{RT}{F^2} \left[ \frac{1/n^+ + 1/n^-}{1/\lambda_+^\circ + 1/\lambda_-^\circ} \right]$	Poling et al. (2001); use Table 7-4 for $\lambda$ values.

where  $D_l$  = liquid-phase diffusion coefficient at 20°C, m<sup>2</sup>/s  
 $k$  = Boltzmann constant,  $1.381 \times 10^{-23}$  J/K (N·m/K)  
 $T$  = absolute temperature, K (273 + °C)  
 $\mu_l$  = liquid viscosity at 20°C,  $1.00 \times 10^{-3}$  N·s/m<sup>2</sup>  
 $d_m$  = molecular diameter, m

Equation 7-30 is valid only for spherical molecules.

The validity of the Stokes–Einstein equation can be evaluated by comparing it against measured values of diffusion coefficients for proteins. Polson (1950) correlated experimental data for globular proteins and obtained the empirical expression:

$$D_l = 2.74 \times 10^{-9} (\text{MW})^{-1/3} \quad (7-31)$$

where  $D_l$  = liquid-phase diffusion coefficient, m<sup>2</sup>/s  
 MW = molecular weight, Da or g/mol

The molecular density of a globular protein is about 1.35 g/cm<sup>3</sup>, so a protein molecule with a MW of 50,000 Da has a diameter of about 4.9 nm (i.e., MW = number of molecules per mole × density of a molecule × volume of a molecule). Substituting this value into Eq. 7-30 results in a diffusion coefficient of  $8.8 \times 10^{-11}$  m<sup>2</sup>/s, compared to a value of  $7.4 \times 10^{-11}$  m<sup>2</sup>/s calculated by Eq. 7-31. Thus, the value calculated with the Stokes–Einstein equation is about 15 percent higher than the calculated value. The similarity of the two values is noteworthy considering that the Stokes–Einstein

equation is derived from first principles and Eq. 7-31 is an empirical expression.

The diffusivities of small uncharged molecules (such as synthetic organic chemicals) in water can be calculated using the Hayduk–Laudie correlation (Hayduk and Laudie, 1974), which is a revised version of a correlation developed by Othmer and Thakar (1953). The Hayduk–Laudie correlation is an empirical equation given by

$$D_l = \frac{13.26 \times 10^{-9}}{(\mu_l)^{1.14} (V_b)^{0.589}} \quad (7-32)$$

where  $D_l$  = liquid-phase diffusion coefficient of solute,  $\text{m}^2/\text{s}$

$\mu_l$  = viscosity of water, cP (1 cP =  $10^{-3}$  kg/m·s)

$V_b$  = molar volume of solute at normal boiling point,  $\text{cm}^3/\text{mol}$

Because the Hayduk–Laudie correlation was developed as a regression of experimental data and is not dimensionally consistent, it is important to use the units given for the equation. The molar volume at the normal boiling point,  $V_b$ , can be estimated using the LeBas method (LeBas, 1915). The atomic volumes for different elements, mixtures, and functional groups for use in calculation of molar volume at the normal boiling point via the LeBas method are presented in Table 7-3. Contributions of the various functional groups are added together along with deductions for certain ring structures. Calculation of the diffusion coefficient of a small neutral molecule using the Hayduk–Laudie correlation is illustrated in Example 7-1.

Electroneutrality requires that positive and negative ions migrate together, so diffusion coefficients are calculated for electrolytes (solutions of charged ions) instead of being calculated for each ion individually. As an example, the values of diffusion coefficients in Table 7-1 demonstrate that sodium and magnesium each diffuse faster when the counterion is chloride than when it is sulfate. In the absence of an electric field, diffusion of ions will generate an electric current in a solution. Conversely, the current through a unit area that results from applying an electric field for a given electrolyte concentration is known as the equivalent conductance. Thus, liquid-phase diffusion coefficients of electrolytes in the absence of an electric field are related to the equivalent conductance and can be calculated using the Nernst–Haskell equation:

$$D_l^\circ = \frac{RT}{F^2} \left( \frac{1/n^+ + 1/n^-}{1/\lambda_+^\circ + 1/\lambda_-^\circ} \right) \quad (7-33)$$

where  $D_l^\circ$  = liquid-phase diffusion coefficient at infinite dilution,  $\text{cm}^2/\text{s}$

$R$  = universal gas constant, 8.314 J/mol·K

$T$  = absolute temperature, K ( $273 + ^\circ\text{C}$ )

 $n^+$  = cation valence $n^-$  = anion valence $F$  = Faraday's constant, 96,500 C/eq $\lambda_+^\circ$  = limiting positive ionic conductance, cm<sup>2</sup>·S/eq $\lambda_-^\circ$  = limiting negative ionic conductance, cm<sup>2</sup>·S/eq

Values for limiting positive ionic conductance at 25°C are tabulated in Table 7-4. Values at other temperatures are available in reference books such as Robinson and Stokes (1959). The limiting ionic conductance is related to electric current and electric field strength in an infinitely dilute

### Example 7-1 Estimating the diffusion coefficient for small neutral molecules in water

Estimate the diffusion coefficients of the following contaminants found in a groundwater: (1) vinyl chloride at 25°C and (2) benzene at 20°C. Use Table 7-3 to find the contributions of the various functional groups to the molar volume. Density and viscosity of water are available in App. C [convert the given units of viscosity to g/cm·s, i.e., centipoise (cP)]. Compare the values to the measured values reported in Table 7-1.

#### Solution

1. Calculate the liquid-phase diffusion coefficient for vinyl chloride.
  - a. Estimate the molar volume at the boiling point using the information in Table 7-3. The chemical formula for vinyl chloride is C<sub>2</sub>H<sub>3</sub>Cl. The contribution of each atom to the molar volume is

$$2C = 2(14.8) = 29.6 \text{ cm}^3/\text{mol}$$

$$3H = 3(3.7) = 11.1 \text{ cm}^3/\text{mol}$$

$$Cl = (21.6) = 21.6 \text{ cm}^3/\text{mol}$$

The molar volume is determined by adding the contributions of each atom:

$$V_b = 29.6 + 11.1 + 21.6 = 62.3 \text{ cm}^3/\text{mol}$$

- b. Calculate the diffusion coefficient using Eq. 7-32. The viscosity of water at 25°C is  $0.89 \times 10^{-3} \text{ kg/m}\cdot\text{s} = 0.89 \text{ cP}$ .

$$D_l = \frac{13.26 \times 10^{-9}}{(0.89 \text{ cP})^{1.14} (62.3 \text{ cm}^3/\text{mol})^{0.589}} = 1.33 \times 10^{-9} \text{ m}^2/\text{s}$$

- c. Compare the calculated value to the measured value in Table 7-1.

$$\frac{1.34 \times 10^{-9} - 1.33 \times 10^{-9}}{1.34 \times 10^{-9}} \times 100 = 1\% \text{ error}$$

2. Calculate the liquid-phase diffusion coefficient for benzene.
  - a. Benzene is an aromatic compound (6 carbon ring) with the chemical formula C<sub>6</sub>H<sub>6</sub>. The contribution of each atom to the molar volume is

$$6C = 6(14.8) = 88.8 \text{ cm}^3/\text{mol} \quad 6H = 6(3.7) = 22.2 \text{ cm}^3/\text{mol}$$

$$\text{Six-member ring} = -15 \text{ cm}^3/\text{mol}$$

The molar volume is determined by adding the contributions of each atom:

$$V_b = 88.8 + 22.2 - 15 = 96 \text{ cm}^3/\text{mol}$$

- b. Calculate the diffusion coefficient using Eq. 7-32. The viscosity of water at 20°C is  $1.00 \times 10^{-3} \text{ kg/m} \cdot \text{s} = 1.00 \text{ cP}$ .

$$D_l = \frac{13.26 \times 10^{-9}}{(1.00 \text{ cP})^{1.14} (96 \text{ cm}^3/\text{mol})^{0.589}} = 0.90 \times 10^{-9} \text{ m}^2/\text{s}$$

- c. Compare the calculated value to the measured value in Table 7-1.

$$\frac{1.02 \times 10^{-9} - 0.90 \times 10^{-9}}{1.02 \times 10^{-9}} \times 100 = 11\% \text{ error}$$

### Comment

The value estimated with the Hayduk–Laudie correlation is within 1 percent of the measured value for vinyl chloride and within 11 percent of the measured value for benzene. These results are typical; the Hayduk–Laudie correlation is often within 10 percent of measured values for many compounds (it should be noted that measured values by different researchers with different methods also vary). As a result of this level of accuracy, it is common to estimate liquid-phase diffusion coefficients with the Hayduk–Laudie correlation rather than obtaining measured values for the species of interest.

Ref: Robinson and Stokes (1959).

solution. Conductance is measured in siemens (S, where  $1 \text{ S} = 1 \text{ A/V}$ ); current is measured in amperes (A, where  $1 \text{ A} = 1 \text{ C/s}$ ); and electric field strength is measured in volts/cm (V/cm, where  $1 \text{ V} = 1 \text{ J/C}$ ). Specifically, the equivalent conductance relates the current flow through an area ( $\text{A/cm}^2$ ) to the electric field strength and the concentration of ions in solution (measured in equivalents, or “mole of charge”), as given by the equation

$$\text{Current flow} = \lambda_i \times \text{electric field strength} \times C_i \quad (7-34)$$

where  $\lambda_i$  = equivalent conductance of electrolyte  $i$ ,  $\text{cm}^2 \cdot \text{S}/\text{eq}$

$C_i$  = concentration of electrolyte  $i$ ,  $\text{eq}/\text{cm}^3$

The charge of 1 electron is  $1.60 \times 10^{-19} \text{ C}$  so the charge of a mole of electrons is the Faraday constant, 96,500 C/eq. As shown in Table 7-4, small ions have a higher equivalent conductance because they migrate through water more rapidly in response to an imposed electric field. Consequently, their diffusion coefficient is higher than that of large ions. Calculation of the diffusion coefficient of electrolytes with the Nernst–Haskell equation is shown in Example 7-2.

### Example 7-2 Estimating diffusion coefficients for electrolytes in water

Estimate the diffusion coefficient of  $\text{MgCl}_2$  in a dilute aqueous solution at  $25^\circ\text{C}$  and compare it to the measured value in Table 7-1. Use the information in Table 7-4 to find the limiting ionic conductances for the ions.

#### Solution

1. From Table 7-4, the limiting ionic conductances are  $53.0 \text{ (cm}^2 \cdot \text{C}^2)/(\text{J} \cdot \text{s} \cdot \text{eq})$  for  $\text{Mg}^{2+}$  and  $76.4 \text{ (cm}^2 \cdot \text{C}^2)/(\text{J} \cdot \text{s} \cdot \text{eq})$  for  $\text{Cl}^-$ .
2. Calculate the diffusion coefficients at infinite dilution using Eq. 7-34:

$$D_i^\circ = \frac{(8.314 \text{ J/mol} \cdot \text{K})(298 \text{ K})}{(96,500 \text{ C/eq})^2} \times \left\{ \frac{\left(\frac{1}{2} + \frac{1}{1}\right) \frac{\text{mol}}{\text{eq}}}{\left(\frac{1}{53.0} + \frac{1}{76.4}\right) \frac{\text{J} \cdot \text{s} \cdot \text{eq}}{\text{cm}^2 \cdot \text{C}^2}} \right\}$$

$$= 1.25 \times 10^{-5} \text{ cm}^2/\text{s}$$

3. Compare the calculated diffusion coefficient to the measured value reported in Table 7-1.

$$\frac{1.25 \times 10^{-5} - 1.19 \times 10^{-5}}{1.19 \times 10^{-5}} \times 100 = 5\% \text{ error}$$

**Comment**

The value calculated with the Nernst–Haskell equation is the diffusion coefficient in an infinitely dilute solution and the measured value in Table 7-1 is for a 0.001 M solution, but the values are within 5 percent of each other.

In a process such as ion exchange, the movement of the ions by diffusion will generate an electric field that can exert an additional force that influences mass transfer. As a result, the mass transfer rate can be many times greater than would be calculated from Fick's law. The Nernst–Planck equation (not covered in this book) can be used to calculate the flux due to the combined forces of a concentration gradient and an electrical field.

**Liquid-Phase Diffusion Coefficient for Oxygen**

The liquid-phase diffusion coefficient of oxygen in water can be determined from a correlation that was obtained from a best fit of literature values (Holmén and Liss, 1984):

$$D_{l,O_2} = 10^{(A+B/T)} (1.0 \times 10^{-9}) \quad (7-35)$$

where  $D_{l,O_2}$  = liquid-phase diffusion coefficient of oxygen,  $m^2/s$

$A$  = fitting parameter, 3.15, unitless

$B$  = fitting parameter,  $-831.0$ , unitless

$T$  = absolute temperature, K ( $273 + ^\circ C$ )

**Gas-Phase Diffusion Coefficients**

The diffusion coefficient of an organic compound in the gas phase can be calculated using a variety of correlations (Lyman, et al. 1990). Consider the Wilke–Lee correlation (Wilke and Lee, 1955), which is a modification of the Hirschfelder–Bird–Spotz correlation (Hirschfelder et al., 1949):

$$D_g = \frac{(1.084 - 0.249\sqrt{1/M_A + 1/M_B}) (T^{1.5}) \sqrt{1/M_A + 1/M_B}}{P_l (r_{AB})^2 f(kT/\epsilon_{AB})} \quad (7-36)$$

where  $D_g$  = gas-phase diffusion coefficient of organic compound A in stagnant gas B,  $cm^2/s$

$T$  = absolute temperature, K ( $273 + ^\circ C$ )

$M_A, M_B$  = molecular weights of A and B, respectively, Da or g/mol

$P_l$  = absolute pressure,  $N/m^2$

$r_{AB}$  = molecular separation at collision, equal to  $(r_A + r_B)/2$ , nm

$r_A$  = molecular separation at collision for component A, nm

$r_B$  = molecular separation at collision for stagnant gas B, nm

$\epsilon_{AB}$  = energy of molecular attraction, equal to  $\sqrt{\epsilon_A \epsilon_B}$ , erg ( $1 \text{ erg} = 10^{-7} \text{ J}$ )

$\epsilon_A$  = energy of molecular attraction for component A, erg

$\epsilon_B$  = energy of molecular attraction for stagnant gas B, erg

$k$  = Boltzmann constant,  $1.381 \times 10^{-16} \text{ g} \cdot \text{cm}^2/\text{s}^2 \cdot \text{K}$

$f(kT/\epsilon_{AB})$  = collision function

The collision function originates from the Cunningham correction factor, discussed in Sec. 7-2. The values of  $r_A$  and  $\epsilon_A$  can be estimated for each component from the following equations:

$$r_A = 1.18 V_{b,A}^{1/3} \quad (\text{in nm for } V_{b,A} \text{ in L/mol}) \quad (7-37)$$

$$\frac{\epsilon_A}{k} = 1.21 T_{b,A} \quad (7-38)$$

where  $V_{b,A}$  = molar volume of component A at normal boiling point,  
L/mol

$T_{b,A}$  = normal boiling point of component A, K

The diffusion coefficient of a substance when the stagnant gas B is air can be calculated by assuming that air behaves like a single substance with respect to molecular collisions. The required parameters for air are

$$r_B = 0.3711 \text{ nm} \quad (7-39)$$

$$\frac{\epsilon_B}{k} = 78.6 \quad (7-40)$$

$$\frac{\epsilon_{AB}}{k} = \sqrt{\frac{\epsilon_A}{k} \times \frac{\epsilon_B}{k}} \quad (7-41)$$

$$f\left(\frac{kT}{\epsilon_{AB}}\right) = 10^\xi \quad (7-42)$$

$$\xi = \begin{pmatrix} -0.14329 - 0.48343 (ee) + 0.1939 (ee)^2 + 0.13612 (ee)^3 \\ -0.20578 (ee)^4 + 0.083899 (ee)^5 - 0.011491 (ee)^6 \end{pmatrix} \quad (7-43)$$

$$ee = \log_{10} \left( \frac{kT}{\epsilon_{AB}} \right) \quad (7-44)$$

Calculation of gas-phase diffusion coefficients with the Wilke–Lee correlation is demonstrated in the following example.

### Example 7-3 Estimating gas-phase diffusion coefficients

Calculate the gas-phase diffusion coefficient of trichloroethene (TCE) in air at 20° C at 1 atm. Given:

A = TCE    B = air

$$M_A = 131.39 \text{ g/mol} \quad M_B = 29 \text{ g/mol}$$

$$V_{b,A} = 98.1 \text{ cm}^3/\text{mol} = 0.0981 \text{ L/mol}$$

$$T_{b,A} = 87^\circ\text{C} = (87 + 273) \text{ K} = 360 \text{ K}$$

### Solution

1. Determine pressure and temperature in proper units:

$$T = (273 + 20^\circ\text{C}) \text{ K} = 293 \text{ K}$$

$$P_1 = 1 \text{ atm} = 101,325 \text{ N/m}^2$$

2. Calculate  $r_{AB}$  using Eq. 7-37 for  $r_A$  and Eq. 7-39 for  $r_B$ .

$$r_A = 1.18 (V_{b,A})^{1/3} = 1.18 (0.0981)^{1/3} = 0.544 \text{ nm}$$

$$r_B = 0.3711 \text{ nm}$$

$$r_{AB} = \frac{1}{2} (r_A + r_B) = \frac{1}{2} (0.544 \text{ nm} + 0.3711 \text{ nm}) = 0.458 \text{ nm}$$

3. Determine  $\varepsilon_{AB}/k$  by calculating  $\varepsilon_A/k$  with Eq. 7-38,  $\varepsilon_B/k$  with Eq. 7-40, and  $\varepsilon_{AB}/k$  with Eq. 7-41.

$$\frac{\varepsilon_A}{k} = 1.21 T_{b,A} = 1.21 (360 \text{ K}) = 435.6$$

$$\frac{\varepsilon_B}{k} = 78.6$$

$$\frac{\varepsilon_{AB}}{k} = \sqrt{\frac{\varepsilon_A}{k} \times \frac{\varepsilon_B}{k}} = \sqrt{(435.6)(78.6)} = 185$$

4. Determine the collision function  $f(kT/\varepsilon_{AB})$ .

- a. Calculate  $kT/\varepsilon_{AB}$ :

$$\frac{kT}{\varepsilon_{AB}} = \frac{T}{\varepsilon_{AB}/k} = \frac{293}{185} = 1.58$$

- b. Calculate  $ee$  using Eq. 7-44:

$$ee = \log_{10} \left( \frac{kT}{\varepsilon_{AB}} \right) = \log_{10} (1.58) = 0.200$$

- c. Calculate  $\xi$  using Eq. 7-43:

$$\xi = \left\{ \begin{array}{l} -0.14329 - [0.48343 (0.200)] + [0.1939 (0.200)^2] + [0.13612 (0.200)^3] \\ - [0.20578 (0.200)^4] + [0.083899 (0.200)^5] - [0.011491 (0.200)^6] \end{array} \right\}$$

$$= -0.231$$

d. Calculate  $f(kT/\varepsilon_{AB})$  using Eq. 7-42:

$$f\left(\frac{kT}{\varepsilon_{AB}}\right) = 10^{\xi} = 10^{-0.231} = 0.587$$

5. Determine the gas-phase diffusion coefficient of TCE in air using Eq. 7-36:

$$\begin{aligned} D_g &= \frac{\left(1.084 - 0.249\sqrt{1/M_A + 1/M_B}\right) \left(T^{1.5}\right) \sqrt{1/M_A + 1/M_B}}{P_I (r_{AB})^2 f(kT/\varepsilon_{AB})} \\ &= \frac{\left(1.084 - 0.249\sqrt{1/131.39 + 1/29}\right) (293)^{1.5} \sqrt{1/131.39 + 1/29}}{(101,325) (0.458)^2 (0.587)} \\ &= 8.52 \times 10^{-2} \text{ cm}^2/\text{s} \end{aligned}$$

## 7-4 Models for Mass Transfer at an Interface

In many common treatment processes, such as air stripping, adsorption, ion exchange, and reverse osmosis, mass transfer occurs at an interface. The interface is the phase boundary between the phase containing the solute or contaminant (typically the water) and the extracting phase (e.g., air or activated carbon). An understanding of mass transfer at an interface is essential to understanding the principles of these processes. This section describes three common models for how mass transfer occurs at an interface.

The mass that is transferred from one phase to another per unit time depends on the mass transfer coefficient, the driving force, and the surface area available, as was introduced in Sec. 7-1. The driving force is caused by contacting the contaminated phase with an extracting phase that does not contain the contaminant. When mass transfer occurs at an interface, the concentration gradient is given by the concentrations in the bulk solution and at the interface, as shown on Fig. 7-3 and in following expression:

$$J_A = k_f (C_b - C_s) \quad (7-45)$$

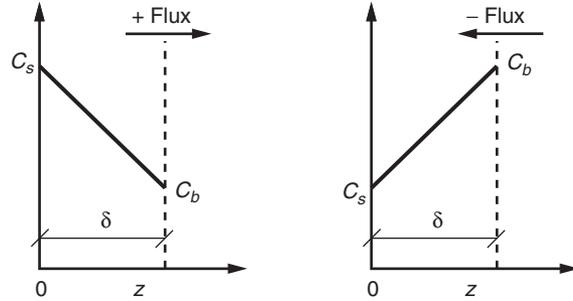

where  $J_A$  = mass flux of solute A to interface,  $\text{mg}/\text{m}^2\cdot\text{s}$

$k_f$  = mass transfer coefficient,  $\text{m}/\text{s}$

$C_s$  = concentration of solute A at interface,  $\text{mg}/\text{L}$

$C_b$  = concentration of solute A in bulk solution,  $\text{mg}/\text{L}$

The mass transfer coefficient depends on the diffusion coefficient and the mass transfer boundary layer thickness  $\delta$ , as shown on Fig. 7-3. As shown on

**Figure 7-3**  
Hypothetical fluxes at interface at steady state.

Fig. 7-3, the direction of flux depends on the direction of the concentration gradient. Common models used to predict the mass transfer coefficient include (1) the film model, (2) the surface renewal or penetration model, and (3) the boundary layer model. Many investigators have taken the theoretical forms of the mass transfer correlations and modified them to fit data that were collected for a variety of geometries (e.g., sphere, cylinder, plate) and flow regimes (e.g., laminar, transition, and turbulent). Several of the common correlations used to determine mass transfer coefficients are given in Sec. 7-5.

### Surface Area Available for Mass Transfer

To calculate the mass flow rate, the flux must be multiplied by the surface area (see Eq. 7-2). It is common to express the area of the interface between phases as a function of the contactor volume (e.g., the surface area of carbon grains is expressed as a function of the volume of the carbon bed). Thus, the mass flow rate is given by the expression

$$M_A = k_f a (C_b - C_s) V \quad (7-46)$$

where  $M_A$  = mass flow of solute A, mg/s

$a$  = specific area, or surface area, available for mass transfer per unit volume of the contactor,  $\text{m}^2/\text{m}^3$

$V$  = contactor volume,  $\text{m}^3$

The specific area is an important concept. For a given contactor volume, the mass transfer rate can increase linearly with an increase in specific area. Thus, designing a mass transfer device with a high specific area can result in a high rate of mass transfer in a small contactor. Mass transfer devices are often designed to have the highest possible specific area within the limitations imposed by hydraulic considerations. Increases in specific area often come at the expense of higher headloss. For example, in a packed bed of activated carbon it would be advantageous to use small carbon granules to increase the specific area, but the pressure drop would become too large and the cost of pumping water through the contactor would be high. In addition, the contactor would have to withstand the increased pressure.

### Example 7-4 Calculating area available for mass transfer

Determine the specific area for the transport of a solute to granular activated carbon (GAC) particles in a carbon adsorber. The porosity ( $\epsilon$ , fraction of void volume) of the carbon bed is 0.45 and the GAC particle diameter is  $d_p = 1 \text{ mm}$ . Assume the surface of the GAC is like that of a smooth sphere.

#### Solution

$$\begin{aligned}
 a &= \left( \frac{\text{surface area of particle}}{\text{volume of particle}} \right) \left( \frac{\text{volume of particles}}{\text{volume of contactor}} \right) \\
 &= \left( \frac{\pi d_p^2}{\left(\frac{1}{6}\right) \pi d_p^3} \right) (1 - \epsilon) = \frac{6(1 - \epsilon)}{d_p} = \frac{6(1 - 0.45)}{0.001 \text{ m}} = 3300 \text{ m}^2/\text{m}^3
 \end{aligned}$$

#### Comment

The grain diameter is in the denominator, so decreasing the size will increase the specific area for the same amount of GAC in the contactor (decreasing the grain size to 0.1 mm would increase the specific area to 33,000  $\text{m}^2/\text{m}^3$ , which would increase the rate of mass transfer by a factor of 10 for the same size contactor if diffusion from the bulk solution to the particle surface is the limiting rate). This action, however, would increase the headloss and make it more difficult to pass water through the contactor.

The relationship between grain size and specific area is demonstrated in Example 7-4.

The film model is the most straightforward of the models that explain mass transfer at an interface. The system is considered to be composed of a well-mixed bulk solution (either gas or liquid), a stagnant film layer, and an interface to another phase (e.g., a solid surface), as shown on Fig. 7-3. As a result of the solution being well mixed, solutes are transported continually to the edge of the stagnant film layer, and no concentration gradients exist in the bulk solution. Mass transfer to the interface occurs when the concentration at the interface to the other phase is different than the concentration in the bulk solution, causing a concentration gradient across the film layer. Because this layer is quiescent, the sole mechanism for transport across this layer is molecular diffusion. Processes that occur at the actual interface (such as a chemical reaction or adsorption to the surface)

#### Film Model

are assumed to occur much faster than the rate of diffusion and, as a result, the rate of mass transfer is described by Fick's first law for diffusion across the film layer:

$$J_A = -D_f \frac{dC}{dz} = -\frac{D_f}{\delta} (C_s - C_b) = k_f (C_b - C_s) \quad (7-47)$$

where  $J_A$  = mass flux,  $\text{mg}/\text{m}^2 \cdot \text{s}$

$D_f$  = fluid-phase diffusion coefficient of solute A,  $\text{m}^2/\text{s}$

$k_f$  = fluid-phase mass transfer coefficient of solute A,  $\text{m}/\text{s}$

$\delta$  = film thickness, as shown on Fig. 7-3,  $\text{m}$

$C$  = concentration,  $\text{mg}/\text{L}$

$z$  = distance in direction of mass transfer (or in direction of concentration gradient),  $\text{m}$

In the film model, the mass transfer coefficient is explicitly related to the film thickness, as shown in the expression

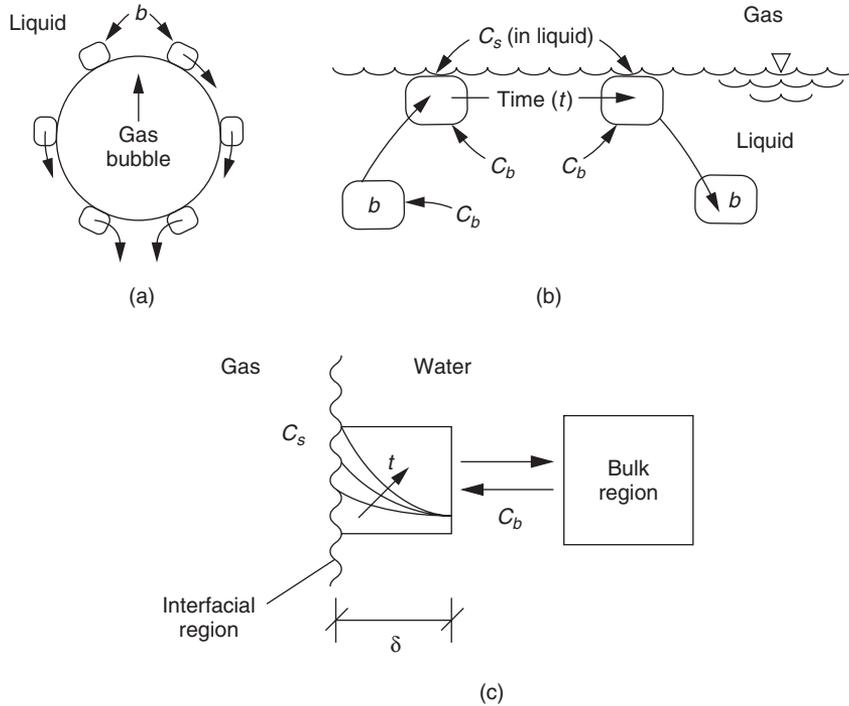

$$k_f = \frac{D_f}{\delta} \quad (7-48)$$

The theoretical stagnant film thickness will vary from 10 to 100  $\mu\text{m}$  for liquids and from 0.1 to 1  $\text{cm}$  for stagnant gases. Unfortunately, there is no way to calculate the film thickness based on fluid mixing; consequently, the film model cannot be used to calculate the local mass transfer coefficient. Nevertheless, the film model is used frequently to develop a conceptual view of mass transfer across an interface and to illustrate the importance of diffusion in controlling the rate of mass transfer.

### Penetration and Surface Renewal Models

According to the penetration model (Higbie, 1935) and the surface renewal model (Danckwerts, 1951, 1955), packets of water move up to the gas–water interface and transfer solute either from the gas to the water or from the water to the gas, and then the packets of fluid return to the bulk solution. The transport of fluid packets to and from the surface is shown on Fig. 7-4a and 7-4b. When a packet of water moves to the interface, the concentration of dissolved gases increases during aeration as shown on the bottom of Fig. 7-4c.

The essential difference between the penetration and surface renewal models is that for a penetration model a fixed residence time at the surface is assumed. For a surface renewal model, it is assumed that there is an equal probability for the fluid elements to move to and from the surface up to a certain residence time. It is likely that a surface renewal model is more plausible because fluid turbulence is thought to be responsible for transporting the fluid element to and from the surface. Consequently, the time that fluid packets remain on the surface is random and all residence times are equally plausible. The surface renewal model can be used to derive the theoretical basis for predicting mass transfer coefficients.

**Figure 7-4**

Schematic of penetration and surface renewal models for gas transfer: (a) gas bubble rising through liquid in which liquid packets  $b$  are in contact with the bubble for a time period  $t$  equal to the time it takes for the bubble to rise one diameter, (b) liquid packets  $b$  in turbulent eddy rising to liquid surface, as in an open channel, and remaining in contact with gas for a time period  $t$ , and (c) increase in concentration of a dissolved gas at liquid surface interface with time for both cases (a) and (b). (Adapted from Treybal, 1980.)

When fluid passes a solid flat plate, a velocity gradient forms because the fluid velocity is assumed to be zero at the surface (no slip condition). Simultaneously, the solutes are transported to or from the surface, resulting in a concentration gradient between the concentration at the surface and the concentration in the bulk solution. The limit of the concentration gradient is not necessarily the same as the velocity gradient. The rate of mass transfer and relationship between the concentration and velocity gradients is related to conditions of the fluid flow. The concentration gradient shown on Fig. 7-5 is for the case where solute is transported from the surface of the plate to the bulk solution and laminar flow conditions exist. For laminar flow past a flat plate, the following theoretical mass transfer correlation can be derived:

$$\frac{k_{f(\text{avg})}L}{D_f} = 0.664 \text{Re}^{1/2} \text{Sc}^{1/3} \quad (7-49)$$

where  $k_{f(\text{avg})}$  = average fluid-phase mass transfer coefficient, m/s

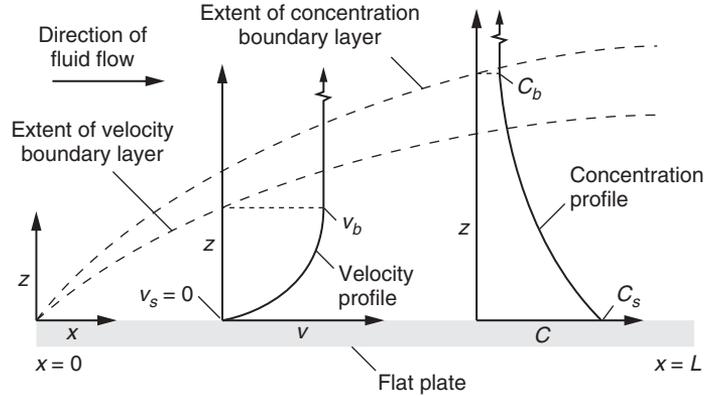

$L$  = length of channel, m

$D_f$  = fluid-phase diffusion coefficient,  $\text{m}^2/\text{s}$

$\text{Re}$  = Reynolds number, dimensionless

$\text{Sc}$  = Schmidt number, dimensionless

## Boundary Layer Models

**Figure 7-5**  
Boundary layer model diagram showing velocity and concentration profiles for laminar flow across flat plate.

The Reynolds and Schmidt numbers for flow past a flat plate are defined as follows:

$$\text{Re} = \frac{\rho_f v L}{\mu_f} \quad (7-50)$$

$$\text{Sc} = \frac{\mu_f}{\rho_f D_f} \quad (7-51)$$

where  $\rho_f$  = fluid-phase density,  $\text{kg}/\text{m}^3$   
 $v$  = velocity above boundary layer,  $\text{m}/\text{s}$   
 $\mu_f$  = fluid-phase viscosity,  $\text{kg}/\text{m} \cdot \text{s}$

The parameter group on the left side of Eq. 7-51 is known as the Sherwood number:

$$\text{Sh} = \frac{k_f L_c}{D_f} \quad (7-52)$$

where  $\text{Sh}$  = Sherwood number, dimensionless  
 $L_c$  = characteristic length,  $\text{m}$

The Sherwood number describes the relationship between the mass transfer coefficient and the diffusion coefficient. For instance, in the film model presented earlier the characteristic length scale is the stagnant film layer thickness ( $\delta$ ), mass transfer occurs only by molecular diffusion, and  $\text{Sh} = 1$ . Equation 7-50 expresses that the relationship between the mass transfer coefficient and the diffusion coefficient depends on the values of the Reynolds and Schmidt numbers; for laminar flow past a flat plate, the mass transfer coefficient will increase relative to the diffusion coefficient as the Reynolds and Schmidt numbers increase.

Numerous theoretical analyses have demonstrated that equations similar to Eq. 7-49 can be derived for many situations. A more general form

of this equation is

$$\text{Sh} = A\text{Gr}^c + B\text{Re}^a \text{Sc}^b \quad (7-53)$$

$$= \frac{k_f L_c}{D_f} = f(\text{Gr}, \text{Sc}, \text{Re}) \quad (7-54)$$

$$\text{Sc} = \frac{\mu_f}{\rho_f D_f} = \frac{\nu_f}{D_f} \quad (7-55)$$

$$\text{Re} = \frac{\rho_f v L_c}{\mu_f} = \frac{v L_c}{\nu_f} \quad (7-56)$$

$$\text{Gr} = \frac{g L_c^3 (\rho_p - \rho_f)}{\rho_f \nu_f^2} \quad (7-57)$$

where

Sh = Sherwood number, dimensionless

Sc = Schmidt number, equal to ratio of momentum diffusivity to mass diffusivity, dimensionless

Gr = Grashof number, equal to ratio of buoyant forces to viscous forces, dimensionless

Re = Reynolds number, equal to ratio of inertial forces to viscous forces, dimensionless

$A, B, a, b, c$  = constants, unitless

$k_f$  = mass transfer coefficient, m/s

$L_c$  = characteristic length, m

$D_f$  = diffusion coefficient,  $\text{m}^2/\text{s}$

$\mu_f$  = fluid-phase viscosity,  $\text{kg}/\text{m} \cdot \text{s}$

$\rho_f$  = fluid-phase density,  $\text{kg}/\text{m}^3$

$\rho_p$  = particle density,  $\text{kg}/\text{m}^3$

$\nu$  = velocity, m/s

$\nu_f$  = fluid-phase kinematic viscosity, equal to  $\mu_f/\rho_f$ ,  $\text{m}^2/\text{s}$

$g$  = acceleration due to gravity,  $9.81 \text{ m}/\text{s}^2$

The coefficients in Eq. 7-53 (i.e.,  $A, B, a, b, c$ ) depend on the geometry (e.g., particles, bubbles, packed bed) and flow regime (i.e., laminar, transition, or turbulent).

The first term on the right side of Eq. 7-53,  $A \text{Gr}^c$ , accounts for molecular diffusion conditions under which there is no advection. The Grashof number accounts for mass transfer due to natural advection, which can be caused by density differences at the interface. A familiar example from heat transfer is a space heater in which air flows past the heater as a result of lighter, heated air that rises. A similar phenomenon is observed for salts dissolved in water because the solution at the salt interface is usually denser and fluid flow will occur at the interface without forced advection. However, in many cases, the buoyant force is not important in

environmental problems because the solutions are very dilute. In such a case, the first term is simply a constant and Eq. 7-53 becomes

$$\text{Sh} = A + B \text{Re}^a \text{Sc}^b \quad (7-58)$$

The second term on the right side of Eqs. 7-53 and 7-58,  $B \text{Re}^a \text{Sc}^b$ , accounts for mass transfer that is enhanced by advection. Many investigators have developed the theoretical bases for Eq. 7-53 for various geometries and flow regimes and have also developed mass transfer correlations by fitting data to Eq. 7-58 for various geometries and flow regimes. The forms of mass transfer correlations for different geometry and flow conditions are discussed briefly in the next subsection. In spite of the plethora of papers on mass transfer (there are at least 100,000 articles in the archival literature), mass transfer correlations for complex geometry and flow conditions do not exist for every situation. For such cases, it is possible to estimate the mass transfer coefficient for component A if the mass transfer for another component, B, is known. This relationship is discussed at the end of this section.

The characteristic length in Eq. 7-50 was the length of the flat plate. A common geometry in environmental applications is spheres (such as where the extracting phase is a bubble or air or a particle or activated carbon).  $\text{Re}$  is defined differently for a sphere than it is for flat surfaces:

$$\text{Re} = \frac{\rho_f v d_p}{\mu_f} \quad (7-59)$$

where  $d_p$  = diameter of sphere or particle, m

## 7-5 Correlations for Mass Transfer Coefficients at an Interface

---

Based on the models in the previous section, numerous mass transfer correlations have been developed to estimate mass transfer coefficients for various geometries and flow regimes. This section describes common forms of mass transfer correlations, and the relationship between mass transfer coefficients and diffusing species.

### Common Mass Transfer Correlations

Mass transfer coefficient correlations for a variety of transfer situations are shown in Table 7-5. Some of these correlations are obtained by analogy to heat transfer, others by measurement or theoretical approximation. Correlations presented in Table 7-5 include (1) Gnielinski correlation for packed beds, which can be used for calculating mass transfer coefficients in gas- and liquid-phase adsorption (see Chap. 15); (2) Onda correlation for absorption and air stripping, which can be used to determine the mass transfer coefficient in packed-tower air stripping (see Chap. 14); and (3) the Gilliland correlation for gases and liquids in pipes. Many other correlations for other geometries and flow regimes are available in the literature. The procedure for calculating a mass transfer coefficient using the Gnielinski correlation is presented in Example 7-5.

**Table 7-5**  
Common mass transfer correlations

Description/Application	Empirical Correlation	Nomenclature
Gnielinski correlation <sup>a</sup> for packed beds; used for calculating external liquid-phase mass transfer coefficient in packed beds; application demonstrated in Chap. 15	$k_f = \frac{[1 + 1.5(1 - \varepsilon)] D_f}{d_p} \left( 2 + 0.644 \text{Re}^{1/2} \text{Sc}^{1/3} \right)$	$k_f$ = fluid-phase mass transfer coefficient, m/s
	$\text{Re} = \frac{\rho_f \Phi d_p v_l}{\mu_f}$	$D_f$ = fluid-phase diffusion coefficient, m <sup>2</sup> /s
	$\text{Sc} = \frac{\mu_f}{\rho_f D_f}$	$\varepsilon$ = bed void fraction, dimensionless
	Constraints :	$d_p$ = diameter of particle, m
	$Pe = \text{Re} \cdot \text{Sc} > 500$	$\rho_f$ = fluid-phase density, kg/m <sup>3</sup>
	$0.7 < \text{Sc} < 10^4, \text{Re} < 2 \times 10^4$	$\Phi$ = sphericity, equal to ratio of surface area of equivalent-volume sphere to actual surface area of particle, dimensionless
	$0.26 < \varepsilon < 0.935$	$v_l$ = superficial liquid velocity, m/s
		$\mu_f$ = fluid-phase viscosity, kg/m · s
		$Re$ = Reynolds number, dimensionless
		$Sc$ = Schmidt number, dimensionless <sup>b</sup>
		$Pe$ = Peclet number, dimensionless

Gilliland correlation<sup>d</sup> for gases or liquids in pipes; used for calculating gas- or liquid-phase mass transfer coefficient in pipes

$$Sh = \frac{k_f D}{D_g \text{ (or } D_l)} = 0.023 Re^{0.833} Sc^{0.33}$$

$$Re = \frac{\rho_g D V_g}{\mu_g} \left( \text{or } \frac{\rho_l D V_l}{\mu_l} \right)$$

$$Sc = \frac{\mu_g}{\rho_g D_g} \left( \text{or } \frac{\mu_l}{\rho_l D_l} \right)$$

For turbulent flow:

$$Re > 2100$$

$$0.6 < Sc < 3000$$

Sh = Sherwood number, dimensionless  
 $k_f$  = fluid-phase mass transfer coefficient, m/s  
 $D$  = diameter of pipe, m  
 $D_l$  = liquid-phase diffusion coefficient, m<sup>2</sup>/s  
 $D_g$  = gas-phase diffusion coefficient, m<sup>2</sup>/s  
 $Re$  = Reynolds number, dimensionless  
 $Sc$  = Schmidt number, dimensionless  
 $\rho_g$  = gas density, kg/m<sup>3</sup>  
 $\mu_g$  = gas viscosity, kg/m · s  
 $\rho_l$  = liquid density, kg/m<sup>3</sup>  
 $\mu_l$  = liquid viscosity, kg/m · s  
 $v_g$  = superficial gas velocity, m/s  
 $v_l$  = superficial liquid velocity, m/s

### Example 7-5 Application of a correlation to determine a mass transfer coefficient

A resort in the mountains has a good water source; however, the water is extremely soft (no hardness) and acidic, which makes cleaning and bathing difficult. One solution is to pass the low-pH water through a packed bed containing crushed limestone ( $\text{CaCO}_3$ ). Determine the film transfer coefficient for limestone media. Given: The media diameter  $d_p$  is 1.0 cm, the bed porosity  $\varepsilon$  is 0.43, the particle sphericity  $\Phi$  is 0.8, the temperature is  $20^\circ\text{C}$ , and the superficial velocity  $v_f$  through the bed is 12 m/h.

#### Solution

Determine the mass transfer coefficient  $k_f$  for limestone particles using the Gnielinski correlation in Table 7-5.

1. Calculate the diffusion coefficient for aqueous calcium carbonate using the Nernst–Haskell equation (see Example 7-2). From Table 7-4, the limiting conductances are  $59.5 \text{ (cm}^2\cdot\text{C}^2)/(\text{J}\cdot\text{s}\cdot\text{eq})$  for  $\text{Ca}^{2+}$  and  $69.3 \text{ (cm}^2\cdot\text{C}^2)/(\text{J}\cdot\text{s}\cdot\text{eq})$  for  $\text{CO}_3^{2-}$ .

$$D_I = \frac{(8.314 \text{ J/mol} \cdot \text{K})(298 \text{ K})}{(96,500 \text{ C/eq})^2} \left[ \frac{\left(\frac{1}{2} + \frac{1}{2}\right) \frac{\text{mol}}{\text{eq}}}{\left(\frac{1}{59.5} + \frac{1}{69.3}\right) \left(\frac{\text{J}\cdot\text{s}\cdot\text{eq}}{\text{cm}^2\cdot\text{C}^2}\right)} \right]$$

$$= 8.52 \times 10^{-6} \text{ cm}^2/\text{s} = 8.52 \times 10^{-10} \text{ m}^2/\text{s}$$

2. Calculate  $\text{Re}$  from the equation in Table 7-5. From App. C,  $\rho_f = 998.2 \text{ kg/m}^3$  and  $\mu_f = 1.002 \times 10^{-3} \text{ kg/m}\cdot\text{s}$  at  $20^\circ\text{C}$ .

$$\text{Re} = \frac{\rho_f \Phi d_p v_f}{\varepsilon \mu} = \frac{\rho_f \Phi d_p v_f}{\varepsilon \mu_f}$$

$$= \frac{(998.2 \text{ kg/m}^3)(0.8)[1.0 \text{ cm} \times (1\text{m}/100 \text{ cm})][12 \text{ m/h} \times (1 \text{ h}/3600 \text{ s})]}{(0.43)(1.002 \times 10^{-3} \text{ kg/m}\cdot\text{s})}$$

$$= 61.8$$

3. Calculate  $\text{Sc}$  using Eq. 7-53:

$$\text{Sc} = \frac{\mu_f}{\rho_f D_f} = \frac{\mu_f}{\rho_f D_I} = \frac{1.002 \times 10^{-3} \text{ kg/m}\cdot\text{s}}{(998.26 \text{ kg/m}^3)(8.52 \times 10^{-10} \text{ m}^2/\text{s})}$$

$$= 1180$$

4. Calculate  $k_f$  using the empirical correlation given in Table 7-5:

$$\begin{aligned} k_f &= \frac{[1 + 1.5(1 - \varepsilon)] D_f}{d_p} (2 + 0.644 \text{Re}^{1/2} \text{Sc}^{1/3}) \\ &= \frac{[1 + 1.5(1 - 0.43)] (8.52 \times 10^{-10} \text{ m}^2/\text{s})}{1 \text{ cm} \times (1 \text{ m}/100 \text{ cm})} [2 + 0.644 (61.8)^{1/2} (1180)^{1/3}] \\ &= 8.76 \times 10^{-6} \text{ m/s} \end{aligned}$$

Despite the availability of mass transfer correlations for diverse situations, there are many cases for which mass transfer correlations do not exist. Under such circumstances, the mass transfer coefficient of one solute can be used to estimate the mass transfer coefficient of another. For example, if the mass transfer coefficient for oxygen is known, the mass transfer coefficient for other compounds can be calculated. The procedure is convenient because the mass transfer coefficient for dissolved oxygen is relatively easy to measure and many correlations are available for oxygen transfer.

Mass transfer correlations depend on the exponent of the Schmidt number (i.e., the  $b$  that appears in Eq. 7-59,  $\text{Sc}^b$ ), and this dependency allows for estimation of the mass transfer coefficient of one compound from the mass transfer coefficient of another compound. Situations that arise include (1) mass transfer occurs only by molecular diffusion, (2) the fluid moves freely to the surface and surface renewal occurs, and (3) the fluid cannot move freely to the surface because the interface is a solid and a boundary layer forms. If mass transfer occurs only by molecular diffusion, the relationship between the mass transfer coefficient and diffusion coefficient is

$$\text{Sh} = \frac{k_f L_c}{D_f} = 1 \quad (7-60)$$

where  $k_f$  = fluid-phase mass transfer coefficient, m/s

$L_c$  = characteristic length, m

$D_f$  = fluid-phase diffusion coefficient,  $\text{m}^2/\text{s}$

For pure molecular diffusion,  $k_f$  is directly proportional to  $D_f$ , that is,  $k_f \propto D_f$ . Thus, if  $k_{f,A}$  for one compound is known, then  $k_{f,B}$  can be determined from the relationship

$$\frac{k_{f,B}}{k_{f,A}} = \frac{D_{f,B}}{D_{f,A}} \quad (7-61)$$

### Relationship between Mass Transfer Coefficients and Diffusing Species

where  $k_{f,B}$  = fluid-phase mass transfer coefficient for B, m/s  
 $k_{f,A}$  = fluid-phase mass transfer coefficient for A, m/s  
 $D_{f,B}$  = fluid-phase diffusion coefficient of B, m<sup>2</sup>/s  
 $D_{f,A}$  = fluid-phase diffusion coefficient of A, m<sup>2</sup>/s

The surface renewal model presented in Sec. 7-4 yields a dependence on the Sherwood number as shown here:

$$\text{Sh} = \frac{k_f L_c}{D_f} \propto \text{Sc}^{0.5} = \left( \frac{\mu_f}{\rho_f D_f} \right)^{0.5} \quad (7-62)$$

Thus, from Eq. 7-61, it can be seen that the surface renewal model predicts that  $k_f$  depends on the diffusion coefficient according to the expression

$$k_f \propto D_f^{0.5} \quad (7-63)$$

Thus, if mass transfer occurs according to the surface renewal model and if  $k_{f,A}$  is known, then  $k_{f,B}$  can be determined from the relationship

$$\frac{k_{f,B}}{k_{f,A}} = \left( \frac{D_{f,B}}{D_{f,A}} \right)^{0.5} \quad (7-64)$$

A third situation is described by the penetration model or boundary layer model. As discussed in Sec. 7-4, the boundary layer model yields a dependence of Sh as shown here:

$$\text{Sh} = \frac{k_f L}{D_f} \propto \text{Sc}^{1/3} = \left( \frac{\mu_f}{\rho_f D_f} \right)^{1/3} \quad (7-65)$$

From Eq. 7-65,  $k_f$  depends on the diffusion coefficient according to the expression

$$k_f \propto D_f^{2/3} \quad (7-66)$$

If  $k_{f,A}$  is known, then  $k_{f,B}$  can be determined from the following expression:

$$\frac{k_{f,B}}{k_{f,A}} = \left( \frac{D_{f,B}}{D_{f,A}} \right)^{2/3} \quad (7-67)$$

The dependency of the ratio of the mass transfer coefficients for constituents A and B on the ratio of the diffusivities of A and B for some common situations that are encountered in water treatment are given in Table 7-6. The procedure to calculate one mass transfer coefficient from another is demonstrated in Example 7-6.

**Table 7-6**

Dependency of ratio of mass transfer coefficients for compounds A and B on ratio of diffusivities of A and B for some common situations in water treatment

Situation	$\frac{k_{f,B}}{k_{f,A}} = \left(\frac{D_{f,B}}{D_{f,A}}\right)^n$	Comment
Transport from fluid to solid or from solid to liquid	$\frac{k_{f,B}}{k_{f,A}} = \left(\frac{D_{f,B}}{D_{f,A}}\right)^{2/3}$	A boundary layer forms because the velocity at the solid–fluid interface is zero.
Mass transfer resistance in water at air–water interface	$\frac{k_{l,B}}{k_{l,A}} = \left(\frac{D_{l,B}}{D_{l,A}}\right)^{0.5}$	For an air–water interface, no velocity gradient exists in the water at the boundary because the viscosity of air is 50 times lower than that for water at 1 atm (the air offers no resistance against which a liquid velocity gradient would form).
Mass transfer resistance in air at air–water interface	$\frac{k_{g,B}}{k_{g,A}} = \left(\frac{D_{g,B}}{D_{g,A}}\right)^{2/3}$	At the air–water interface, a boundary layer forms in the air because the higher viscosity of the water causes the water to essentially act as a solid surface. At very high air Reynolds numbers the air velocity gradient can decay and the dependency would tend toward $\frac{1}{2}$ .

where  $k_f, k_l$ , and  $k_g$  = fluid-, liquid-, and gas-phase mass transfer coefficients for solutes A and B, m/s  
 $D_f, D_l$ , and  $D_g$ , = fluid-, liquid-, and gas-phase diffusion coefficients for solutes A and B, m<sup>2</sup>/s  
 $n$  = exponent used to describe the relationship between the ratio of the mass transfer coefficients of compounds A and B to the ratio of diffusion coefficients of compounds A and B

### Example 7-6 Determination of mass transfer coefficient by relating mass transfer coefficients and diffusion coefficients

The mass transfer coefficient of oxygen in a mass transfer device measured at 20°C is  $k_{l,O_2} = 0.0045$  m/s. Estimate the mass transfer coefficient of benzene at 20°C on the water side of an air–water interface in the device by relating mass transfer coefficients and diffusivities of benzene to those of oxygen. From Table 7-1, the liquid diffusion coefficient for benzene at 20°C is  $D_{l,benzene} = 1.02 \times 10^{-9}$  m<sup>2</sup>/s.

#### Solution

Determine the mass transfer coefficient for benzene,  $k_{l,benzene}$ , using the relationship for mass transfer resistance in the water at the air–water interface in Table 7-6.

1. Determine the diffusion coefficient of oxygen at 20°C using Eq. 7-35:

$$\begin{aligned} D_{l,O_2} &= 10^{(A+B/T)} (1.0 \times 10^{-9}) \\ &= 10^{3.15 - 831.0/(273+20)K} (1.0 \times 10^{-9}) \\ &= 2.06 \times 10^{-9} \text{ m}^2/\text{s} \end{aligned}$$

2. Determine  $k_{l,\text{benzene}}$  using Eq. 7-62:

$$\begin{aligned} \frac{k_{l,B}}{k_{l,A}} &= \left( \frac{D_{l,B}}{D_{l,A}} \right)^{0.5} \Rightarrow \frac{k_{l,\text{benzene}}}{k_{l,O_2}} = \left( \frac{D_{l,\text{benzene}}}{D_{l,O_2}} \right)^{0.5} \Rightarrow \\ k_{l,\text{benzene}} &= k_{l,O_2} \left( \frac{D_{l,\text{benzene}}}{D_{l,O_2}} \right)^{0.5} = (0.0045 \text{ m/s}) \left( \frac{1.02 \times 10^{-9} \text{ m}^2/\text{s}}{2.06 \times 10^{-9} \text{ m}^2/\text{s}} \right)^{0.5} \\ &= 0.0032 \text{ m/s} \end{aligned}$$

## 7-6 Design of Treatment Systems Controlled by Mass Transfer

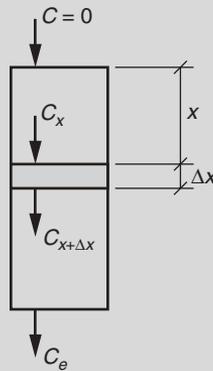

When treatment devices are controlled by the rate of mass transfer, the concepts presented in this chapter can be used for design. The relationship between mass transfer and process design will be developed more fully in Chaps. 14 (Air Stripping and Aeration), 15 (Adsorption), and 17 (Reverse Osmosis), but an illustration of how mass transfer concepts can be used to design a treatment system is presented in the following example.

### Example 7-7 Design of a packed column treatment system controlled by mass transfer

An acid waste stream is to be neutralized by continuous (steady state) flow through a column packed with a rapidly dissolving calcium carbonate media. Determine the hydraulic residence time and bed depth necessary so that the column effluent is 99 percent saturated with calcium carbonate, assuming that the dissolution is limited only by the rate of diffusion through the boundary layer. The media characteristics are the same as in Example 7-5; the media diameter  $d_p$  is 1.0 cm, the bed porosity  $\varepsilon$  is 0.43, the particle sphericity  $\Phi$  is 0.8, and the superficial velocity  $v$  through the bed is 12 m/h.

**Solution**

1. A schematic of the media bed is shown below. Set up a mass balance (see Chap. 6) using the liquid in a differential unit of depth in the bed as the control volume. Since the system is at steady state, the accumulation term is zero. The differential element has two mass input terms, one from advective flow of water containing calcium carbonate from the previous differential element ( $QC_x$ ), and the other from the dissolution of the calcium carbonate. The mass flow due to diffusion through the boundary layer is described by Eq. 7-46, except that the concentration gradient is  $(C_s - C_x)$ , where  $C_s$  is the calcium carbonate concentration at the surface of the media (which is at the saturation concentration) and  $C_x$  is the concentration in the bulk solution. The mass output term is  $QC_{x+\Delta x}$ . The volume of the differential element is  $V = A\Delta x$ , where  $A$  is the cross-sectional area of the column. The mass balance can be set up and algebraically rearranged as follows:

$$0 = [\text{mass in}] - [\text{mass out}] \quad (1)$$

$$0 = QC_x + k_f a (C_s - C_x) V - QC_{x+\Delta x} \quad (2)$$

$$\frac{C_{x+\Delta x} - C_x}{\Delta x} = \frac{k_f a}{Q} (C_s - C_x) A \quad (3)$$

2. The term on the left is the derivative  $dC/dx$  after taking the limit as  $\Delta x \rightarrow 0$ . The equation is algebraically rearranged again so that both sides of the equation can be integrated across the depth of the column:

$$\frac{dC}{dx} = \frac{k_f a}{Q} (C_s - C) A \quad (4)$$

$$\int_0^{C_e} \frac{dC}{C_s - C} = \frac{k_f a A}{Q} \int_0^L dx \quad (5)$$

3. Integrating Eq. 5 and recognizing that  $A \times L = V$  and  $V/Q = \tau$  (the hydraulic residence time) yields

$$-\ln\left(\frac{C_s - C_e}{C_s}\right) = \frac{k_f a A}{Q} L = k_f a \frac{V}{Q} = k_f a \tau \quad (6)$$

4. The specific area is determined as in Example 7-4, except that the sphericity increases the surface area to be greater than that of a sphere. Substituting the values from the problem statement yields

$$a = \frac{6(1 - \varepsilon)}{\Phi d_p} = \frac{6(1 - 0.43)}{(0.8)(0.01 \text{ m})} = 428 \text{ m}^{-1} \quad (7)$$

5. In Example 7-5,  $k_f$  was determined to be  $8.76 \times 10^{-6}$  m/s. The concentration in the effluent of the column is  $0.99C_s$ . Then  $(C_s - C_e)/C_s = (C_s - 0.99C_s)/C_s = 0.01$ . Rearranging Eq. 6 and plugging in the necessary values yields

$$\begin{aligned} \tau &= \frac{-\ln[(C_s - C_e)/C_s]}{k_f a} = \frac{-\ln(0.01)}{(8.76 \times 10^{-6} \text{ m/s})(428 \text{ m}^{-1})} \\ &= 1230 \text{ s} = 20.5 \text{ min} = 0.34 \text{ h} \end{aligned}$$

6. The depth of the column is determined by multiplying the superficial velocity by the detention time:

$$L = v\tau = (12 \text{ m/h})(0.34 \text{ h}) = 4.1 \text{ m}$$

### Comment

When dissolution is rapid as in this example, the size of the column will be controlled by the rate of mass transfer. Examining steps 4 through 6 indicates that reducing the size of the media would increase the specific area and thereby decrease the required depth of the column. For instance, reducing the diameter of the media to 1 mm would increase the specific area to  $4280 \text{ m}^{-1}$  and decrease the depth of the column to 0.41 m. These calculations demonstrate the importance of specific area in designing mass transfer equipment.

In many situations, dissolution kinetics are slower and the process is controlled by the rate of dissolution and not by the rate of mass transfer (i.e., calcium carbonate diffuses through the boundary layer faster than it dissolves, so that the concentration at the surface ( $C_s$ ) is not

the saturated concentration). The difference between reaction-limited and mass-transfer-limited processes is an additional complication in designing treatment equipment.

## 7-7 Evaluating the Concentration Gradient with Operating Diagrams

The last sections have dealt with development of theory and correlations needed to determine mass transfer coefficients. This section explores the other half of the primary mass transfer equation (Eq. 7-3), the concentration gradient. The concentration gradient and the impact it has on mass transfer can be evaluated graphically. Graphical analysis of concentration gradients depends on the type of contacting equipment. The major types of contacting equipment are described next, followed by a discussion of operating diagrams, also known as McCabe–Thiele diagrams.

Two major methods are used for bringing two phases into contact: batch operation and continuous operation. Continuous systems may be operated with or without discrete stages.

### Contact Modes

#### BATCH OPERATION

A batch operation is a contained system with no flow in or out. Typically, the two phases are brought together, allowed to approach equilibrium, and then separated. An example of a batch operation is an adsorption equilibrium isotherm conducted by adding powdered activated carbon (PAC) to a bottle.

#### CONTINUOUS OPERATION

A continuous operation involves flow within the system. Three flow patterns are possible with continuous operations: (1) co-current, (2) countercurrent, and (3) cross flow. A co-current operation consists of a system in which the two contacting phases flow in the same direction. In water treatment, there are natural draft co-current stripping devices in which the falling water creates a natural draft of air to flow through the device.

A countercurrent operation consists of a system in which the two contacting phases flow in opposite directions. Countercurrent operation represents the preferred mode of operation for many air-stripping processes, such as packed towers, as will be discussed in Chap. 14.

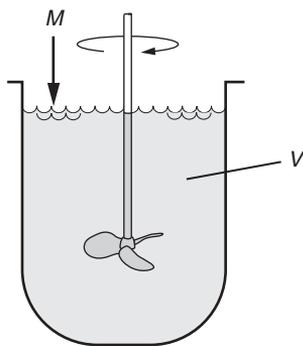

In a cross-flow operation, the two contacting phases flow perpendicular to one another. Sedimentation is an example of a cross-flow process and is widely used in water treatment, but cross-flow operations in general are less common for mass-transfer-controlled processes in water treatment.

In a staged operation, the process is operated as a series of stages. The two phases are mixed with each other in each phase, and the concentrations

in both phases are uniform within each stage. The flow pattern in a staged operation can be co-current, cross flow, or countercurrent. An example of a countercurrent staged operation is a low-profile air stripper, which will be examined in Chap. 14.

### Development of Operating Diagrams

The impact of the concentration gradient on the rate of mass transfer between two phases can be evaluated graphically using a concept called operating diagrams, or McCabe–Thiele diagrams (McCabe and Thiele, 1925). Operating diagrams are drawn by plotting the solute concentration in the extracting phase (e.g., air for gas transfer, activated carbon for adsorption) as a function of the solute concentration in the aqueous phase. The operating diagram consists of two lines: (1) an equilibrium line and (2) an operating line. Operating diagrams can be used to determine the minimum amount of the extracting phase needed for treatment and to examine graphically the trade-off between the size of the mass transfer contacting device and the quantity of extracting phase needed (e.g., air–water ratio for stripping or PAC required for adsorption).

**Figure 7-6**  
Batch contactor for powdered activated carbon.

#### EQUILIBRIUM LINE

The equilibrium line is derived from two-phase equilibrium relationships and gives the solute concentration in the extracting phase that exists when the extracting and aqueous phases are in equilibrium with each other. Examples of two-phase equilibrium relationships are Henry's law for air stripping and the Freundlich isotherm for adsorption. Equilibrium relationships were introduced in Chap. 5, and additional details on Henry's law and Freundlich isotherms will be provided in Chaps. 14 and 15, respectively.

#### OPERATING LINE

The operating line is derived from a mass balance on the contacting device, relating the solute concentration in each phase initially to the solute concentration in each phase after contact has begun. An example using a batch reactor, in which PAC is added to a vessel containing a solution of water and an organic solute, is shown on Fig. 7-6. Initially, there is no solute adsorbed onto the PAC. The mass balance for this system is as follows:

$$\left( \begin{array}{c} \text{Mass present} \\ \text{initially in solution} \end{array} \right) = \left( \begin{array}{c} \text{mass} \\ \text{adsorbed} \end{array} \right) + \left( \begin{array}{c} \text{mass remaining} \\ \text{in solution after} \\ \text{adsorption} \end{array} \right) \quad (7-68)$$

$$VC_0 = Mq + VC \quad (7-69)$$

where  $V$  = volume of liquid in vessel, L

$C_0$  = initial concentration of solute in vessel, mg/L

$M$  = mass of carbon, g

- $q$  = concentration of solute adsorbed to the activated carbon  
at any time, mg/g
- $C$  = concentration of the solute in the water after adsorption,  
mg/L

Equation 7-69 can be rearranged as follows:

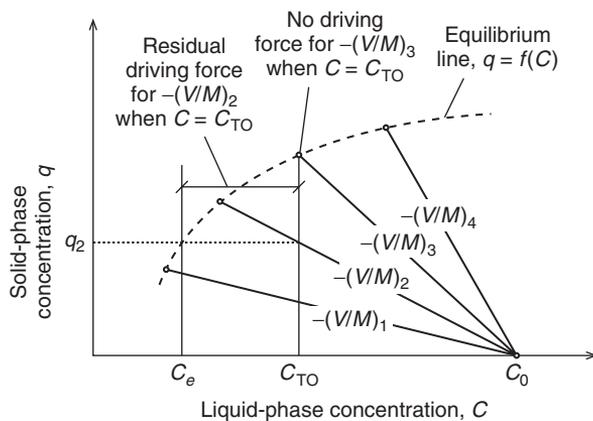

$$q = \frac{V}{M} (C_0 - C) \quad (7-70)$$

The operating line, which is the solute concentration in the extracting phase as a function of the concentration in the aqueous phase at any point in time after contact has started, is defined by Eq. 7-70. When the PAC is first added to the vessel, there is no solute on the PAC. As time proceeds, the solute becomes adsorbed onto the PAC, and  $q$  and  $C$  at a particular time are related to one another by the operating line. It should be noted that although adsorption in a batch reactor proceeds toward equilibrium over the passage of time, the operating line does not identify the time progression of the process but only relates the dependent variables  $q$  and  $C$ .

The operating diagram for the relationship described in Eq. 7-70 is shown on Fig. 7-7. Equation 7-70 is the equation of a straight line with a slope of  $-V/M$ , and several operating lines with different values for  $V/M$  have been shown. The equilibrium line is shown on Fig. 7-7 as a dashed line.

#### DRIVING FORCE

The driving force for mass transfer, as shown on Fig. 7-7, is the difference between the actual solute concentration in solution and the concentration in solution that would be in equilibrium with the extracting phase. Initially, the solute is entirely in the aqueous phase, and the solute is transferred rapidly to the PAC. As time progresses, the concentration on the PAC increases and the concentration in the aqueous phase decreases, which slows

**Figure 7-7**

Operating lines for a constant initial concentration  $C_0$  and different adsorbent doses,  $V/M$  (equilibrium line is also plotted for reference).

the rate of mass transfer. After a very long time, the solute concentration in the water is in equilibrium with the concentration on the PAC, and bulk mass transfer ceases. Thus, the concentration gradient, or driving force, is defined as the difference between the actual and equilibrium concentration  $C_e$  in the aqueous phase.

Because the equilibrium concentration is identified by the equilibrium line and the actual concentration (determined by mass balance) is identified by the operating line, the horizontal distance between these lines describes the concentration gradient. Equilibrium occurs and mass transfer ceases when the operating line and equilibrium line intersect.

### Analysis Using Operating Diagrams

The operating diagram can be used to determine the minimum amount of extracting phase required for treatment, which is an initial indicator of the feasibility of a process. For example, if millions of tons of activated carbon are required to treat a given water, then adsorption with activated carbon is not a feasible treatment option and no further analysis is necessary. If a separation process appears to be feasible based on the amount of extracting phase, then more detailed design and economic calculations are warranted.

An operating line analysis for an adsorption process is shown on Fig. 7-7. For a given volume of water, the quantity of PAC required can be defined by the  $V/M$  ratio, with greater values of  $V/M$  (greater slope of the operating line) corresponding to smaller amounts of PAC. If the treatment objective is the concentration shown as  $C_{TO}$  on Fig. 7-7, the minimum amount of PAC required can be determined from the operating line with the slope of  $(V/M)_3$ , which is the operating line that intersects the equilibrium line at the value of  $C_{TO}$ . Operating lines with greater slope, shown as  $(V/M)_4$ , intersect the equilibrium line at a concentration higher than  $C_{TO}$  and therefore would be unable to meet the treatment objective.

The operating diagram also qualitatively demonstrates the trade-off between the quantity of the extracting phase and the size of the contacting device. For the operating line identified as  $(V/M)_3$ , the driving force (horizontal distance between the equilibrium and operating lines) becomes infinitesimally small as equilibrium is approached. The small driving force results in a slow rate of mass transfer, requiring an exceedingly long time to reach the treatment objective. In a flow-through system treating a specified water flow rate, a long time corresponds to a long detention time and hence a very large contactor. The operating lines labeled as  $(V/M)_1$  and  $(V/M)_2$  have lower slopes, which correspond to greater quantities of carbon, but have larger concentration gradients when the actual concentration (operating line) reaches the treatment objective, resulting in shorter contact times. Thus, for the operating lines shown, the line labeled  $(V/M)_1$  would use the most carbon but have the smallest contactor, the line labeled  $(V/M)_2$  would have an intermediate carbon usage rate and contactor size, the line labeled  $(V/M)_3$  would use the minimum amount

of carbon but have a large (theoretically, infinitely large) contactor, and the line labeled  $(V/M)_4$  would be unable to meet the treatment objective.

Equation 7-70 is for a batch operation, but a similar relationship can be derived for cocurrent continuous plug flow operation. If a quantity of PAC per time,  $M_r$ , is added to water with a flow rate,  $Q$ , the mass balance is the same as presented previously in Eq. 7-68.

$$\left( \begin{array}{c} \text{Mass present} \\ \text{initially in solution} \end{array} \right) = \left( \begin{array}{c} \text{mass} \\ \text{adsorbed} \end{array} \right) + \left( \begin{array}{c} \text{mass remaining} \\ \text{in solution after} \\ \text{adsorption} \end{array} \right)$$

$$QC_0 = M_r q + QC \quad (7-71)$$

$$q = \frac{Q}{M_r} (C_0 - C) \quad (7-72)$$

where  $Q$  = flow rate, L/s

$C_0$  = initial concentration of solute in the solution, mg/L

$M_r$  = PAC feed rate, mass added per time, g/s

$C$  = concentration of the solute in the water at any time, mg/L

$q$  = concentration of solute adsorbed to the activated carbon at any time, mg/g

The PAC dosage in the plug flow system,  $M_r/Q$ , is identical to the PAC dosage in the batch reactor,  $M/V$ , and Eqs. 7-70 and 7-72 are essentially identical.

An example calculation of the minimum amount of extracting phase required for treatment is presented for PAC in Example 7-8.

### Example 7-8 Minimum amount of PAC required to achieve given level of treatment

Many adsorption equilibrium lines, as discussed in Chap. 15, can be described by the Freundlich isotherm:

$$q_e = KC_e^{1/n}$$

where  $q_e$  = equilibrium concentration of solute in solid phase, mg/g

$K$  = Freundlich capacity factor,  $(\text{mg/g})[\text{L/mg}]^{1/n}$

$C_e$  = equilibrium concentration of solute in aqueous phase, mg/L

$1/n$  = Freundlich intensity factor, dimensionless

Calculate the minimum dose of PAC that is required for the removal of geosmin, an odor-producing compound. The initial concentration is 50 ng/L, and the treatment objective  $C_{T0}$  is 5 ng/L. The  $K$  and  $1/n$  values for geosmin

are  $200 \text{ (mg/g)[L/mg]}^{1/n}$  and 0.39, respectively. A reasonable PAC dose would be less than 10 to 20 mg/L. Is the process feasible and should more detailed studies be conducted?

### Solution

1. The lowest PAC dose occurs when the PAC is used to capacity, which is when the concentration on the PAC would be in equilibrium with  $C_{T0}$ . The concentration on the PAC at equilibrium is calculated with the equilibrium relationship:

$$q_e = KC_{T0}^{1/n}$$

2. The minimum PAC dose occurs when the operating line (Eq. 7-70) intersects the equilibrium line at the treatment objective:

$$q_e = \frac{V}{M} (C_0 - C_{T0})$$

3. The intersection of the equilibrium and operating lines is determined by equating the two equations given above and solving for the minimum dose:

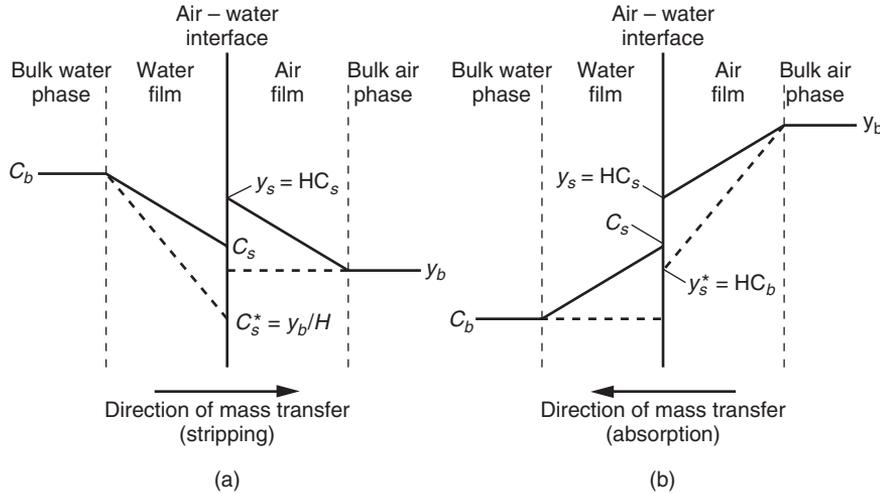

$$\begin{aligned} \left(\frac{M}{V}\right)_{\min} &= \frac{C_0 - C_{T0}}{KC_{T0}^{1/n}} = \frac{(50 \times 10^{-6} - 5 \times 10^{-6}) \text{ mg/L}}{200 \times (5 \times 10^{-6})^{0.39} \text{ mg/g}} \\ &= 2.63 \times 10^{-5} \text{ g/L} = 0.0263 \text{ mg/L} \end{aligned}$$

### Comment

A dosage of 0.0263 mg/L is within the acceptable range, and additional tests that simulate water plant conditions (jar tests) can be planned. The tests would be needed because the presence of natural organic matter (NOM) will reduce the adsorption capacity. Further, the computed value is the minimum dose of PAC, which yields an exceedingly small driving force as equilibrium is approached, resulting in an extremely low rate of mass transfer and an unreasonably large PAC contactor. In practice, the required dosage to remove geosmin is at least 100 times greater than 0.0263 mg/L because of the impact of NOM and mass transfer.

## 7-8 Mass Transfer across a Gas–Liquid Interface

The various models and correlations that have been developed to describe the transport across a single interface have been introduced and discussed in Secs. 7-4 and 7-5. In this section, the methods for describing the transport

**Figure 7-8**

Two-film model: mass transfer driving gradients that occur for (a) stripping and (b) absorption.

of solute across a gas–liquid interface are considered. Because boundary layers can form on both the liquid and gas sides of the interface, the two-film model can be used to describe mass transfer. Chemical reactions can increase the rate of mass transfer and are considered in the next section.

The driving force for mass transfer between one phase and another results from the displacement of the system from equilibrium. The two-film model describes the interaction of two films (one gas and one liquid) at the gas–liquid interface. The two situations where mass transfer occurs between air and water at steady state are shown on Fig. 7-8. The situation for stripping where mass is transferred from the water to the air is shown on Fig. 7-8a, and the situation for absorption in which mass is transferred from the air to the water is shown on Fig. 7-8b. A detailed explanation is only provided for stripping because the mechanisms and assumptions for mass transfer are essentially identical for both cases, and the only difference is that mass is transferred in the opposite direction.

The two-film model is used to describe the mass transfer rate for (a) the air stripping of VOCs such as methane, trichloroethane, and tetrachloroethane and other gases such as hydrogen sulfide and (b) the absorption of gases such as oxygen, carbon dioxide, nitrogen, or ozone. The following discussion will address the stripping of a volatile component A from water. As shown on Fig. 7-8a, the concentration of A in the bulk water is larger than the concentration of A at the air–water interface. Consequently, A diffuses from the bulk solution, where its liquid concentration is  $C_b$ , to the air–water interface, where its liquid concentration is  $C_s$ . The difference between  $C_b$

### Conditions in Bulk Solution

and  $C_s$  is the driving force for stripping in the liquid phase. There is a discontinuity in the concentration at the air–water interface because A partitions in air at a different concentration based on equilibrium or Henry’s law (see Chap. 14). Similarly, the concentration of A in the air at the air–water interface,  $y_s$ , is larger than the concentration of A in the bulk air,  $y_b$ , and it diffuses from the air–water interface to the bulk air. The difference between  $y_s$  and  $y_b$  is the driving force for stripping in the gas phase.

### Conditions at Interface

Local equilibrium occurs at the air–water interface because random molecular movement (on a local scale of nanometers in water and thousands of nanometers on the air side) causes constituent A to dissolve in the aqueous phase and volatilize into the air at a rate more rapidly than diffusion to or away from the air–water interface. Accordingly, local equilibrium may be assumed and Henry’s law can be used to relate  $y_s$  to  $C_s$  (Lewis and Whitman, 1924):

$$y_s = HC_s \quad (7-73)$$

where  $y_s$  = gas-phase concentration of A at air–water interface, mg/L

$H$  = Henry’s law constant, L of water/L of air, dimensionless

$C_s$  = liquid-phase concentration of A at air–water interface, mg/L

For a dilute solution where no accumulation occurs at the surface, the flux of A through the gas-phase film must be equal to the flux through the liquid-phase film. Thus

$$J_A = k_l (C_b - C_s) = k_g (y_s - y_b) \quad (7-74)$$

where  $J_A$  = flux of A across air–water interface, mg/m<sup>2</sup>·s

$k_l$  = liquid-phase mass transfer coefficient for rate at which contaminant A is transferred from bulk aqueous phase to air–water interface, m/s

$C_b$  = liquid-phase concentration of A in bulk solution, mg/L

$C_s$  = liquid-phase concentration of A at air–water interface, mg/L

$k_g$  = gas-phase mass transfer coefficient for rate at which contaminant A is transferred from air–water interface to bulk gas phase, m/s

$y_s$  = gas-phase concentration of A at air–water interface, mg/L

$y_b$  = gas-phase concentration of A in bulk solution, mg/L

Both  $k_l$  and  $k_g$  are sometimes referred to as local mass transfer coefficients for the liquid and gas phases because they depend upon the conditions at or near the air–water interface in their particular phase. The flux cannot be determined directly from Eq. 7-74 because the interfacial concentrations  $y_s$  and  $C_s$  are not known and cannot be measured easily. Consequently, it is necessary to define another flux equation in terms of hypothetical concentrations that are easy to determine. If it is hypothesized that all

the resistance to mass transfer is on the liquid side, then there is no concentration gradient on the gas side and a hypothetical concentration,  $C_s^*$ , can be defined as shown on Fig. 7-8a:

$$y_b = HC_s^* \quad (7-75)$$

where  $C_s^*$  = liquid-phase concentration of A that is in equilibrium with bulk air concentration, mg/L

Alternatively, it can be hypothesized that all the resistance to mass transfer is on the gas side, in which case there is no concentration gradient on the liquid side and a hypothetical concentration  $y_s^*$  can be defined as shown on Fig. 7-8b:

$$y_s^* = HC_b \quad (7-76)$$

where  $y_s^*$  = gas-phase concentration of A that is in equilibrium with bulk water concentration, mg/L

For stripping operations, mass balances are normally written on the liquid side, and it is convenient to calculate the mass transfer rate using the hypothetical concentration  $C_s^*$  and an overall mass transfer coefficient  $K_L$ , as shown in the equation

$$J_A = K_L (C_b - C_s^*) \quad (7-77)$$

where  $J_A$  = mass flux of A across air–water interface, mg/m<sup>2</sup>·s

$K_L$  = overall mass transfer coefficient, m/s

$C_b$  = liquid-phase concentration of A in bulk solution, mg/L

$C_s^*$  = liquid-phase concentration of A at air–water interface assuming no concentration gradient in air phase, mg/L

Since no mass accumulates at the interface, the hypothetical, gas-side, and liquid-side mass fluxes given in Eqs. 7-74 and 7-77 must all be equal to one another:

$$J_A = k_l (C_b - C_s) = k_g (y_s - y_b) = K_L (C_b - C_s^*) \quad (7-78)$$

Equation 7-78 relates  $K_L$  to  $k_l$  and  $k_g$  and accounts for mass transfer resistances on both the gas and liquid sides of the interface, which is known as the two-film model. The individual expressions in Eq. 7-78 can be rearranged as follows:

$$C_b - C_s = \frac{J_A}{k_l} \quad (7-79)$$

$$y_s - y_b = \frac{J_A}{k_g} \quad (7-80)$$

$$C_b - C_s^* = \frac{J_A}{K_L} \quad (7-81)$$

### Overall Mass Transfer Relationship

The overall mass transfer coefficient can be related to the local mass transfer coefficients starting with the relationship

$$C_b - C_s^* = (C_b - C_s) + (C_s - C_s^*) \quad (7-82)$$

Substituting Eqs. 7-73 and 7-75 into Eq. 7-80, and then substituting Eqs. 7-79 to 7-81 into Eq. 7-82 yields

$$\frac{J_A}{K_L} = \frac{J_A}{k_l} + \frac{J_A}{Hk_g} \quad (7-83)$$

or

$$\frac{1}{K_L} = \frac{1}{k_l} + \frac{1}{Hk_g} \quad (7-84)$$

Thus, according to the two-film model, the mass flux across the interface can be calculated using the expression

$$J_A = K_L \left( C_b - \frac{y_b}{H} \right) \quad (7-85)$$

Equation 7-85 is convenient to use because the driving force for stripping ( $C_b - y_b/H$ ) involves concentrations that are easy to measure. The overall mass transfer coefficient can be estimated from the local mass transfer coefficients, and the local mass transfer coefficients can be determined from correlations.

### Determining the Phase That Controls Mass Transfer

Evaluating which phase controls the mass transfer rate is important in optimizing the design and operation of aeration and air-stripping processes. For example, when the liquid-phase resistance controls the mass transfer rate, increasing the mixing of the air will have little impact on the removal efficiency. From Eq. 7-84, the overall resistance to mass transfer is equal to the sum of the resistance in the liquid and gas phases and can be rewritten as

$$R_T = R_L + R_G/H \quad (7-86)$$

where  $R_T$  = overall resistance to mass transfer, equal to  $1/K_L$ , s/m

$R_L$  = liquid-phase resistance to mass transfer, equal to  $1/k_l$ , s/m

$R_G$  = gas-phase resistance to mass transfer, equal to  $1/k_g$ , s/m

To evaluate which phase controls the rate of mass transfer, Eq. 7-86 can be rearranged as follows to evaluate the liquid resistance as a fraction of total resistance:

$$\frac{R_L}{R_T} = \frac{1/k_l}{1/k_l + 1/Hk_g} = \frac{H}{H + k_l/k_g} \quad (7-87)$$

Based on Eq. 7-87, the fraction of total resistance contributed by the liquid resistance depends on the value of  $H$  relative to  $k_l/k_g$ . Reported values of

the ratio  $k_g/k_l$  range are (1) 40 to 200 (Munz and Roberts, 1989) for surface aerators, (2) 5 to 50 for packed towers, and (3) 2.2 to 3.6 for diffused bubble aeration (Hsieh et al., 1993). Inverting these values to obtain  $k_l/k_g$  yields 0.005 to 0.025 for surface aerators, 0.02 to 0.2 for packed towers, and 0.28 to 0.45 for diffused bubble aeration. Assuming  $k_l/k_g = 0.01$ , the liquid phase controls the rate of mass transfer for compounds with  $H$  values greater than about 0.05. The gas phase controls mass transfer of compounds with  $H$  values less than 0.002. For compounds with  $H$  values between 0.002 and 0.05, the liquid and the gas phase both control the rate of mass transfer. A higher value of  $H$  indicates that the solute will have a greater concentration in the gas phase for a given concentration in the liquid phase, so the general trend expressed by Eq. 7-87 is that the phase that is less preferred by the solute is the phase that controls the mass transfer rate.

When designing aeration and stripping processes, the rate of mass transfer is often expressed on a volumetric basis rather than an interfacial area basis. The flux term is converted to a volumetric basis by multiplying by the surface area available for mass transfer per contactor vessel volume,  $a$ , as defined in Sec. 7-4. Equation 7-84 can be expressed in terms of a volumetric mass transfer rate by dividing by the area  $a$ :

$$\frac{1}{K_L a} = \frac{1}{k_l a} + \frac{1}{H k_g a} \quad (7-88)$$

where  $K_L$  = overall liquid mass transfer coefficient, m/s  
 $a$  = specific surface area  $\text{m}^2/\text{m}^3$   
 $k_l$  = liquid-phase mass transfer coefficient, m/s  
 $k_g$  = gas-phase mass transfer coefficient, m/s

The combined coefficient  $K_L a$  can then be incorporated into equations for mass transfer across a gas–liquid interface, using Eqs. 7-46 and 7-73:

$$M_A = K_L a \left( C_b - \frac{y_b}{H} \right) V \quad (7-89)$$

where  $M_A$  = mass flow of A, mg/s  
 $K_L a$  = overall liquid-side mass transfer coefficient,  $\text{s}^{-1}$   
 $V$  = volume of contactor,  $\text{m}^3$

To relate the mass transfer coefficients of one compound to another when mass transfer resistances exist on both the water and gas side of the interface, Eq. 7-84 or 7-88 is combined in several ways depending on which mass transfer coefficients are known. In one approach the overall mass transfer coefficient of B can be determined from the gas- and liquid-side

### Application of the Two-Film Model

### Relationship between Overall Mass Transfer Coefficients and Diffusing Species

mass transfer coefficients for compound A. The following equation can be derived by combining Eq. 7-88 with Eqs. 7-64 and 7-67:

$$\frac{1}{K_{L,B}a} = \frac{1}{k_{l,A}a \left(\frac{D_{l,B}}{D_{l,A}}\right)^n} + \frac{1}{H_B k_{g,A}a \left(\frac{D_{g,B}}{D_{g,A}}\right)^m} \quad (7-90)$$

where  $K_{L,B}$  = overall mass transfer rate of B,  $s^{-1}$

$a$  = specific surface area  $m^2/m^3$

$k_{l,A}$  = liquid-phase mass transfer coefficient of compound A,  $m/s$

$D_{l,B}$  = liquid-phase diffusion coefficient of compound B,  $m^2/s$

$D_{l,A}$  = liquid-phase diffusion coefficient of compound A,  $m^2/s$

$n$  = empirical exponent

$H_B$  = Henry's constant for compound B, L of water/L of air, dimensionless

$k_{g,A}$  = gas-phase mass transfer coefficient of compound A,  $m/s$

$D_{g,A}$  = gas-phase diffusion coefficient of compound A,  $m^2/s$

$D_{g,B}$  = gas-phase diffusion coefficient of compound B,  $m^2/s$

$m$  = empirical exponent

As discussed in Sec. 7-5 and shown in Table 7-6,  $n$  and  $m$  have values between  $\frac{1}{2}$  for no boundary layer (no velocity gradient at the interface) and  $\frac{2}{3}$  for a boundary layer (velocity gradient at the interface). Normally, the gas side has a velocity gradient and the water side has no velocity gradient, so that  $n$  and  $m$  are  $\frac{1}{2}$  and  $\frac{2}{3}$ , respectively.

In another approach, the ratio of  $k_g/k_l$  is assumed to be a constant for all compounds. This ratio is relatively constant for a given device and does not depend on the compound (Hsieh et al., 1993; Munz and Roberts, 1989). Therefore, the following simplification can be made:

$$\frac{k_{g,i}a}{k_{l,i}a} = \frac{k_g}{k_l} \quad (7-91)$$

where  $k_{g,i}$  = gas-phase mass transfer coefficient of compound  $i$ ,  $m/s$

$k_{l,i}$  = liquid-phase mass transfer coefficient of compound  $i$ ,  $m/s$

$a$  = specific surface area  $m^2/m^3$

$k_g/k_l$  = ratio of gas-phase mass transfer coefficient to liquid-phase mass transfer coefficient, which tends to be constant for a given separation device

Values of the inverse of the ratio  $k_g/k_l$  were presented in the earlier discussion on determination of the phase that controls the mass transfer rate.

Rewriting Eq. 7-88 in terms of a compound  $c$  yields

$$\frac{1}{K_{L,i}a} = \frac{1}{k_{l,i}a} + \frac{1}{H_i k_{g,i}a} \quad (7-92)$$

Multiplying both sides of Eq. 7-92 by  $k_{l,i}a$  and solve for  $K_{L,i}a$  yields

$$K_{L,i}a = k_{l,i}a \left[ 1 + \frac{1}{H_i (k_{g,i}a/k_{l,i}a)} \right]^{-1} \quad (7-93)$$

where  $K_{L,i}$  = overall mass transfer coefficient for compound  $i$ , m/s  
 $H_i$  = Henry's constant for compound  $i$ , L of water/L of air,  
dimensionless

Substituting Eq. 7-91 into Eq. 7-93 results in the expression

$$K_{L,i}a = k_{l,i}a \left[ 1 + \frac{1}{H_i (k_g/k_l)} \right]^{-1} \quad (7-94)$$

It is convenient to choose a reference compound that is easy to measure and has all resistance to mass transfer on the liquid side, such as oxygen, because the overall mass transfer coefficient is equal to the liquid-phase mass transfer coefficient for such a compound:

$$\frac{1}{K_{L,O_2}a} = \frac{1}{k_{l,O_2}a} + \frac{1}{H_{O_2}k_{g,O_2}a} \cong \frac{1}{k_{l,O_2}a} \quad (7-95)$$

$$K_{L,O_2}a = k_{l,O_2}a \quad (7-96)$$

where  $K_{L,O_2}$  = overall mass transfer coefficient for oxygen,  $s^{-1}$   
 $k_{l,O_2}$  = liquid-phase mass transfer rate constant for oxygen,  $s^{-1}$   
 $a$  = specific surface area  $m^2/m^3$   
 $H_{O_2}$  = Henry's law constant for oxygen, L of water/L of air,  
dimensionless  
 $k_{g,O_2}$  = gas-phase mass transfer coefficient for oxygen, m/s

The mass transfer coefficient of a given compound,  $i$ , can be related to the mass transfer coefficient for oxygen by dividing Eq. 7-94 by Eq. 7-96:

$$\frac{K_{L,i}a}{K_{L,O_2}a} = \frac{k_{l,i}a}{k_{l,O_2}a} \left[ 1 + \frac{1}{H_i (k_g/k_l)} \right]^{-1} \quad (7-97)$$

where  $K_{L,i}$  = overall mass transfer coefficient for component  $i$ ,  $s^{-1}$   
 $k_{l,i}$  = liquid-phase mass transfer coefficient for component  $i$ ,  $s^{-1}$   
 $H_i$  = Henry's law constant for component  $i$ , L of water/L of air,  
dimensionless  
 $a$  = specific surface area  $m^2/m^3$   
 $k_l$  = liquid-phase mass transfer coefficient, m/s

$k_g$  = gas-phase mass transfer coefficient, m/s  
 $k_g/k_l$  = ratio of gas-phase to liquid-phase mass transfer coefficients, which tends to be relatively constant for a given device and does not depend on the compound

The ratio of the mass transfer coefficients  $k_{l,i}a/k_{l,O_2}a$  in Eq. 7-97 can be determined from Table 7-6 for the case where the mass transfer resistance is in the water at the air–water interface:

$$\frac{k_{l,i}a}{k_{l,O_2}a} = \frac{k_{l,i}}{k_{l,O_2}} = \left( \frac{D_{l,i}}{D_{l,O_2}} \right)^{1/2} \quad (7-98)$$

where  $D_{l,i}$  = liquid-phase diffusion coefficient of compound  $i$ ,  $m^2/s$   
 $D_{l,O_2}$  = liquid-phase diffusion coefficient of oxygen,  $m^2/s$

The final expression for determining the mass transfer coefficient of any compound  $i$  using oxygen as a reference compound results from substituting Eq. 7-98 into Eq. 7-97:

$$K_{L,i}a = K_{L,O_2}a \left( \frac{D_{l,i}}{D_{l,O_2}} \right)^{1/2} \left[ 1 + \frac{1}{H_i(k_g/k_l)} \right]^{-1} \quad (7-99)$$

The procedure for determining an overall mass transfer coefficient from diffusion coefficients is demonstrated in Example 7-9.

### Example 7-9 Determining the overall mass transfer coefficient using oxygen as reference compound

Calculate the overall mass transfer coefficient  $K_La$  of benzene at 20°C using oxygen as a reference compound for a mechanical surface aerator. Given: The mass transfer rate constant of oxygen ( $K_{L,O_2}a$ ) for the device has been measured at  $0.0015 \text{ s}^{-1}$ . From Table 7-1, the liquid diffusion coefficient of benzene at 20°C is  $D_{l,b} = 1.02 \times 10^{-9} \text{ m}^2/\text{s}$ . From Example 7-6, the liquid diffusion coefficient of oxygen at 20°C is  $D_{l,O_2} = 2.06 \times 10^{-9} \text{ m}^2/\text{s}$ . The Henry's law constant of benzene at 20°C is  $H = 0.188$  (see Chap. 14).

#### Solution

1. Determine  $k_g/k_l$ . As discussed in the section on determination of the phase that controls mass transfer, for mechanical surface aeration devices,  $k_g/k_l$  values vary from 40 to 200. Choose a value of  $k_g/k_l = 40$ .

2. Determine  $K_L a$  for benzene from Eq. 7-99:

$$\begin{aligned} K_L a_{(\text{benzene})} &= K_{L,O_2} a \left( \frac{D_{l(\text{benzene})}}{D_{l,O_2}} \right)^{1/2} \left[ 1 + \frac{1}{H(k_g/k_l)} \right]^{-1} \\ &= (0.0015 \text{ s}^{-1}) \left( \frac{1.02 \times 10^{-9}}{2.06 \times 10^{-9}} \right)^{1/2} \left[ 1 + \frac{1}{(0.188)(40)} \right]^{-1} \\ &= 0.00093 \text{ s}^{-1} \end{aligned}$$

### Comment

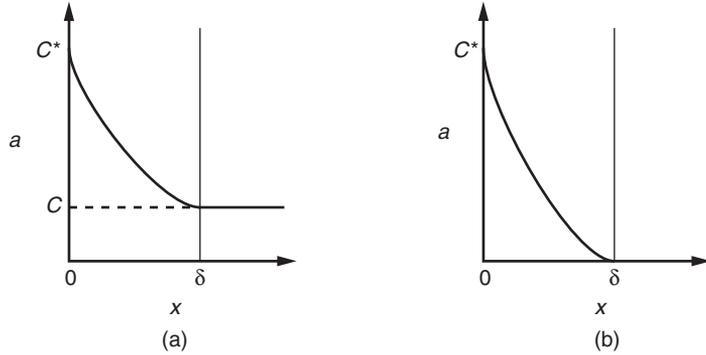

Choosing a value of  $k_g/k_l = 40$  represents a conservative estimate of the mass transfer rate constant. The mass transfer rate constant predicted by Eq. 7-99 will be at its lowest value for the range of  $k_g/k_l$  values applicable to mechanical surface aeration ( $40 \leq k_g/k_l \leq 200$ ) when  $k_g/k_l = 40$ .

## 7-9 Enhancement of Mass Transfer across an Interface by Chemical Reactions

If a chemical reaction occurs after a solute enters the water at the air–water interface, the mass transfer rate of absorption may be faster than the rate of transfer by diffusion alone. The reason for the increase is that the reaction occurs within the mass transfer boundary layer. The reaction causes a much sharper concentration gradient; and, as predicted by Fick's first law, the larger concentration gradient causes a faster mass transfer rate. There are two possible situations: (a) as shown on Fig. 7-9a, some solute is left after the mass transfer boundary layer and (b) as shown on Fig. 7-9b, there is no solute left after the mass transfer boundary layer because the chemical reaction proceeds rapidly.

Several gases commonly used in water treatment applications, notably chlorine, sulfur dioxide, carbon dioxide, and ozone, undergo hydrolysis reactions or rapid chemical reactions with other solutes and water. The increase in rate of mass transfer must be considered in the process design of absorption equipment. The magnitude of this increase depends on the type of chemical reaction (e.g., reversible, irreversible, series), reaction order, reaction rate constants, concentration of reactants, and the solute diffusion coefficients (Danckwerts, 1970).

While innumerable reaction combinations are possible, chemical reactions for gases in water used in water treatment fall mainly in two categories: first-order, irreversible reactions and rapid or instantaneous reversible reactions.

**Figure 7-9**

Concentration profiles in the mass transfer boundary layer for two situations where a chemical reaction is occurring: (a) some solute is left after the mass transfer boundary layer and (b) no solute is left after the mass transfer boundary layer.

Consider a first-order, irreversible reaction in the water phase with rate constant  $k_1$ , as illustrated by the nearly irreversible reaction of  $\text{SO}_2$  in water:

where  $k_r$  = first-order reaction rate constant,  $\text{s}^{-1}$

Assuming that mass transfer resistances in the gas phase are negligible, it has been shown that the gas transfer flux at steady state is given by the expression (Danckwerts, 1970)

$$J_A = k_l \left[ C^* - \frac{C}{\cosh(\text{Ha})} \right] \frac{\text{Ha}}{\tanh(\text{Ha})} \quad (7-101)$$

where  $J_A$  = gas transfer flux,  $\text{mg}/\text{m}^2 \cdot \text{s}$   
 $k_l$  = liquid-phase mass transfer coefficient,  $\text{m}/\text{s}$   
 $C^*$  = liquid-phase concentration in equilibrium with bulk gas concentration,  $\text{mg}/\text{L}$   
 $C$  = concentration in bulk water,  $\text{mg}/\text{L}$   
 $\text{Ha}$  = Hatta number, dimensionless  
 $\cosh$  = hyperbolic cosine  
 $\tanh$  = hyperbolic tangent

The Hatta number is given by the expression

$$\text{Ha} = \frac{\sqrt{D_l k_r}}{k_l} \quad (7-102)$$

where  $D_l$  = diffusion coefficient of solute in water,  $\text{m}^2/\text{s}$   
 $k_r$  = first-order reaction rate constant,  $\text{s}^{-1}$

When a single gas such as pure chlorine or carbon dioxide is absorbed, mass transfer resistances in the gas phase are negligible, and Eq. 7-101 can be used to predict the enhancement of the mass transfer rate due to reaction. The mass transfer coefficient  $k_l$  shown in Eq. 7-101 can be estimated using a mass transfer correlation, and the Hatta number can be calculated from the diffusion coefficient and first-order rate constant of the species.

The second term that appears on the right-hand side of Eq. 7-101 defines the driving force. If  $Ha > 5$ , the reaction occurs entirely in the water near the interface, and the bulk water concentration of the dissolving solute is zero, as shown on Fig. 7-9b. In this case, Eq. 7-101 simplifies to the following expression [note that  $\tanh(5) = 1$ ]:

$$J_A = k_l Ha C^* \quad (7-103)$$

The flux in the absence of reaction for a zero bulk solution concentration would be

$$J_A = k_l C^* \quad (7-104)$$

By comparing Eqs. 7-103 and 7-104, it is seen that the rate of mass transfer is enhanced by a factor that is equal to the Hatta number,  $Ha$ :

$$E_{\text{flux}} = \frac{\text{flux with reaction}}{\text{flux without reaction}} = \frac{(Ha) k_l}{k_l} = Ha \quad (7-105)$$

where  $E_{\text{flux}}$  = enhancement in mass transfer due to reaction

Enhancement factors for many other chemical reaction types are summarized by several authors (Danckwerts, 1970; Levenspiel, 1998; Sherwood et al., 1975). Enhancements of  $Ha = 1000$  are possible for fast radical reactions. The impact of hydrolysis on the rate of mass transfer is demonstrated in Example 7-10.

### Example 7-10 Impact of rapid hydrolysis reactions on mass transfer

Many gases added to water during water treatment that undergo rapid hydrolysis reactions can accelerate the rate of absorption. Calculate the enhancement of initial mass transfer rate for the absorption of pure gaseous chlorine into water. The initial chlorine concentration in the bulk solution is equal to zero. Given: The temperature is  $20^\circ\text{C}$ . Tests were conducted using oxygen, and the oxygen liquid-phase mass transfer coefficient  $k_{l,O_2}$  was determined to be  $10^{-4}$  m/s. Using Eq. 7-32, the liquid-phase diffusion coefficient for chlorine,  $D_{l,Cl_2}$ , based on a molar volume of  $43.2 \text{ cm}^3/\text{mol}$  ( $2 \times 21.6$ , see Table 7-3), is  $1.41 \times 10^{-9} \text{ m}^2/\text{s}$ . Using Eq. 7-35, the liquid-phase diffusion coefficient for oxygen,  $D_{l,O_2}$ , is  $2.06 \times 10^{-9} \text{ m}^2/\text{s}$ . The rate constant  $k_r$  for chlorine is  $11 \text{ s}^{-1}$  at  $20^\circ\text{C}$  (Eigen and Kustin, 1962). Chlorine reacts with water as follows:

The reaction to form HOCl is nearly complete and can be considered a pseudo-first-order, irreversible reaction.

### Solution

The enhancement is equal to the relative initial mass transfer rate, which is equal to the ratio of the mass transfer flux for chlorine enhanced by reaction to the mass transfer flux for chlorine in the absence of reaction.

1. The initial mass transfer flux for chlorine without considering the hydrolysis reaction is given by Eq. 7-45, for which the initial chlorine concentration in the bulk solution is equal to 0:

$$J_{\text{Cl}_2} = k_{l,\text{Cl}_2} C_{\text{Cl}_2}^*$$

2. The enhanced gas transfer flux due to reaction is described by the following expression (Eq. 7-101) when the bulk concentration is zero:

$$J_{\text{Cl}_2} = k_{l,\text{Cl}_2} C_{\text{Cl}_2}^* \frac{\text{Ha}}{\tanh(\text{Ha})}$$

3. Thus, the enhancement of the initial mass transfer rate for the absorption of pure gaseous chlorine is given by the ratio of the mass transfer with (step 2) and without (step 1) the hydrolysis reaction.

$$\text{Relative initial mass transfer rate} = \frac{k_{l,\text{Cl}_2} [\text{Ha}/\tanh(\text{Ha})]}{k_{l,\text{Cl}_2}} = \frac{\text{Ha}}{\tanh(\text{Ha})}$$

- a. Determine  $k_{l,\text{Cl}_2}$  using the relationship for mass transfer resistance in the water at the air–water interface in Table 7-6. Rearranging the expression in Table 7-6 to solve for  $k_{l,\text{Cl}_2}$  yields

$$\begin{aligned} k_{l,\text{Cl}_2} &= k_{l,\text{O}_2} \left( \frac{D_{l,\text{Cl}_2}}{D_{l,\text{O}_2}} \right)^{1/2} = (10^{-4} \text{ m/s}) \left( \frac{1.41 \times 10^{-9}}{2.06 \times 10^{-9}} \right)^{1/2} \\ &= 8.26 \times 10^{-5} \text{ m/s} \end{aligned}$$

- b. Determine Ha using Eq. 7-102:

$$\begin{aligned} \text{Ha} &= \frac{\sqrt{D_l k_r}}{k_l} = \frac{\sqrt{D_{l,\text{Cl}_2} k_r}}{k_{l,\text{Cl}_2}} = \frac{[(1.41 \times 10^{-9} \text{ m}^2/\text{s}) (11 \text{ s}^{-1})]^{1/2}}{(8.26 \times 10^{-5} \text{ m/s})} \\ &= 1.51 \end{aligned}$$

- c. Determine  $\tanh(\text{Ha})$ :

$$\tanh(\text{Ha}) = \tanh(1.51) = 0.907$$

d. Determine the relative rate:

$$\text{Relative rate} = \frac{\text{Ha}}{\tanh(\text{Ha})} = \frac{1.51}{0.907} = 1.66$$

### Comment

The initial mass transfer rate for chlorine is 66 percent faster because of the hydrolysis reaction. The value of  $\cosh(\text{Ha})$  for chlorine is 2.37; consequently, the second term in the mass transfer rate expression (see Eq. 7-101) is lower by a factor of 2.37 because of the hydrolysis of chlorine, and the mass transfer rate for chlorine would always be significantly enhanced by chemical reaction. Therefore, the mass transfer device can be smaller than expected by considering mass transfer alone.

## Problems and Discussion Topics

- 7-1 Explain which method or method(s) of estimating diffusion coefficients are best suited for the following cases:
- Methane gas diffusing in water
  - A sugar cube diffusing in a cup of iced tea
  - A globular protein diffusing in blood
  - NaCl diffusing in water
- 7-2 Using the Stokes–Einstein equation, derive an expression for diffusion coefficient  $D_l$  of a large molecule diffusing through water as a function of the water temperature  $T$ , water viscosity  $\mu_l$ , molecular weight of the molecule (MW), and molecular density of the molecule ( $\rho_M$ ). *Hint:* Use the definition of density to relate  $\rho_M$  to MW and molecular diameter  $d_M$ . Be sure to specify units of measure.
- 7-3 Estimate the diffusion coefficient for humic acid in water at 25°C using (a) the Stokes–Einstein equation and (b) the Polson equation. The MW of humic acid is 3000 and molecular diameter is 0.8 nm.
- 7-4 Use (a) the Hayduk–Laudie correlation and (b) the Nernst–Haskell equation to estimate the diffusion coefficient of acetic acid ( $\text{CH}_3\text{COOH}$ ) in water at 25°C assuming no electrical field is present in the solution. Compare the results from these two different methods to the measured value cited in Table 7-1. Assume  $\text{CH}_3\text{COOH}$  is fully protonated for the Hayduk–Laudie correlation and fully dissociated for the Nernst–Haskell equation. *Hint:* One of the oxygen atoms in  $\text{CH}_3\text{COOH}$  has a double bond to carbon while the other oxygen has a single bond to hydrogen and a single bond to carbon.

- 7-5 Using (a) the Hayduk–Laudie correlation and (b) the Nernst–Haskell equation, estimate the diffusion coefficient in water of one of the following compounds (compound to be selected by the instructor): chloroacetate ( $\text{ClCH}_2\text{COOH}$ ), cyanoacetate ( $\text{CNCH}_2\text{COOH}$ ), or benzoic acid ( $\text{C}_6\text{H}_5\text{COOH}$ ). Calculate the diffusion coefficient at the following temperatures: 10, 15, 20, 25, 30, and 40°C. Compare the two methods (Hayduk–Laudie correlation and Nernst–Haskell equation) by plotting the diffusion coefficient as a function of temperature.
- 7-6 Estimate the diffusion coefficient of the dissolved gas  $\text{CO}_2$  in water at 25°C. Compare the result to the value given in Table 7-1.
- 7-7 Estimate the diffusion coefficient of one of the following dissolved gases (compound to be selected by the instructor) in water:  $\text{O}_2$ ,  $\text{CO}_2$ ,  $\text{Cl}_2$ , or  $\text{NH}_3$ . Calculate the diffusion coefficient at the following temperatures: 10, 15, 20, 25, 30, and 40°C and plot as a function of temperature.
- 7-8 Determine the specific surface area (the area available for mass transfer per volume) of the particle, for the following particles: sphere (diameter  $d$ ), square (side length  $L$ ), and cylinder (length  $L$  and diameter  $d$ ).
- 7-9 Determine the specific surface area (the area available for oxygen transfer per volume) for a concrete sewer pipe that has a circular cross section of radius  $r$  filled to a channel height  $h$  and having a length  $L$  for the following cases: (a)  $h \leq r$  and (b)  $h > r$ .
- 7-10 Raw water that has an influent pH of 2.8 is to be fed to a packed bed of crushed limestone to raise the pH and add hardness (as  $\text{Ca}^{2+}$ ). The temperature is 25°C, the bed porosity is 0.5, and the particle sphericity is 0.75. Calculate the film transfer coefficient for limestone media for 0.5-, 1.5-, 2-, or 3- cm limestone particles (particle size to be specified by the instructor). The flow rate is 800 L/min and the superficial velocity is 10 m/h. Use the Nernst–Haskell equation to estimate the diffusion coefficient.
- 7-11 Determine the mass transfer coefficient of tetrachloroethene (PCE) on the water side of an air–water interface by relating mass transfer coefficients and diffusivities of PCE to those of oxygen. Given: The temperature is 15°C. Calculate the liquid diffusion coefficient of PCE at 15°C from the Hayduk–Laudie correlation. The mass transfer coefficient of oxygen in the mass transfer device at 15°C is  $k_{l,\text{O}_2} = 0.0045$  m/s.
- 7-12 During an experiment, various amounts of PAC are added to separate 500-mL bottles filled with water containing 25 mg/L of an organic contaminant. The contents of the sealed bottles were mixed and allowed to equilibrate for 2 weeks (this is adequate time to achieve

equilibrium). Analysis of the water revealed that the aqueous-phase organic contaminant decreased to the concentrations specified in the table below. Plot the operating lines (McCabe–Thiele diagram) and specify the  $V/M$  ratios. Draw the phase equilibrium line.

Item	Bottle				
	A	B	C	D	E
PAC dosage, mg	6	10	20	40	200
Aqueous equilibrium concentration, mg/L	16.2	11.7	6.1	3.1	2.1

7-13 Derive the following expression based on the two-film model:

$$\frac{1}{K_G a} = \frac{H}{k_l a} + \frac{1}{k_g a}$$

7-14 Many gases added to water during water treatment undergo rapid hydrolysis reactions that accelerate the rate of absorption. Calculate the enhancement of initial mass transfer rate for the absorption of carbon dioxide into water. The temperature is 20°C. Tests were conducted using oxygen, and the oxygen liquid-phase mass transfer coefficient was determined to be  $10^{-4}$  m/s. The liquid diffusion coefficient for oxygen,  $D_{l,O_2}$ , is  $2.067 \times 10^{-9}$  m<sup>2</sup>/s. The rate constant  $k_1$  for CO<sub>2</sub> is 0.02 s<sup>-1</sup>. The CO<sub>2</sub> reacts with water as follows:

At neutral pH, the absorption of carbon dioxide can be thought of as the following irreversible reaction:

7-15 Estimate the enhancement of the mass transfer rate for SO<sub>2</sub> absorption. For SO<sub>2</sub>, the pertinent reactions are

At neutral pH, H<sub>2</sub>SO<sub>3</sub> rapidly dissociates, and the SO<sub>2</sub> reaction with water becomes pseudo–first order, given as

For  $\text{SO}_2$ , the rapid hydrolysis reaction dramatically enhances the rate of absorption. The first-order rate constant  $k_1$  at  $20^\circ\text{C}$  is  $3.4 \times 10^6 \text{ s}^{-1}$  (Eigen et al., 1961).

- 7-16 Calculate the mass transfer rate constant of tetrachloroethene (PCE),  $K_L a$ , at  $13^\circ\text{C}$  using oxygen as a reference compound for a mechanical surface aerator. Given: The mass transfer rate constant of oxygen is  $K_{L,\text{O}_2} a = 0.0015 \text{ s}^{-1}$ . Calculate the liquid diffusion coefficient of PCE at  $13^\circ\text{C}$  using the Hayduk–Laudie correlation. The Henry's law constant of PCE at  $13^\circ\text{C}$  is  $H = 0.50$ .

## Terminology for Chemical Oxidation and Reduction

---

<b>Term</b>	<b>Definition</b>
Advanced oxidation processes	Processes that generate hydroxyl radical at room temperature and pressure.
Anode	Electrode in a electrochemical cell where oxidation takes place.
Cathode	Electrode in a electrochemical cell where reduction takes place.
Chromophores	Functional groups or bonds on chemical compounds responsible for the absorption of light.
Conventional oxidation processes	Oxidation processes that achieve oxidation without the generation of hydroxyl radicals,
Electron acceptor	Reactant that gains electrons in a redox reaction; an oxidant.
Electron donor	Reactant that loses electrons in a redox reaction; a reductant.
Oxidant	Reactant that causes the oxidation of a reduced species in a redox reaction. Oxidants are electron acceptors.
Oxidation reaction	Chemical half-reaction in which a reactant loses electrons.
Reductant	Reactant that causes the reduction of an oxidized species in a redox reaction. Reductants are electron donors.
Redox reaction	Abbreviated name for oxidation–reduction reaction
Reduction reaction	Chemical half-reaction in which a reactant gains electrons.

---

In water treatment, chemical oxidation and reduction processes are used for the treatment of specific inorganic or organic species found in water. For organic compounds, the purpose is to convert compounds into harmless or nonobjectionable forms. For example, it is desirable to oxidize toxic organic compounds into carbon dioxide and mineral acids (e.g., HCl) or taste and odor compounds into nonodorous compounds. Inorganic metal species (e.g., iron or manganese) are oxidized to insoluble forms and are removed by precipitation. Other inorganic species such as hydrogen sulfide, an odorous gas, is oxidized to nonodorous sulfate.

Because many types of oxidation processes have been developed and are used in various applications, it is useful to note some important differences between (1) conventional oxidation processes, (2) oxidation processes

carried out at elevated temperatures and/or pressure, and (3) advanced oxidation processes. Conventional chemical oxidation processes employing such oxidants as chlorine, chlorine dioxide, or potassium permanganate do not produce highly reactive species, such as the hydroxyl radical ( $\text{HO}\cdot$ ), which are produced in the other two types of oxidation processes (the dot placed after the hydroxyl and other radical species indicates that there is an unpaired electron in the outer orbital). Hydroxyl radicals are reactive electrophiles that readily react with most organic compounds by undergoing addition reactions with double bonds or extracting hydrogen atoms from organic compounds. Reaction with conventional oxidants are more specific with regard to the types of organic molecules that can be oxidized, and the reaction rates for conventional oxidants are slower than the reaction rates involving  $\text{HO}\cdot$ . Nevertheless, conventional oxidation processes can be effective in oxidizing certain organic and inorganic compounds. Wet oxidation, supercritical oxidation, gas-phase combustion, and catalytic oxidation processes are also known to oxidize organic matter. These processes require elevated temperatures and/or high pressures and are carried out by free-radical reactions involving  $\text{HO}\cdot$ . In advanced oxidation processes (AOPs),  $\text{HO}\cdot$  radicals are generated at ambient temperature and atmospheric pressure.

The purpose of this chapter is to introduce the general subject of conventional oxidation. AOPs will be described in Chap. 18. Topics to be considered include (1) an introduction to the use of chemical oxidation in water treatment, (2) the fundamentals of chemical oxidation and reduction, (3) discussion of the common chemical oxidants used in water treatment, and (4) photolysis theory and applications. The chemistry, storage, and production of oxidants used for disinfection are considered in Chap. 13. Ultraviolet disinfection is also discussed in Chap. 13. By-products formed during disinfection are discussed in Chap. 19. The process engineering aspect of iron and manganese oxidation and removal and arsenic [As(III)] oxidation are addressed in Chap. 20.

## 8-1 Introduction to Use of Oxidation Processes in Water Treatment

---

Historically, the term “oxidation” was used to describe the combining of an element with oxygen to form an oxide and “reduction” was used to describe the removal of an oxygen from an oxide to yield the element (McMurry and Fay, 2003). Today, the terms oxidation and reduction have new and more inclusive definitions. *Oxidation* involves the loss of one or more electrons and *reduction* involves the gain of one or more electrons. Taken together, oxidation and reduction reactions are referred to as *redox* reactions. Before discussing the details of conventional oxidation, it is important to introduce the oxidants used in water treatment and their principal applications.

Water treatment can employ either oxidation or reduction as a treatment process, although oxidation is the most common of the two. Oxidation is used to destroy chemical constituents that are in a reduced state, such as toxic organic or odorous compounds and inorganic compounds such as iron, manganese, or hydrogen sulfide. Reduction is used for denitrification and quenching of residual oxidants.

### Commonly Used Oxidants

The principal oxidants used in water treatment and their corresponding applications are summarized in Table 8-1. With the exception of the hydroxyl radical, which is involved in AOPs, the other oxidants are often termed *conventional* in that they are in common use. Oxidants that are frequently used in water treatment are (1) chlorine, (2) ozone, (3) chlorine dioxide, (4) permanganate, and (5) hydrogen peroxide. The oxidants are usually added at the beginning (e.g., preoxidation) or end (e.g., disinfection) of the water treatment process; however, oxidants are also added at a variety of intermediate points depending on the treatment objectives.

### Application of Conventional Oxidants in Water Treatment

The principal applications of chemical oxidation are for

1. Taste and odor control
2. Hydrogen sulfide removal
3. Color removal
4. Iron and manganese removal
5. Disinfection

**Table 8-1**  
Oxidants and their applications in water treatment

Purpose	Oxidants	Applications
Oxidation of reduced inorganic species	Chlorine, hydrogen peroxide, permanganate, chlorine dioxide	Convert soluble metals such as Fe(II) and Mn(II) to insoluble forms; oxidize odorous sulfide; destroy metal organic complexes
Oxidation of organics	Ozone, AOPs, ultraviolet light, permanganate, chlorine dioxide	Destroy taste- and odor-causing compounds; destroy toxic organics [e.g., pesticides, benzene, trichloroethene, methyl tertiary-butyl ether (MTBE)]; eliminate color; reduce natural organic matter and disinfection by-product precursors
Coagulation aids	Ozone	Reduce amount of coagulant and/or improve coagulation process
Biocidal agents	Ozone, chlorine, iodine, ultraviolet light	Control nuisance growths such as algae in pretreatment basins or reservoirs; as primary disinfectants to meet $Ct^a$ regulations (discussed in Chap. 13)

<sup>a</sup> $Ct$  = product of oxidant residual concentration (mg/L) and contact time (min).

Each of the above applications, with the exception of disinfection, is introduced in the following discussion. Because of the importance of disinfection in water treatment, a separate chapter (Chap. 13) is devoted to this subject.

#### **TASTE AND ODOR CONTROL**

Because of the various combinations of inorganic and organic compounds that cause tastes and odors in water supplies, a wide variety of treatment processes are employed to treat taste and odors. Because most known taste and odor compounds are present in a reduced form, some form of oxidation is usually effective. Generally, no simple treatment process is cost effective for all taste and odor issues, and a case-by-case analysis is recommended. The use of granular and powdered activated carbon (GAC and PAC) for the control of taste and odor is discussed in Chap. 15.

Both surface waters and groundwaters can be contaminated with anthropogenic chemicals that impart taste and odor. Taste and odor in surface waters and groundwaters are discussed separately in the following sections.

##### *Taste and odor in surface waters*

Both inorganic and organic compounds can cause taste and odor problems. The most significant taste and odor problem in surface waters is from naturally occurring organic compounds that are produced by algal blooms and bacteria. Taste and odor outbreaks are seasonal, and according to a recent survey in North America, outbreaks usually occur between June and October (Graham et al., 2000). The three principal organoleptic compounds, geosmin, 2-methylisoborneol (MIB), and cyclocitral are thought to be produced and released into the water by actinomycetes and cyanobacteria. Reported threshold odor concentrations for geosmin and MIB are very low, 4 and 9 ng/L, respectively (McGuire et al., 1981). Geosmin and MIB concentrations above 7 and 12 ng/L have resulted in consumer complaints (Simpson and MacLeod, 1991). Accordingly, the treatment objective for these compounds must be in the low-nanogram-per-liter concentrations. Achieving exceptionally low values (below 5 ng/L) can be a challenge because during peak summer months the concentrations of geosmin and MIB in the raw water can reach 17 and 70  $\mu\text{g/L}$ , respectively (Bruce et al., 2002). A comparison of a number of taste and odor control methods for geosmin and MIB is presented in Table 8-2. No single technology or oxidant does an excellent job with the exception of ozone and ozone/hydrogen peroxide.

##### *Taste and odor in groundwaters*

The most important taste and odor problems for groundwater are from naturally occurring inorganic compounds and mercaptans (organic sulfides), which are caused by the reducing environment found in groundwater. The

**Table 8-2**

Removal of geosmin and methylisoborneol (MIB) that were spiked into filtered water at initial concentration of 100 ng/L

Chemical	Chemical Feed Rate, mg/L	Removal, %	
		Geosmin	MIB
Powdered activated carbon	10	40	62
	25	52	65
Potassium permanganate	0.8	42	28
Chlorine	2	45	33
Hydrogen peroxide	1	50	72
Ozone	2.5	94	77
Ozone and hydrogen peroxide	2.5, 0.5	97	95

Source: Adapted from Kawamura (2000).

most important components that cause taste and/or odor are iron, manganese, and hydrogen sulfide. Manganese and hydrogen sulfide removal are discussed in this section following the discussion of the removal of organic taste- and odor-causing compounds.

*Commonly used oxidants for taste and odor control*

The oxidants most commonly employed for the destruction of chemicals that cause tastes and odors are hydrogen peroxide, chlorine, permanganate, ozone, and chlorine dioxide. AOPs (discussed in Chap. 18) are also effective at destroying geosmin and MIB (Glaze et al., 1990). However, it is unlikely that AOPs would be used for taste and odor control because ozone alone appears to be effective in eliminating geosmin and MIB (ozone can be an AOP because it generates HO• when it reacts with natural organic matter). Other benefits of ozone are (1) it is the only effective oxidant that does not increase total dissolved solids (TDS) and (2) water purveyors can receive disinfection credit for its use.

Chlorine often increases odor problems, especially when used to destroy odors of industrial or algal origin due to (1) formation of volatile products or (2) lyses of algae cells and release of odorants (Burttschell et al., 1959). For example, when low dosages of chlorine are added to water that contains phenols, chlorophenol compounds are formed and impart an objectionable medicinal taste to the water. The taste-producing intensity of the water increases up to a maximum after which increasing chlorine doses reduces and finally eliminates chlorophenolic tastes (Ettinger and Ruchhoft, 1951; Riddick, 1951). However, application of large doses of chlorine are not recommended because of the formation of chlorination by-products; consequently, measures must be taken to remove the phenol before chlorination.

**HYDROGEN SULFIDE REMOVAL**

Hydrogen sulfide ( $\text{H}_2\text{S}$ ) is occasionally present in groundwaters. Hydrogen sulfide has an objectionable and readily identifiable “rotten-egg” odor, so it must be removed from drinking water to make the water aesthetically acceptable. Hydrogen sulfide also increases the corrosiveness of some waters to metal and concrete, and sulfides promote the growth of various filamentous sulfur bacteria, leading to a general degradation of water quality. Oxidants that have been used for the removal of hydrogen sulfide include (1) chlorine, (2) hydrogen peroxide, (3) potassium permanganate, and (4) ozone.

The biggest problem associated with hydrogen sulfide removal using oxidation is the formation of polysulfides (usually  $\text{S}_8$ ) and turbidity. The formation of polysulfides is unavoidable if the hydrogen sulfide concentration is greater than about 1 mg/L, and oxidant dosages in excess of the stoichiometric requirement and pH values greater than 8 are required to assure conversion to sulfate. At pH values above 9, it appears that polysulfides do not form, which may be the reason that alkaline groundwaters that contain sulfides and have been lime softened do not exhibit threshold odors after chlorination.

There are significant problems with polysulfides that include (1) removal difficulty, (2) unique taste and odor problems, and (3) the ability to complex with metals in distribution systems, leading to the formation of black water. In most cases, pilot studies are required to determine the most suitable treatment methods to avoid the formation of polysulfides and/or to evaluate liquid–solid separation methods to remove polysulfides once formed.

**COLOR REMOVAL**

Color, primarily imparted to water by the degradation of dead plant matter (also known as natural organic matter, or NOM), is characteristically yellow in color and is often associated with double bonds in polyaromatic hydrocarbons. The soluble organic carbon that is formed from the degradation of dead plant matter includes humic acids and other substances that are generally referred to as humic substances. As discussed in Chap. 2, color can be expressed in platinum–cobalt units or light absorption at a specified wavelength. The double bonds that absorb visible light also absorb UV light, and color and UV light absorption at 254 nm correlate with one another. Furthermore, UV light absorption and disinfection by-product (DBP) formation are related; consequently, color, UV light absorption at 254 nm, and DBP formation are all related to one another. The reason that these parameters are related to one another is that the reaction centers correspond to the chromophores on NOM (e.g., double bonds and metal humic complexation sites) (Benjamin et al., 1997).

Chlorine has been used to remove color, but it is no longer considered a viable option because chlorine reacts with NOM to form chlorinated

by-products. Chlorine dioxide is effective at color removal, but the production of the by-product chlorite has to be considered. Ozone is also effective at color removal, depending on the ozone-to-dissolved organic carbon (DOC) dosage ratio. However, ozone produces biodegradable compounds such as aldehydes and ketones, and these may stimulate biofilm growth in the distribution system. Thus, when ozone is used as an oxidant, the production of biodegradable organic matter has to be considered and biological treatment downstream of the coagulation process may be required. As discussed in Chap. 11, biologically active filtration can be used to remove the biodegradable organic matter. Because of the relationship between color and DBP formation, processes that are used to reduce the concentration of NOM for DBP formation control, presented in Sec. 19-2, can also be used for color removal.

#### **OXIDATION AS A COAGULATION AID**

Oxidants may aid the coagulation and flocculation process in several ways. First, it appears that particles adsorb negatively charged NOM that imparts a negative charge on the particles, causing particle repulsion and stability. Oxidant addition is thought to react with the adsorbed negatively charged NOM and make it more polar, which causes some of the NOM to desorb, leading to particles with a lower net negative surface charge. In addition, the oxidant may react with the adsorbed organics and make them bind more readily with Al(III) and Fe(III). As a result, the particles lose some of their negative charge or are destabilized more easily using metal salts and therefore flocculate more readily. Second, oxidants can react with NOM in the bulk solution and produce carboxylic acid groups that bind calcium ions, and this binding can cause direct precipitation of NOM.

Depending on the oxidant and dosage, chemical oxidants are also thought to destroy the functional groups that are responsible for metal complexation. The amount of metal coagulant that must be added for particle destabilization will be reduced by either NOM precipitation or reduction in NOM metal complexation sites (Reckhow et al., 1986).

#### **IRON AND MANGANESE REMOVAL**

Some of the chemistry of iron and manganese removal is reviewed here, but process engineering details are discussed in Chap. 20. Oxidants that have been used to oxidize and precipitate iron and manganese include (1) oxygen, (2) chlorine, (3) chlorine dioxide, (4) hydrogen peroxide, (5) ozone, and (6) potassium permanganate. However, because iron forms a strong complex with NOM, it has been found that oxygen, permanganate, chlorine dioxide, and free chlorine are unable to oxidize iron in many waters (Knocke et al., 1991). As a result, the feasibility of using chemical oxidation for iron removal has to be evaluated on a case-by-case basis using batch or

pilot testing. Chemical oxidation may have to be combined with processes such as coagulation and adsorption, which are used to remove NOM.

#### OXIDATION OF SELECTED TRACE ORGANIC CONSTITUENTS

Another important role of chemical oxidation is the destruction of anthropogenic or synthetic toxic organics. Conventional oxidants that have been used for this purpose include (1) hydrogen peroxide, (2) ozone, (3) chlorine, (4) chlorine dioxide, and (5) potassium permanganate. As noted previously, the use of HO• for the oxidation of trace constituents is considered in Chap. 18.

## 8-2 Fundamentals of Chemical Oxidation and Reduction

---

The fundamental concepts involved in oxidation and reduction reactions are introduced and discussed in this section. These concepts include (1) fundamentals of redox reactions, (2) standard electrode potentials and redox equilibrium reactions, (3)  $E_H$ -pH predominance area diagrams, and (4) rate of oxidation–reduction processes.

Redox reactions, as discussed in the previous section, are processes in which electrons are exchanged between reacting constituents (atoms, molecules, or ions). The driving force for the exchange of electrons between constituents is a decrease in the electrical potential, which is analogous to what happens when a live electrical wire is grounded and electrons flow from wire to ground (McMurry and Fay, 2003).

### Introduction to Redox Reactions

#### HALF REACTIONS

When an oxidant is added to water and a redox reaction takes place, electrons are transferred from the reductant to the oxidant. The constituent that gains electrons is reduced and is sometimes called the *oxidant*, whereas the constituent that loses electrons is oxidized and is called the *reductant*. For example, consider the oxidation reduction reaction:

In the above reaction, the manganese ( $\text{Mn}^{2+}$ ) ion is oxidized with ozone to produce manganese oxide precipitate, while ozone is reduced to aqueous oxygen. Manganese loses two electrons while ozone gains two electrons.

Because electrons are exchanged in the reaction, the redox reaction in Eq. 8-1 can be separated into the following two half reactions:

Equation 8-2 is referred to as the oxidation half-reaction because the manganese ion loses two electrons, and Eq. 8-3 is referred to as the reduction half reaction because the ozone ion gains two electrons. Ozone is an oxidant because it causes manganese to be oxidized, and ozone itself is reduced. Manganese is a reductant because it causes ozone to be reduced, and manganese is oxidized. Sometimes to reduce confusion the terms *electron acceptor* or *electron donor* are used. In this reaction, ozone is the electron acceptor and manganese is the electron donor.

#### BALANCING REDOX REACTIONS

Characterizing redox reactions requires that the reactions be balanced. Oxidation–reduction reactions are balanced most commonly using either (1) the half-reaction method or (2) the oxidation number method. The half-reaction method for balancing oxidation–reduction reactions is as follows:

1. Write down all principal reactants and products for one of the half reactions, except for the hydrogen and oxygen atoms.
2. Balance all atoms, except for the hydrogen and oxygen atoms, with probable forms that may be found in solution (e.g., for Cl in an oxidation reaction, it would be  $\text{Cl}^-$ ).
3. Balance the oxygen atoms with the oxygen in water ( $\text{H}_2\text{O}$ ).
4. Balance the hydrogen atoms with  $\text{H}^+$ .
5. Balance the charge with electrons. If the reactants generate electrons, then the half reaction is an oxidation reaction (loss of electrons is oxidation—LEO). If the reactants consume electrons, then the half reaction is a reduction reaction (gain of electrons is reduction—GER).
6. Write down all principal reactants and products for the other half reaction except for the hydrogen and oxygen atoms.
7. Balance all atoms except for the hydrogen and oxygen atoms with probable forms that may be found in solution (e.g., for C in an oxidation reaction, it may be  $\text{CO}_2$ ).
8. Balance the oxygen atoms with the oxygen in water ( $\text{H}_2\text{O}$ ).
9. Balance the hydrogen atoms with  $\text{H}^+$ .
10. Balance the charge with electrons.
11. The final step is to obtain a balanced reaction. For this step, both half reactions are added together so that electrons are eliminated from the equation.

The following example illustrates the application of the half-reaction method for balancing redox reactions.

**Example 8-1 Balancing redox reactions**

Balance the oxidation–reduction reaction for hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) oxidation of 1,1-dichloroethene ( $\text{C}_2\text{H}_2\text{Cl}_2$ ).

**Solution**

1. Write the unbalanced reaction involving  $\text{H}_2\text{O}_2$  and  $\text{C}_2\text{H}_2\text{Cl}_2$ :

2. Balance the reaction, starting with the half reaction for hydrogen peroxide:

- a. First, the expected reactants and products other than oxygen and hydrogen should be balanced as shown. In this case, there are no atoms other than hydrogen or oxygen. Consequently, the next step is to balance the oxygen on the left side of the expression with the oxygen in water on the right side:

- b. Next, balance hydrogen by placing  $2\text{H}^+$  on the left-hand side of the expression:

- c. Finally, balance the charge by placing two electrons on the left side of the expression:

The above expression represents the reduction half reaction because the reactant gains electrons; however, hydrogen peroxide is the oxidant (or electron acceptor) because it accepts electrons from the oxidation half reaction.

3. Evaluate the oxidation half reaction in which the reactant loses electrons.
- a. Balance the expected reactants and products other than hydrogen and oxygen:

- b. Balance the reaction for oxygen using the oxygen in water:

c. Balance the reaction for hydrogen with  $H^+$ .

d. Balance the charge with electrons:

The above expression represents the oxidation half reaction because electrons are lost by the reactant. Dichloroethene is called the reductant (or electron donor) in this case because it causes the reduction of the oxidant.

4. Add the reduction and oxidation half reactions and eliminate electrons from the reaction. By multiplying the reduction half reaction by a factor of 4 and adding it to the oxidation half reaction, electrons are eliminated from the reaction and the final form of the equation is obtained.

a. Multiplying the reduction half reaction by a factor of 4 yields the expression

b. Adding the reduction half reaction from step 4a to the oxidation half reaction from step 3d yields

5. Obtain the final redox reaction by eliminating molecules that have stoichiometric coefficients on both sides of the equation from step 4b. The final expression is obtained by eliminating molecules that have stoichiometric coefficients appearing on both sides of the equation (e.g., eight electrons). Subtracting the number of molecules on one side of the equation or the other such that the molecule no longer appears on both sides of the equation (e.g., subtract  $4H_2O$  from both sides of the equation), the final redox reaction is

### Comment

While hydrogen peroxide is capable of oxidizing dichloroethene, the reaction is generally not practical in full-scale treatment systems because the reaction rate is too slow. Removal of dichloroethene requires advanced oxidation (Chap. 18).

**Standard  
Electrode  
Potentials and  
Redox  
Equilibrium  
Reactions**

The gain or loss of electrons from redox reactions can be characterized from the standard electrode potentials for oxidation and reduction half reactions. Every oxidation or reduction half reaction can be characterized by the electrical potential, or electromotive force (emf). This potential is called the standard electrode potential and is measured in volts. The standard electrode potentials for many of the reactions that occur in water treatment are provided in the electronic Table E1 at the website listed in App. E.

Using the International Union of Pure and Applied Chemists (IUPAC) convention:

1. Half reactions are written as reduction reactions.
2. To obtain the oxidation reaction, the direction of the reduction reaction is reversed and the reduction potential is multiplied by a factor of  $-1$ .
3. The reported standard electrode potential values are given with respect to a reference standard hydrogen electrode [sometimes referred to as a standard hydrogen electrode (SHE) or normal hydrogen electrode (NHE)].

The value of the redox potential can be illustrated using oxygen. The value corresponds to the following two half reactions:

The overall redox reaction can be obtained by multiplying Eq. 8-5 by 2, adding Eqs. 8-4 and 8-5, and eliminating electrons and  $\text{H}^+$  from both sides of the equation:

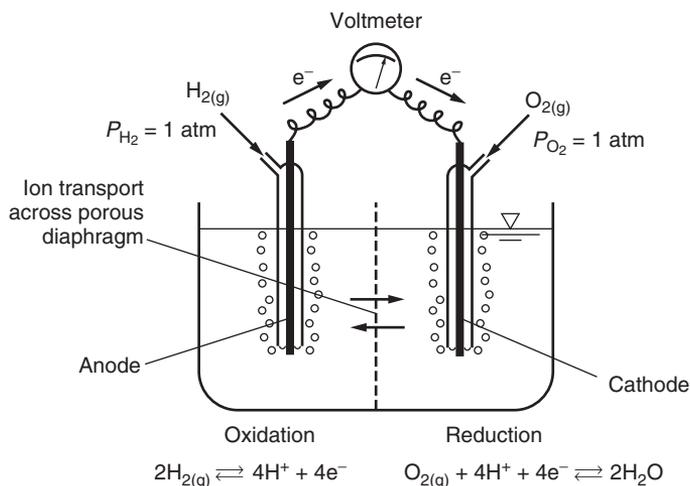

where  $E_{\text{Rxn}}^\circ$  = standard electrode potential for overall redox reaction, V

The value of  $E_{\text{Rxn}}^\circ$  can be determined by simply adding the reduction and oxidation potentials together, noting the sign convention, because the numbers of electrons transferred in the reaction are identical for reduction and oxidation reactions. The value of  $E_{\text{Rxn}}^\circ$  is obtained using the equation

$$\begin{aligned} E_{\text{Rxn}}^\circ &= E_{\text{red}}^\circ + E_{\text{ox}}^\circ \\ &= 1.27 + 0 = 1.27\text{V} \end{aligned} \quad (8-7)$$

A positive value of  $E_{\text{Rxn}}^\circ$  can be taken as a general indication that a reaction will proceed as written. However, as will be demonstrated later,

**Figure 8-1**

Cell potential for reaction between  $\text{H}_2$  and  $\text{O}_2$ .

both the electrical potential and free energy of a given reaction must be evaluated at the expected concentrations in solution.

#### MECHANISTIC DESCRIPTION OF ELECTRODE POTENTIALS WITH AN ELECTROCHEMICAL CELL

An electrochemical cell is set up as shown on Fig. 8-1, and 1.27 V (ignoring the resistance of the wires and assuming that suitable electrodes are present) is measured for unit activities of all species in the cell under the following conditions: 1 atm of hydrogen and oxygen in equilibrium with the water phase and 1 M concentration of  $\text{H}^+$ . Oxidation takes place at the *anode*, where hydrogen gas is oxidized, and reduction takes place at the *cathode*, where oxygen is reduced. Electrons flow from the anode to the cathode and ions in solution migrate either to the cathode or anode depending on their charge to ensure that electroneutrality is maintained. Cations migrate toward the anode, and anions migrate toward the cathode. The anode is negatively charged because electrons are produced at this electrode, and the cathode is positively charged because electrons are used at this electrode.

#### ASSESSING REACTION FEASIBILITY

Every reaction is written with respect to the hydrogen electrode, so it is easy to assess whether a reaction is possible by examining the respective electrode potentials of each half reaction because the hydrogen reaction can be eliminated from the overall reaction when the two half reactions are added together.

Returning to the manganese/ozone example (Eqs. 8-1 to 8-3), the standard reduction potential for  $\text{MnO}_2(\text{s})$  is +1.230 V, corresponding to the combination of the following two half reactions:

The standard reduction reaction for ozone corresponds to a combination of the following two half reactions:

Ozone is a much more powerful electron acceptor (oxidant) than manganese oxide because  $E_{\text{Rxn}}^\circ$  for ozone is +2.08 V, as compared to +1.230 V for manganese oxide. Consequently, ozone can bring about the oxidation of the manganese ion when the activity of the products and reactants is equal to one.

#### DETERMINING WHETHER A REACTION WILL PROCEED

Thus far, only the potential for a redox reaction has been evaluated under standard conditions (unit activity is covered in Chap. 5). However, to consider whether a reaction proceeds as written, the free energy and electrical potential of a given reaction must be evaluated at the expected concentrations in solution. The methodology used to determine if a reaction will occur is presented below. Consider the generic redox reaction

where  $a, b, c, d$  = stoichiometric coefficients, unitless

#### *Relating free-energy change to electrical potential*

The free-energy change and cell potential for the reaction in Eq. 8-14 are given by the following expressions (refer to Chap. 5):

$$\Delta G_{\text{Rxn}} = \Delta G_{\text{Rxn}}^\circ + RT \ln \left( \frac{\{\text{C}\}^{c/a} \{\text{D}\}^{d/a}}{\{\text{A}\} \{\text{B}\}^{b/a}} \right) \quad (8-15)$$

$$E_{\text{Rxn}} = \frac{\Delta G_{\text{Rxn}}}{-nF} \quad (8-16)$$

$$E_{\text{Rxn}} = E_{\text{Rxn}}^{\circ} - \frac{RT}{nF} \ln \left( \frac{\{C\}^{c/a} \{D\}^{d/a}}{\{A\} \{B\}^{b/a}} \right)$$

$$\text{or } E_{\text{Rxn}}^{\circ} - \frac{2.303RT}{nF} \log \left( \frac{\{C\}^{c/a} \{D\}^{d/a}}{\{A\} \{B\}^{b/a}} \right) \quad (8-17)$$

where  $\Delta G_{\text{Rxn}}$  = free-energy change of reaction, J/mol

$\Delta G_{\text{Rxn}}^{\circ}$  = free-energy change of reaction under standard conditions, J/mol

$E_{\text{Rxn}}$  = electrode potential of reaction =  $E_{\text{ox}} + E_{\text{red}}$ , V

$E_{\text{Rxn}}^{\circ}$  = standard electrode potential of reaction, V

$n$  = number of electrons transferred in reaction, eq/mol

$F$  = Faraday's constant, 96,500 C/eq

$R$  = universal gas constant, 8.314 J/mol · K

$T$  = absolute temperature, K

$\{i\}$  = activity of constituent  $i$  (A, B, C, or D), mol/L

Equation 8-17 is known as the Nernst equation. The base-10 form of the equation is useful when dealing with reactions involving the hydrogen ion because, as shown later, the hydrogen ion concentration can be expressed as pH.

The electrode potential  $E_{\text{Rxn}}^{\circ}$  may be calculated from  $\Delta G_{\text{Rxn}}^{\circ}$  by adding all the reactions that are involved using the  $-nFE^{\circ}$  values because the  $\Delta G_{\text{Rxn}}^{\circ}$  and  $-nFE^{\circ}$  values are additive. For example,  $E_{\text{Rxn}}^{\circ}$  may be calculated from the oxidation and reduction reaction as shown in the following equations:

$$\Delta G_{\text{Rxn}}^{\circ} = -n_{\text{Rxn}}FE_{\text{Rxn}}^{\circ} = \Delta G_{\text{ox}}^{\circ} + \Delta G_{\text{red}}^{\circ} = -n_{\text{ox}}FE_{\text{ox}}^{\circ} - n_{\text{red}}FE_{\text{red}}^{\circ} \quad (8-18)$$

where  $n_{\text{Rxn}}$  = number of electrons transferred in overall reaction, eq/mol

$E_{\text{Rxn}}^{\circ}$  = standard electrode potential of redox reaction, V

$\Delta G_{\text{ox}}^{\circ}$  = standard free-energy change of oxidation half reaction, J/mol

$\Delta G_{\text{red}}^{\circ}$  = standard free-energy change of reduction half reaction, J/mol

$E_{\text{ox}}^{\circ}$  = standard electrode potential of oxidation half reaction, V

$E_{\text{red}}^{\circ}$  = standard electrode potential of reduction half reaction, V

$n_{\text{ox}}$  = number of electrons produced in oxidation half reaction, eq/mol

$n_{\text{red}}$  = number of electrons obtained in reduction half reaction, eq/mol

### Example 8-2 Oxidation power of oxygen and hydrogen peroxide

Investigate whether oxygen ( $O_2$ ) or hydrogen peroxide ( $H_2O_2$ ) is the more powerful oxidant from a consideration of free energy.

#### Solution

- Write the reduction and oxidation half reactions of  $H_2O_2$  as well as the overall reaction. From Table E1 at the website listed in App. E, the half reaction of  $H_2O_2$  can be written with respect to the hydrogen electrode as follows:

- Calculate  $\Delta G_{\text{Rxn}, H_2O_2}^\circ$  using Eq. 8-18 (note  $J/C = V$ ):

$$\begin{aligned} \Delta G_{\text{Rxn}, H_2O_2}^\circ &= -nFE_{\text{Rxn}, H_2O_2}^\circ = -(2 \text{ eq/mol}) (96,500 \text{ C/eq}) (1.780 \text{ J/C}) \\ &= -343,540 \text{ J/mol} \quad (-343.5 \text{ kJ/mol}) \end{aligned}$$

- Write the reduction and oxidation half reactions of  $O_2$  as well as the overall reaction: The half reaction of  $O_2$  can be written with respect to the hydrogen electrode as follows:

- Calculate  $\Delta G_{\text{Rxn}, O_2}^\circ$  by rearranging Eq. 8-18:

$$\begin{aligned} \Delta G_{\text{Rxn}, O_2}^\circ &= -nFE_{\text{Rxn}, O_2}^\circ = -(4 \text{ eq/mol}) (96,500 \text{ C/eq}) (1.27 \text{ J/C}) \\ &= -490,220 \text{ J/mol} \quad (-490 \text{ kJ/mol}) \end{aligned}$$

#### Comment

The free-energy change per mole of oxidant is greater for oxygen than it is for peroxide. (Note: Only two electrons are transferred in the hydrogen peroxide reaction versus four in the oxygen reaction.) Consequently, it is impossible to tell which is the more powerful oxidant by examining

the free energy. Using the standard electrode potential, it can be seen that  $\text{H}_2\text{O}_2$  is a more powerful oxidant than  $\text{O}_2$  by comparing  $E_{\text{Rxn},\text{H}_2\text{O}_2}^\circ$  to  $E_{\text{Rxn},\text{O}_2}^\circ$  because the redox potential of  $\text{H}_2\text{O}_2$  is greater than  $\text{O}_2$ . In addition, the power of  $\text{H}_2\text{O}_2$  as compared to  $\text{O}_2$  can be illustrated by the fact that the following reaction is feasible from a thermodynamic point of view (at unit activity):

The free energy describes the overall energy transferred in a chemical reaction, and therefore cannot be used to tell which oxidant is more powerful. The important factor in oxidant strength is the amount of energy in each electron; thus, the standard electrode potential, which is the amount of energy released per coulomb of electron and has units of volts (J/C), can be used to compare oxidant strength.

#### *Potential of combined reactions*

When the potential of an oxidation (or reduction) reaction is a combination of several reactions (e.g., reactions 1 and 2), the following expression must be used:

$$-(n_{\text{ox},1} + n_{\text{ox},2})FE_{\text{ox,sum}}^\circ = -n_{\text{ox},1}FE_{\text{ox},1}^\circ - n_{\text{ox},2}FE_{\text{ox},2}^\circ \quad (8-19)$$

$$E_{\text{ox,sum}}^\circ = \frac{n_{\text{ox},1}E_{\text{ox},1}^\circ + n_{\text{ox},2}E_{\text{ox},2}^\circ}{n_{\text{ox},1} + n_{\text{ox},2}} \quad (8-20)$$

$$E_{\text{red,sum}}^\circ = \frac{n_{\text{red},1}E_{\text{red},1}^\circ + n_{\text{red},2}E_{\text{red},2}^\circ}{n_{\text{red},1} + n_{\text{red},2}} \quad (8-21)$$

where  $E_{\text{ox,sum}}^\circ$  = standard electrode potential of combined oxidation half reaction, V

$E_{\text{red,sum}}^\circ$  = standard electrode potential of combined reduction half reaction, V

$E_{\text{ox},i}^\circ$  = standard electrode potential of  $i$ th oxidation half reaction, V

$E_{\text{red},i}^\circ$  = standard electrode potential of  $i$ th reduction half reaction, V

$n_{\text{ox},i}$  = number of electrons produced in  $i$ th oxidation half reaction, eq/mol

$n_{\text{red},i}$  = number of electrons obtained in  $i$ th reduction half reaction, eq/mol

The application of Eq. 8-20 is illustrated in the following example.

### Example 8-3 Oxidation of bromide to bromate

Determine the oxidation potential for converting bromide ( $\text{Br}^-$ ) to bromate ( $\text{BrO}_3^-$ ) from the hypobromous/bromide acid reaction and bromate/hypobromous reaction.

#### Solution

- From Table E1 at the website listed in in App. E, determine the two half reactions, their potentials, and the overall reaction:

- Determine the potential for the oxidation reaction using Eq. 8-20 and the values from the online table of standard redox potentials

$$E_{\text{ox,sum}}^\circ = \frac{2(-1.33 \text{ V}) + 4(1.49 \text{ V})}{2 + 4} = -1.437 \text{ V}$$

#### Comment

It is important to recognize that the potential is the sum of the potentials of the oxidation and reduction components (see Eq. 8-21) only when the overall redox reaction is being considered.

#### *Determining equilibrium constant from electrical potential*

In the Nernst equation (Eq. 8-15), equilibrium is achieved when either the free-energy change or electrical potential is zero. Thus, the equilibrium constant can be calculated from the free energy or electrical potential as shown below:

$$0 = E_{\text{Rxn}}^\circ - \frac{RT}{nF} \ln K_{\text{eq}} \quad (8-22)$$

$$K_{\text{eq}} = e^{nFE_{\text{Rxn}}^\circ/RT} = e^{-\Delta G_{\text{Rxn}}^\circ/RT} \quad (8-23)$$

where  $K_{\text{eq}}$  = equilibrium constant

The utility of the equilibrium constant in redox reactions is illustrated in the following example.

### Example 8-4 Oxidation of Fe(s) with dissolved oxygen

Calculate the equilibrium constant and  $\Delta G_{\text{Rxn}}^{\circ}$  for the corrosion of Fe(s) to  $\text{Fe}^{2+}$  by dissolved oxygen. Determine the oxygen concentrations that are needed for pH values equal to 5.5, 7.0, and 8.5 such that the reaction is thermodynamically favorable. Given:  $[\text{Fe}^{2+}] = 10^{-6}$  M and temperature is 298 K.

#### Solution

1. Write the reduction and oxidation half reactions for corrosion of Fe(s) to  $\text{Fe}^{2+}$  by reacting with oxygen as well as the overall reaction:

From Table E1 at the website listed in App. E, the corrosion of Fe(s) to  $\text{Fe}^{2+}$  by reacting with oxygen can be written as

2. Calculate the equilibrium constant  $K_{\text{eq}}$  using Eq. 8-23:

$$K_{\text{eq}} = \exp\left(\frac{nFE_{\text{Rxn}}^{\circ}}{RT}\right) = \exp\left[\frac{(4 \text{ eq/mol})(96,500 \text{ C/eq})(1.71 \text{ J/C})}{(8.314 \text{ J/mol} \cdot \text{K})(298 \text{ K})}\right]$$

$$= 4.97 \times 10^{115}$$

3. Determine the equilibrium oxygen concentrations at pH values equal to 5.5, 7.0, and 8.5 using the expression developed in step 1 [ $2\text{Fe(s)} + \text{O}_2(\text{aq}) + 4\text{H}^{+} \rightleftharpoons 2\text{Fe}^{2+} + 2\text{H}_2\text{O}$ ] and the equilibrium value developed in step 2:

$$K_{\text{eq}} = \frac{\{\text{Fe}^{2+}\}^2 \{\text{H}_2\text{O}\}^2}{\{\text{Fe(s)}\}^2 \{\text{O}_2(\text{aq})\} \{\text{H}^{+}\}^4}$$

Neglecting activity coefficient corrections and assuming the activity of solids and liquids is equal to 1,

$$[\text{O}_2(\text{aq})] = \frac{[\text{Fe}^{2+}]^2}{[\text{H}^{+}]^4 K_{\text{eq}}} = \frac{(10^{-6})^2}{[\text{H}^{+}]^4 (4.97 \times 10^{115})}$$

Therefore,

$$[\text{O}_2(\text{aq})] = \begin{cases} \frac{[\text{Fe}^{2+}]^2}{[\text{H}^+]^4 K_{\text{eq}}} = \frac{(10^{-6})^2}{(10^{-8.5})^4 (4.97 \times 10^{115})} = 2.01 \times 10^{-94} \text{ M at pH 8.5} \\ \frac{[\text{Fe}^{2+}]^2}{[\text{H}^+]^4 K_{\text{eq}}} = \frac{(10^{-6})^2}{(10^{-7})^4 (4.97 \times 10^{115})} = 2.01 \times 10^{-100} \text{ M at pH 7} \\ \frac{[\text{Fe}^{2+}]^2}{[\text{H}^+]^4 K_{\text{eq}}} = \frac{(10^{-6})^2}{(10^{-5.5})^4 (4.97 \times 10^{115})} = 2.01 \times 10^{-106} \text{ M at pH 5.5} \end{cases}$$

Note: When the reaction quotient  $Q = K_{\text{eq}}$ ,  $\Delta G = 0$ . If  $\Delta G < 0$ , the reaction is thermodynamically favorable. Thus, if the actual oxygen concentrations are greater than the equilibrium values computed above as a function of pH, the reaction will proceed as written in step 1.

### Comment

For all cases, the reactions are thermodynamically favorable for small oxygen concentrations. The oxygen concentrations that are calculated here are extremely small. In fact, for a pH of 5.5, there would be one molecule of oxygen per  $3.00 \times 10^{83}$  L of water, which may, in fact, be more than all the water in the entire universe. Many redox reactions have high equilibrium constants, and as a result they tend to be irreversible reactions when the rate of reaction is fast.

### *Impact of pH on reduction potential*

Reaction conditions, especially pH, can have an important impact on reduction potential. For example, pH can have a large influence on the standard potential, and if 1 mole of hydrogen ion appears on the left-hand side of the equation (as a reactant), then the potential drops according to the following equation for a unit increase in pH:

$$\begin{aligned} \Delta E_{\text{red}}^{\circ} &= - \left( \frac{2.303RT}{nF} \right) \log \left( \frac{1}{[\text{H}^+]} \right) \\ &= - \left[ \frac{(2.303) (8.314 \text{ J/mol} \cdot \text{K}) (298 \text{ K})}{(96,500 \text{ C/eq}) (n \text{ eq/mol})} \right] \text{pH} \\ &= - \left( \frac{0.0591}{n} \right) \times \text{pH} \end{aligned} \quad (8-24)$$

where  $\Delta E_{\text{red}}^{\circ}$  = change in potential, V  
 $R$  = universal gas constant, 8.314 J/mol · K  
 $T$  = absolute temperature, K  
 $n$  = number of electrons transferred, eq/mol  
 $F$  = Faraday's constant, 96,500 C/eq  
 $[\text{H}^+]$  = concentration of hydrogen ion, mol/L  
 $\text{pH} = \log([\text{H}^+]) = \log(1/[\text{H}^+])$ , unitless

Consequently, the electrode potential for HO• is 0.413 V lower at pH 7 than for unit activity assuming that all other species are at unit activity or it would be 2.18 V instead of 2.59 V as reported in the electronic Table E1 at the website listed in App. E. If there are 2 moles of hydrogen ion on the left-hand side of the reduction reaction, then the reduction potential would be 0.826 V lower at pH 7 for unit activity of all other species if the number of electrons accepted is 1. For ozone and oxygen, the electrode potential would be 0.413 V less than is reported in the table of standard redox potentials at pH 7 because the number of hydrogen ions on the left side is the same as the number of electrons.

*Evaluating free-energy change and electrical potential over a concentration range*

To determine whether a redox reaction can proceed from the initial concentrations in solution to the treatment objective,  $\Delta G_{\text{Rxn}}^{\circ}$  and  $E_{\text{Rxn}}^{\circ}$  must be evaluated over that concentration range. Because the concentrations of all the reactants and products change over that concentration range, as described in Chap. 5, the concentrations of the constituents can be related to one another and to the conversion using stoichiometry. The following relationships from Chap. 5, repeated here for convenience, are valid if there are no competing reactions and no volume change upon reaction:

$$C_A = C_{A0} (1 - X_A) \quad (8-25)$$

$$C_B = C_{B0} - \frac{b}{a} C_{A0} X_A \quad (8-26)$$

$$C_C = C_{C0} + \frac{c}{a} C_{A0} X_A \quad (8-27)$$

$$C_D = C_{D0} + \frac{d}{a} C_{A0} X_A \quad (8-28)$$

$$C_B = C_{B0} - \frac{b}{a} (C_{A0} - C_A) \quad (8-29)$$

$$C_C = C_{C0} + \frac{c}{a} (C_{A0} - C_A) \quad (8-30)$$

$$C_D = C_{D0} + \frac{d}{a} (C_{A0} - C_A) \quad (8-31)$$

where  $C_i$  = concentration of constituent  $i$  (A, B, C, D), mol/L  
 $C_{i0}$  = initial concentration of constituent  $i$  (A, B, C, D), mol/L  
 $X_A$  = conversion of constituent A, dimensionless  
 $a, b, c, d$  = stoichiometry coefficients

Equations 8-25 to 8-28 or Eqs. 8-29 to 8-31 may be substituted into Eq. 8-15 to determine whether  $\Delta G$  is negative as a function of  $X_A$  or  $C_A$ . Similarly, Eqs. 8-25 to 8-28 or Eqs. 8-29 to 8-31 may be substituted into Eq. 8-17 to determine whether  $E_{R_{xn}}$  is positive as a function of  $X_A$  or  $C_A$ . Equations 8-25 to 8-28 or Eqs. 8-29 to 8-31 can also be used to determine if one of the reactants will be exhausted before the desired conversion is achieved. The following example is used to illustrate the application of these types of thermodynamic calculations in water treatment applications.

### Example 8-5 Oxidation of manganese with ozone

Manganese [Mn(II)] is soluble in water and is present in many groundwaters because insoluble forms (e.g.,  $MnO_2$ ) that are contained in minerals are reduced to soluble forms. The subsurface is a reducing environment because electron acceptors such as oxygen have been used up by heterotrophic bacteria in the top organic-rich layer of soil. Ozone ( $O_3$ ) is sometimes used to remove  $Mn^{2+}$ . Assume that the ozone and dissolved oxygen (DO) do not react with anything but  $Mn^{2+}$  (a simplifying assumption because ozone will react with many other constituents in a real water) and the pH is constant. Then:

1. Balance the overall redox reaction for the oxidation of  $Mn^{2+}$  to  $MnO_2(s)$  with  $O_3$ .
2. Calculate the equilibrium constant.
3. Calculate the equilibrium  $Mn^{2+}$  concentration when the pH is 7, DO is 5 mg/L, and the ozone concentration is 0.5 mg/L.
4. Obtain expressions for DO, ozone, and  $MnO_2(s)$  concentrations in terms of  $Mn^{2+}(s)$  concentration. The initial reactant concentrations are [DO] = 10 mg/L, ozone concentration = 3 mg/L, and  $Mn^{2+}$  = 2 mg/L and pH is 7.
5. Plot the free energy as a function of the conversion of  $Mn^{2+}$  from 0.01 to 0.999.

Use the stoichiometric table to determine all reacting species as a function of  $X_A$  and then eliminate  $X_A$  by using the final concentration  $C_A$ . After substituting  $C_A$  back into the expressions, DO, ozone, and  $MnO_2$  concentrations can be obtained in terms of the final concentration of  $Mn^{2+}$ .

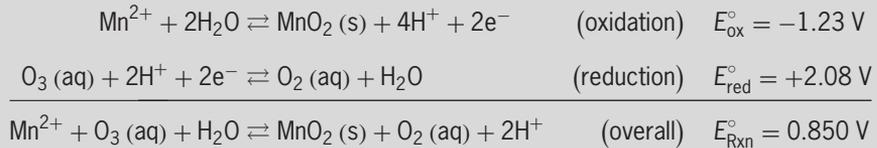

**Solution**

1. Balance the overall redox reaction:

a. Identify the oxidation and reduction reactions and determine the standard electrode potential:

b. Balance the overall redox reaction by adding the two half reactions:

$$E_{\text{Rxn}}^\circ = 2.08 + (-1.23) = 0.850 \text{ V}$$

2. Calculate the equilibrium constant:

a. Calculate  $\Delta G_{\text{Rxn}}^\circ$  using Eq. 8-16:

$$\begin{aligned} \Delta G_{\text{Rxn}}^\circ &= -nFE_{\text{Rxn}}^\circ = -(2 \text{ eq/mol})(96,500 \text{ C/eq})(0.850 \text{ J/C}) \\ &= -164,050 \text{ J/mol} = -164.05 \text{ kJ/mol} \end{aligned}$$

b. Calculate the equilibrium constant  $K_{\text{eq}}$  using Eq. 8-23:

$$K_{\text{eq}} = e^{-\Delta G_{\text{Rxn}}^\circ/RT} = e^{-(-164.05)/(8.314 \times 10^{-3} \times 298)} = 5.71 \times 10^{28}$$

3. Calculate the equilibrium  $\text{Mn}^{2+}$  concentration when the pH is 7, DO is 5 mg/L, and the ozone concentration is 0.5 mg/L:

$$[\text{H}^+] = 10^{-7} \text{ M}$$

$$[\text{O}_3(\text{aq})] = 0.5 \text{ mg/L} = 1.04 \times 10^{-5} \text{ M}$$

$$[\text{O}_2(\text{aq})] = 5 \text{ mg/L} = 1.56 \times 10^{-4} \text{ M}$$

$$K_{\text{eq}} = \frac{[\text{O}_2(\text{aq})][\text{H}^+]^2}{[\text{Mn}^{2+}][\text{O}_3(\text{aq})]}$$

$$\begin{aligned} [\text{Mn}^{2+}] &= \frac{[\text{O}_2(\text{aq})][\text{H}^+]^2}{K_{\text{eq}}[\text{O}_3(\text{aq})]} = \frac{(1.56 \times 10^{-4})(10^{-7})^2}{(5.71 \times 10^{28})(1.04 \times 10^{-5})} \\ &= 2.63 \times 10^{-42} \text{ M} = 1.44 \times 10^{-37} \text{ mg/L} \end{aligned}$$

4. Obtain an expression for DO, ozone, and  $\text{MnO}_2$  in terms of  $\text{Mn}^{2+}$ :  
Initial concentrations:

$$[\text{Mn}^{2+}]_0 = 2 \text{ mg/L} = 3.64 \times 10^{-5} \text{ M}$$

$$[\text{O}_3(\text{aq})]_0 = 3 \text{ mg/L} = 6.25 \times 10^{-5} \text{ M}$$

$$[\text{O}_2(\text{aq})]_0 = 10 \text{ mg/L} = 3.13 \times 10^{-4} \text{ M}$$

According to the overall reaction and Eqs. 8-29 to 8-31, the molar concentrations of  $\text{O}_3(\text{aq})$  and  $\text{O}_2(\text{aq})$  can be expressed in terms of  $[\text{Mn}^{2+}]$  as

$$\begin{aligned} [\text{O}_3(\text{aq})] &= [\text{O}_3(\text{aq})]_0 - ([\text{Mn}^{2+}]_0 - [\text{Mn}^{2+}]) \\ &= 6.25 \times 10^{-5} - (3.64 \times 10^{-5} - [\text{Mn}^{2+}]) \\ &= 2.61 \times 10^{-5} + [\text{Mn}^{2+}] \end{aligned}$$

$$\begin{aligned} [\text{O}_2(\text{aq})] &= [\text{O}_2(\text{aq})]_0 + ([\text{Mn}^{2+}]_0 - [\text{Mn}^{2+}]) \\ &= 3.13 \times 10^{-4} + (3.64 \times 10^{-5} - [\text{Mn}^{2+}]) \\ &= 3.49 \times 10^{-4} - [\text{Mn}^{2+}] \end{aligned}$$

Because  $\text{MnO}_2(\text{s})$  is a solid in water, its activity is unity.

5. Plot the free energy as a function of the conversion of  $\text{Mn}^{2+}$  from 0.01 to 0.999:  
a. Obtain an expression of free energy as a function of the conversion of  $\text{Mn}^{2+}$ :

Assume the conversion of  $\text{Mn}^{2+}$  is  $X_{\text{Mn}^{2+}}$ . According to the overall reaction and Eqs. 8-25 to 8-28, the molar concentrations of  $\text{Mn}^{2+}$ ,  $\text{H}^+$ ,  $\text{O}_3(\text{aq})$ , and  $\text{O}_2(\text{aq})$  can be expressed as

$$\begin{aligned} [\text{Mn}^{2+}] &= [\text{Mn}^{2+}]_0(1 - X_{\text{Mn}^{2+}}) \\ &= 3.64 \times 10^{-5}(1 - X_{\text{Mn}^{2+}}) \\ [\text{H}^+] &= [\text{H}^+]_0 + 2[\text{Mn}^{2+}]_0 X_{\text{Mn}^{2+}} \\ &= 10^{-7} + 7.28 \times 10^{-5} X_{\text{Mn}^{2+}} \end{aligned}$$

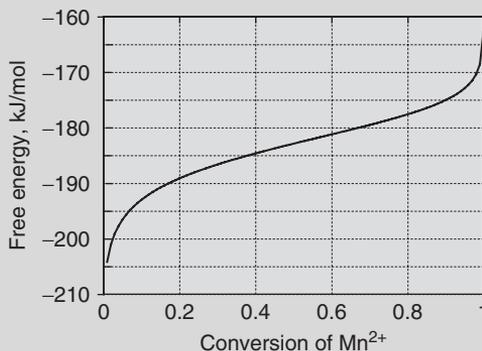

$$\begin{aligned} [\text{O}_3(\text{aq})] &= [\text{O}_3(\text{aq})]_0 - [\text{Mn}^{2+}]_0 X_{\text{Mn}^{2+}} \\ &= 6.25 \times 10^{-5} - 3.64 \times 10^{-5} X_{\text{Mn}^{2+}} \end{aligned}$$

$$\begin{aligned} [\text{O}_2(\text{aq})] &= [\text{O}_2(\text{aq})]_0 - [\text{Mn}^{2+}]_0 X_{\text{Mn}^{2+}} \\ &= 3.13 \times 10^{-4} + 3.64 \times 10^{-5} X_{\text{Mn}^{2+}} \end{aligned}$$

The free-energy expression (Eq. 8-15) can be written as given below by substituting the quotient  $Q$  for the logarithmic term in Eq. 8-15. The quotient is described in greater detail in Chap. 5.

$$\begin{aligned} \Delta G_{\text{Rxn}} &= \Delta G_{\text{Rxn}}^{\circ} + RT \ln(Q) = \Delta G_{\text{Rxn}}^{\circ} + RT \ln \left( \frac{[\text{O}_2(\text{aq})][\text{H}^+]^2}{[\text{Mn}^{2+}][\text{O}_3(\text{aq})]} \right) \\ &= -164.05 + (8.314 \times 10^{-3})(298) \\ &\quad \times \ln \left\{ \frac{(3.13 \times 10^{-4} + 3.64 \times 10^{-5} X_{\text{Mn}^{2+}})(10^{-7} + 7.28 \times 10^{-5} X_{\text{Mn}^{2+}})^2}{[3.64 \times 10^{-5} (1 - X_{\text{Mn}^{2+}})](6.25 \times 10^{-5} - 3.64 \times 10^{-5} X_{\text{Mn}^{2+}})} \right\} \end{aligned}$$

- b. Plot the free energy as a function of the conversion of  $\text{Mn}^{2+}$  from 0.01 to 0.999:

### $E_H$ -pH Predominance Area Diagrams: Definition and Example for Chlorine

The  $E_H$ -pH (or  $p\varepsilon$ -pH) diagram is a visual tool used for determining predominant chemical species at various pH values and is useful when analyzing redox equilibria. Because most redox reactions depend on pH and the electrical potential, the thermodynamically preferred species can be shown on a two-dimensional diagram in which pH and the electrical potential are the axes. Acid-base, complexation, and precipitation reactions can

also be displayed on these diagrams because oxidants and reductants are involved in these types of reactions. These types of diagrams are called predominance area diagrams and are constructed based on the following rules:

1. Boundaries between major species are drawn for a given set of conditions (e.g., total chlorine concentration).
2. The boundary lines are drawn where the concentrations of the two species involved in the redox reaction are equal; consequently, one species predominates in concentration on one side of the line.

The construction of a predominance area diagram will be illustrated for chlorine; however, first the stability domain for water/oxygen will be identified.

#### OXYGEN

For the reduction of gaseous oxygen (from the electronic Table E1 at the website listed in App. E) the following half reaction may be written:

$$E_H = E^\circ - \frac{0.059}{n} \log \frac{1}{[\text{H}^+]^4 P_{\text{O}_2}} \quad (8-33)$$

$$= E^\circ - \frac{0.059}{4} (4\text{pH} - \log P_{\text{O}_2}) \quad (8-34)$$

where  $E_H$  = electrode potential as function of pH, V  
 $E^\circ$  = standard electrode potential, V  
 $n$  = number of electrons transferred, eq/mol  
 $P_{\text{O}_2}$  = partial pressure of oxygen, atm

For gas-phase concentrations the equilibrium expression can be written in terms of the partial pressure (McMurry and Fay, 2003). It should be noted that the partial pressure is used because it can be measured easily. Assuming  $P_{\text{O}_2} = 0.21$  atm (see Table B-2, App. B), Eq. 8-34 results in the expression

$$E_H = 1.24 - 0.059\text{pH} \quad (8-35)$$

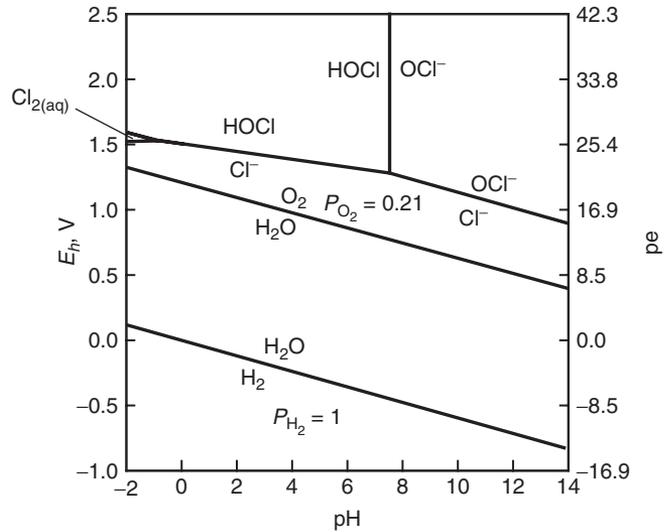

Equation 8-35 can be plotted as a straight line (see Fig. 8-2). For a given pH, with  $E_H$  values above the line, water would be reduced and  $\text{O}_2$  would be formed. For  $E_H$  values below the line, water is stable and the preferred species.

#### HYDROGEN

For the reduction of hydrogen, the following half reaction may be written:

$$E_H = E^\circ - \frac{0.059}{2} (-2\text{pOH} + \log P_{\text{H}_2}) \quad (8-37)$$

**Figure 8-2**

Predominance area diagram for chlorine system with total chlorine species concentration  $C_{T,Cl}$  of  $10^{-4}$  mol/L ( $C_{T,Cl} = 10^{-4}$  mol/L =  $2[Cl_2(aq)] + [HOCl] + [OCl^-] + [Cl^-]$ ).

Assuming  $P_{H_2} = 1$  atm, Eq. 8-37 results in the expression

$$E_H = -0.059pH \quad (8-38)$$

Equation 8-38 can also be plotted as a straight line as shown on Fig. 8-2. For a given pH,  $E_H$  values above the line water would be stable. For  $E_H$  values below the line water would be reduced and hydrogen would be formed. The lines for oxidation and reduction of water are plotted on Fig. 8-2 and the region where water is stable is identified on the figure.

#### CHLORINE SPECIES

The species that are formed when chlorine is added to water are  $Cl_2(aq)$ , HOCl,  $OCl^-$ , and  $Cl^-$  and the predominance of these species can be plotted if the total mass of chlorine species is fixed. A concentration of  $10^{-4}$  M is used to illustrate the development of a predominance diagram for chlorine. The total concentration of chlorine is given by the relationship

$$C_{T,Cl} = 10^{-4} \text{ M} = 2[Cl_2(aq)] + [HOCl] + [OCl^-] + [Cl^-] \quad (8-39)$$

When chlorine is added to water, it reacts with the water to form hypochlorous acid:

The equilibrium constant for the above reaction is  $4 \times 10^{-4}$  at  $25^\circ\text{C}$ . The equilibrium constant for 0, 15, 35, and  $45^\circ\text{C}$  has been reported as approximately  $1.5 \times 10^{-4}$ ,  $3 \times 10^{-4}$ ,  $5 \times 10^{-4}$ , and  $6 \times 10^{-4}$ , respectively

**Table 8-3**

Values of dissociation constant for hypochlorous acid (HOCl) at different temperatures<sup>a</sup>

Temperature, °C	$K_a \times 10^8$ , mol/L
0	1.5
5	1.7
10	2.0
15	2.3
20	2.6
25	2.9

<sup>a</sup>Computed using equation from Morris (1966).

(Faust and Aly, 1998). Hypochlorous acid is a weak acid that can dissociate at or near neutral pH:

The equilibrium constant for the reaction is  $10^{-7.5}$  ( $\text{p}K_a = 7.5$  at  $25^\circ\text{C}$ ). The dissociation constants for hypochlorous acid at several temperatures are provided in Table 8-3. The reduction reaction and potential for hypochlorous acid are

where  $E_{\text{SHE}}^\circ$  = standard hydrogen electrode potential, V

The following equation can be used to estimate the  $\text{p}K_a$  of hypochlorous acid as a function of temperature (Morris, 1966):

$$\text{p}K_a = \frac{3000.0}{T} - 10.0686 + 0.0253 T \quad (8-43)$$

where  $T$  = absolute temperature, K ( $273 + ^\circ\text{C}$ )

Calculation of the equilibrium concentrations of the chlorine species formed when chlorine is added to water is illustrated in Example 8-6.

### Example 8-6 Hydrolysis of chlorine

Calculate the equilibrium concentrations of HOCl and  $\text{Cl}_2(\text{aq})$  in solution for a chlorine addition of 2 mg/L at  $25^\circ\text{C}$ . Assume that the pH is 5 and does not change and that at pH 5 the amount of HOCl that disassociates into  $\text{H}^+$  and  $\text{OCl}^-$  is insignificant. Express the chlorine concentrations in terms of milligrams per liter of  $\text{Cl}_2(\text{aq})$ .

**Solution**

1. Calculate the initial  $\text{Cl}_2(\text{aq})$  concentration in moles per liter:

$$[\text{Cl}_2(\text{aq})]_0 = \frac{2 \text{ mg/L}}{(35.45 \text{ g/mol}) \times (2 \text{ mol}) \times (10^3 \text{ mg/g})}$$

$$= 2.82 \times 10^{-5} \text{ mol/L}$$

2. Calculate the percentage of  $\text{Cl}_2(\text{aq})$  that is hydrolyzed: The percentage of  $\text{Cl}_2(\text{aq})$  that is converted into HOCl is  $X_{\text{Cl}_2(\text{aq})}$ , and the molar concentrations of  $\text{Cl}^-$ , HOCl,  $\text{H}^+$ , and  $\text{Cl}_2(\text{aq})$  can be expressed as

$$[\text{Cl}_2(\text{aq})] = [\text{Cl}_2(\text{aq})]_0 [1 - X_{\text{Cl}_2(\text{aq})}] = 2.82 \times 10^{-5} [1 - X_{\text{Cl}_2(\text{aq})}]$$

$$[\text{Cl}^-] = [\text{HOCl}] = [\text{Cl}_2(\text{aq})]_0 X_{\text{Cl}_2(\text{aq})} = 2.82 \times 10^{-5} X_{\text{Cl}_2(\text{aq})}$$

The equilibrium constant for Eq. 8-40 can be written as

$$K_{\text{eq}} = \frac{[\text{Cl}^-][\text{HOCl}][\text{H}^+]}{[\text{Cl}_2(\text{aq})]} = \frac{(2.82 \times 10^{-5} X_{\text{Cl}_2(\text{aq})})^2 (10^{-5})}{2.82 \times 10^{-5} (1 - X_{\text{Cl}_2(\text{aq})})}$$

$$= 4 \times 10^{-4}$$

$$X_{\text{Cl}_2(\text{aq})} = 0.999999$$

3. Calculate the equilibrium concentrations of HOCl and  $\text{Cl}_2(\text{aq})$ :
- a. In units of moles per liter:

$$[\text{Cl}_2(\text{aq})] = (2.82 \times 10^{-5} \text{ mol/L})(1 - 0.999999)$$

$$= 2.82 \times 10^{-11} \text{ mol/L}$$

$$[\text{HOCl}] = [\text{Cl}^-] = (2.82 \times 10^{-5} \text{ mol/L})(0.999999)$$

$$= 2.82 \times 10^{-5} \text{ mol/L}$$

- b. In units of milligrams per liter as  $\text{Cl}_2(\text{aq})$ :

$$C_{\text{Cl}_2(\text{aq})} = (2.82 \times 10^{-11} \text{ mol/L})(70.9 \text{ g/mol})(1000 \text{ mg/g})$$

$$= 2 \times 10^{-6} \text{ mg/L as Cl}_2$$

$$C_{\text{HOCl}} = \frac{(2.82 \times 10^{-5} \text{ mol HOCl/L})(70.9 \text{ g/mol Cl}_2)(1000 \text{ mg/g})}{1 \text{ mol HOCl/mol Cl}_2}$$

$$= 1.9998 \text{ mg/L as Cl}_2$$

**Comment**

Chlorine is hydrolyzed almost completely by the reaction with water at 25°C. For the temperatures that are normally encountered in water treatment, the hydrolysis equilibrium constant is large even at low temperatures. Regarding the influence of pH, if the pH were higher, then HOCl would dissociate, resulting in even less Cl<sub>2</sub>(aq).

The species that are initially formed when chlorine is added to water further react with chlorine. The reactions of hypochlorous acid (HOCl), hypochlorite (OCl<sup>-</sup>), and chloride (Cl<sup>-</sup>) are necessary to develop a predominance diagram for chlorine and are discussed in the following sections.

*Hypochlorous acid*

The reactions of hypochlorous acid must be written as reduction reactions. The reduction reaction involving hypochlorous acid and chlorine (from Table E1 at the website listed in App. E) is given by the following:

$$E_H = E^\circ - \frac{0.059}{2} \log \left\{ \frac{[\text{Cl}_2(\text{aq})]}{[\text{H}^+]^2 [\text{HOCl}]^2} \right\} \quad (8-45)$$

At the boundary, [HOCl] equals [Cl<sub>2</sub>(aq)], and when HOCl and Cl<sub>2</sub>(aq) predominate in the solution,  $C_{T,\text{Cl}} \approx 2[\text{Cl}_2(\text{aq})] + [\text{HOCl}] = 10^{-4} \text{ M}$  and  $[\text{HOCl}] = [\text{Cl}_2(\text{aq})] = 3.33 \times 10^{-5} \text{ M}$ , and Eq. 8-45 can be rewritten as

$$E_H = 1.61 - \frac{0.059}{2} \left\{ 2\text{pH} + \log \left[ \frac{3.33 \times 10^{-5}}{(3.33 \times 10^{-5})^2} \right] \right\} \quad (8-46)$$

$$= 1.47 - 0.059 \text{ pH} \quad (8-47)$$

The reduction reaction involving chlorine and the chloride ion (from Table E1 at the website listed in App. E) is given by the following:

$$E_H = E^\circ - \frac{0.059}{2} \log \left( \frac{[\text{Cl}^-]^2}{[\text{Cl}_2(\text{aq})]} \right) \quad (8-49)$$

Similarly, at the boundary [Cl<sup>-</sup>] equals [Cl<sub>2</sub>(aq)], and when Cl<sup>-</sup> and Cl<sub>2</sub>(aq) predominate in the solution,  $C_{T,\text{Cl}} \approx 2[\text{Cl}_2(\text{aq})] + [\text{Cl}^-] = 10^{-4} \text{ M}$  and  $[\text{Cl}^-] = [\text{Cl}_2(\text{aq})] = 3.33 \times 10^{-5} \text{ M}$ , and Eq. 8-49 can be rewritten as

$$E_H = 1.52 \text{ V} \quad (8-50)$$

The acid–base equilibria for hypochlorous acid is given by the following:

$$K_a = \frac{[\text{OCl}^-][\text{H}^+]}{[\text{HOCl}]} \quad (8-52)$$

$$\text{p}K_a = \text{pH} - \log \left( \frac{[\text{OCl}^-]}{[\text{HOCl}]} \right) \quad (8-53)$$

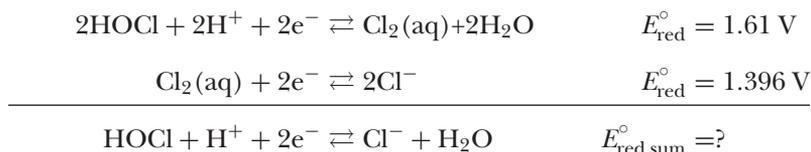

At the boundary,  $[\text{OCl}^-]$  equals  $[\text{HOCl}]$  and the pH equals the  $\text{p}K_a$ :

$$\text{pH} = \text{p}K_a = 7.5 \quad (8-54)$$

The reduction reaction involving hypochlorous acid and the chloride ion is given by the expression

The standard cell potential must be determined using the combined reactions shown below:

The value of  $E_{\text{red,sum}}^\circ$  can be computed using Eq. 8-21:

$$E_{\text{red,sum}}^\circ = \frac{n_{\text{red},1}E_{\text{red},1}^\circ + n_{\text{red},2}E_{\text{red},2}^\circ}{n_{\text{red},1} + n_{\text{red},2}} = \frac{2(1.61 \text{ V}) + 2(1.396 \text{ V})}{2 + 2} = 1.50 \text{ V}$$

The  $E_H$  can be determined using the expression

$$E_H = E^\circ - \frac{0.059}{2} \log \left( \frac{[\text{Cl}^-]}{[\text{HOCl}][\text{H}^+]} \right) \quad (8-56)$$

At the boundary,  $[\text{Cl}^-]$  equals  $[\text{HOCl}]$  and Eq. 8-56 may be rewritten as

$$E_H = 1.50 - \frac{0.059}{2} \text{pH} \quad (8-57)$$

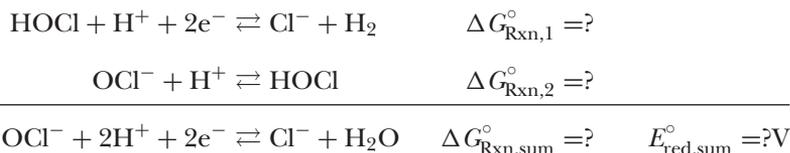

#### *Hypochlorite ion*

The reduction reaction involving hypochlorite and the chloride ion is given by the expression

The two reactions involved are shown below. Because the reaction involving the hypochlorite does not entail the gain or loss of an electron, the

standard cell potential must be determined using the free energy as follows:

The value of  $\Delta G_{\text{Rxn},1}^\circ$  for the reaction involving hypochlorous acid can be determined using Eq. 8-18, rewritten as follows:

$$\begin{aligned} \Delta G_{\text{Rxn},\text{HOCl}}^\circ &= -nFE_{\text{Rxn},1}^\circ \quad E_{\text{Rxn},1}^\circ = 1.5 \text{ V} = 1.5 \text{ J/C} \\ &= -(2 \text{ eq/mol}) (96,500 \text{ C/eq}) (1.5 \text{ J/C}) \\ &= -289,000 \text{ J/mol} \end{aligned}$$

The value of  $\Delta G_{\text{Rxn},\text{OCl}^-}^\circ$  for the reaction involving the hypochlorite ion can be determined using Eq. 8-23, rewritten as follows:

$$\begin{aligned} \Delta G_{\text{Rxn},\text{OCl}^-}^\circ &= -RT \ln K_{\text{eq}} \quad \text{where } K_{\text{eq}} = 10^{7.5} \\ &= -(8.314 \text{ J/mol} \cdot \text{K}) (298 \text{ K}) \ln (10^{7.5}) \\ &= -42,800 \text{ J/mol} \end{aligned}$$

The value of  $\Delta G_{\text{Rxn,sum}}^\circ$  can be obtained using Eq. 8-18 as follows:

$$\begin{aligned} \Delta G_{\text{Rxn,sum}}^\circ &= \Delta G_{\text{Rxn},\text{HOCl}}^\circ + \Delta G_{\text{Rxn},\text{OCl}^-}^\circ \\ &= (-289,000 \text{ J/mol}) + (-42,800 \text{ J/mol}) \\ &= -331,800 \text{ J/mol} \end{aligned}$$

The value of  $E_{\text{red,sum}}^\circ$  can be obtained by rearranging Eq. 8-18:

$$\begin{aligned} E_{\text{red,sum}}^\circ &= \frac{\Delta G_{\text{Rxn,sum}}^\circ}{-n_{\text{Rxn,sum}}F} = \frac{-331,800 \text{ J/mol}}{-(2 \text{ eq/mol}) (96,500 \text{ C/eq})} \times \frac{1 \text{ V}}{1 \text{ J/C}} \\ &= 1.72 \text{ V} \end{aligned}$$

The  $E_H$  can be determined from the equation

$$E_H = E^\circ - \frac{0.059}{2} \log \left( \frac{[\text{Cl}^-]}{[\text{OCl}^-][\text{H}^+]^2} \right) \quad (8-59)$$

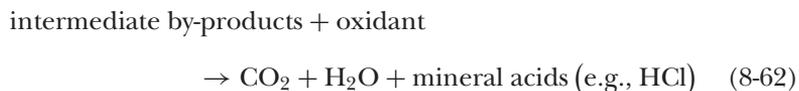

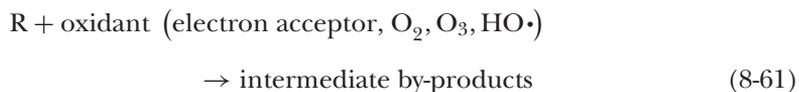

At the boundary,  $[\text{Cl}^-]$  equals  $[\text{HOCl}]$  and the following expression may be obtained:

$$E_H = 1.72 - 0.059 \text{ pH} \quad (8-60)$$

The predominance area diagram can then be constructed by noting that the reduction reaction is favored and the products predominate when  $E_H$  values are higher than the line, as shown on Fig. 8-2. Based on this diagram, the following conclusions may be drawn: (1)  $\text{Cl}_2(\text{aq})$  predominates at low pH, (2)  $\text{Cl}_2(\text{aq})$  disproportionates into HOCl and  $\text{Cl}^-$  at higher pH values, (3)  $\text{Cl}^-$  predominates for typical  $E_H$ -pH values in natural waters, and (4) HOCl,  $\text{OCl}^-$ , and  $\text{Cl}_2(\text{aq})$  are more powerful oxidants than oxygen from a thermodynamic point of view.

### Rate of Oxidation-Reduction Processes

The reaction between an organic compound R (reductant) and an oxidant proceeds as shown in the following elementary reaction; and, based on numerous laboratory and full-scale studies, it has been found that second-order rate constants may be used to assess the rate of reaction:

$$r_R = -k_{\text{ox}} C_{\text{ox}} C_R \quad (8-63)$$

where  $r_R$  = rate of disappearance of organic compound R, mol/L · s  
 $k_{\text{ox}}$  = second-order rate constant for oxidation reaction, L · mol/s  
 $C_{\text{ox}}$  = concentration of oxidant, mol/L  
 $C_R$  = concentration of organic compound R, mol/L

For an oxidant dosage of 0.1 mM, the half lives of compounds with second-order rate constants of 10, 100, 1000, and 10000 L/mol · s are 11.5 min, 1.15 min, 6.93 s, and 0.693 s, respectively. These half-lives are for the oxidation of the parent compound only, and destruction of by-products needs to be considered if the by-products are toxic.

## 8-3 Conventional Chemical Oxidants

Common chemical oxidants used in water treatment are (1) oxygen, (2) chlorine, (3) chlorine dioxide, (4) hydrogen peroxide, (5) ozone, and (6) permanganate. The forms of these oxidants and the method of application are summarized in Table 8-4. With respect to oxidation rate, the following general trend is typically observed; however, there will be exceptions depending on the type of compound that is oxidized:

**Table 8-4**

Common oxidants, forms, and application methods

Oxidant	Forms	Application Methods
Chlorine, free	Chlorine gas, sodium hypochlorite (NaOCl) solution	Gas eductors and spray jets
Chlorine dioxide	Chlorine dioxide gas produced onsite using 25% sodium chlorite solution; sodium chlorite solution reacted with following constituents to form chlorine dioxide [ClO <sub>2</sub> (g)]: gaseous chlorine (Cl <sub>2</sub> ), aqueous chlorine (HOCl), or acid (usually hydrochloric acid, HCl)	Gas eductors
Hydrogen peroxide	Liquid solution	Concentrated solution mixed with water to be treated
Oxygen	Gas and liquid	Pure oxygen or oxygen in air is applied as gas
Ozone	A gas generated onsite by passing compressed air or pure oxygen across an electrode	Applied to water as a gas; mass transfer is an important issue; ozone contactors are usually bubble columns to ensure high transfer efficiency
Permanganate	Available in bulk as granules	Added as dry chemical using feeder or as concentrated solution (no more than 5% by weight due to its limited solubility)

The behavior of the hydroxyl radical, HO•, is discussed in Chap. 18. The purpose of this section is to present information on the conventional oxidants used in water treatment, including (1) the physical and chemical characteristics of the oxidants and (2) their application as oxidants in water treatment operations.

Although the oxygen in the atmosphere has always been with us, Joseph Priestly is credited with the discovery of oxygen in 1775. However, it was Lavoisier who later explained correctly that oxygen was an active constituent of air. He called the gas *oxygen*, which means “acid former,”

## Oxygen (O<sub>2</sub>)

because he incorrectly assumed that all acids contained it. Because oxygen is so readily available, it has been used to oxidize a variety of constituents and compounds found in water. However, as will be demonstrated, the oxidation kinetics are usually too slow to be of practical use in water treatment.

#### PHYSICAL AND CHEMICAL CHARACTERISTICS

Oxygen is a colorless, odorless, and tasteless gas. Under standard conditions ( $0^{\circ}\text{C}$  and 1 atm) about 5 volumes of oxygen will dissolve in 100 volumes of water. Air is comprised of 21 and 23 percent oxygen by volume and weight, respectively (see App. B).

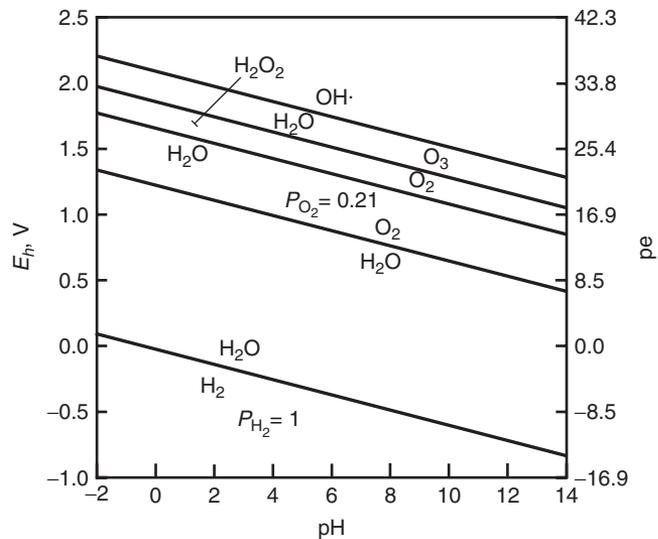

#### *Oxidation potential*

The reduction reaction for oxygen at  $25^{\circ}\text{C}$  is given by the expression

#### *Predominance area diagram for oxygen*

The predominance area diagram for oxygen is shown on Fig. 8-3. The lines that are plotted show the point at which the concentrations of the species are equal; consequently, the species that are indicated on the opposite side of the line are preferred for the particular  $E_H$  and pH value. For example, for an oxygen partial pressure of 0.21 atm, oxygen is the preferred species above the line and water is the preferred species below the line.

**Figure 8-3**  
Predominance area diagram for oxygen system  
for oxygen concentration of 0.21 atm.

**APPLICATIONS OF OXYGEN AS AN OXIDANT**

In surface water bodies such as lakes, rivers, and oceans, oxygen is the oxidant that dominates conditions, determining, for example, the forms that iron, manganese, and sulfur will take. But the rate at which oxygen acts on these species is generally too slow to be useful as a unit process in water treatment plants. The oxidation of ferrous iron Fe(II) is the one notable exception to this observation. Ferrous iron can be oxidized quickly by oxygen under controlled conditions, particularly at alkaline pH. However, Fe(II) is occasionally complexed by NOM to the degree that oxygen is unable to oxidize it in reasonable time.

*Oxidation of iron*

Oxidation of Fe(II) with oxygen can be described by the reaction

The amount of oxygen required for the oxidation of iron is 0.14 mg O<sub>2</sub>/mg Fe<sup>2+</sup>.

Since the pioneering work of Stumm and Lee (1961), more than 300 papers have been written on the rates and mechanisms of ferrous iron oxidation (King, 1998). Based on this body of work, and particularly the work of Millero (Millero and Izaguirre, 1989; Millero and Sotolongo, 1989; Millero, 1989, 1990a,b; Millero et al., 1987) and Wehrli (1990), it has been demonstrated that the overall oxidation rate of ferrous iron in a completely mixed batch reactor (CMBR) can be described as a pseudo-second-order reaction:

$$-\frac{d[\text{Fe(II)}]}{dt} = -r_{\text{Fe(II)}} = P_{\text{O}_2} [\text{Fe(II)}] k_{\text{app}} \quad (8-67)$$

where [Fe(II)] = concentration of ferrous iron, mol/L

$r_{\text{Fe(II)}}$  = overall oxidation rate of ferrous iron, mol/L · min

$t$  = time, min

$P_{\text{O}_2}$  = partial pressure of oxygen, atm

$k_{\text{app}}$  = apparent rate constant, 1/min · atm

It has also been demonstrated that Fe(II) forms a number of ligand complexes in solution. The following are among the more common inorganic ligand complexes: FeCO<sub>3</sub><sup>0</sup>, Fe(CO<sub>3</sub>)<sub>2</sub><sup>2-</sup>, Fe(CO<sub>3</sub>)(OH)<sup>-</sup>, FeCl<sup>+</sup>, FeSO<sub>4</sub><sup>0</sup>, Fe(OH)<sup>+</sup>, and Fe(OH)<sub>2</sub><sup>0</sup>. As mentioned earlier, complexes with NOM have also been shown to have important influence on the rate of oxidation (Theis and Singer, 1974). In the presence of these ligand complexes, the apparent rate constant  $k_{\text{app}}$  can be computed as the sum

$$k_{\text{app}} = 4(k_1\alpha_{\text{Fe}^{2+}} + k_2\alpha_{\text{FeOH}^+} + \dots + k_n\alpha_n) \quad (8-68)$$

where  $k_1, k_2, \dots, k_n$  = first-order rate constant for 1st, 2nd, ... nth Fe(II) species

$\alpha_{\text{Fe}^{2+}}, \alpha_{\text{FeOH}^+}, \dots, \alpha_n$  = fraction of total Fe(II) in solution  
present as species  $\text{Fe}^{2+}, \text{FeOH}^+, \dots,$   
species  $n$

and the factor 4 comes from reaction stoichiometry (King, 1998).

Although thermodynamic constants and rate constants are available for  $\text{Fe}^{2+}$  and for the inorganic ligand complexes listed above, it is usually not practical to calculate  $k_{\text{app}}$  from first principles. The fact that the rate of oxidation takes the form of a pseudo-first-order reaction when  $P_{\text{O}_2}$  is constant in Eq. 8-65 means that bench-scale testing can be used to develop a value of  $k_{\text{app}}$  characteristic of a particular water quality. Such testing should always be conducted to assess the feasibility and gain design criteria for facilities used to oxidize Fe(II) using oxygen.

### Example 8-7 Oxidation of Fe(II) in presence of oxygen

Bench-scale tests have been conducted to examine the rate of oxidation of Fe(II) in a particular well water in the presence of oxygen. The results are shown below:

Time, min	Fe(II), mg/L
0	5
8.3	0.55
16.7	0.30
24.8	0.19
41.7	0.05

Assuming that the partial pressure of oxygen is maintained at 0.21 atm during the tests, determine  $k_{\text{app}}$ .

#### Solution

1. Set up a spreadsheet with the following columns:

Column 1—time, min

Column 2—concentration of Fe(II), mg/L

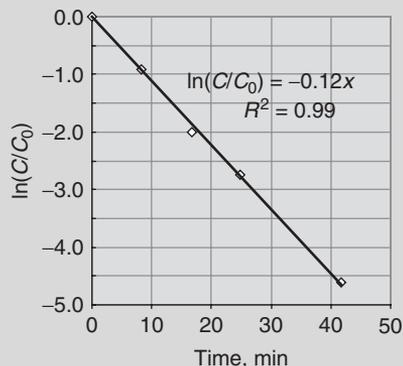

Column 3— $C/C_0$

Column 4— $\ln(C/C_0)$

The spreadsheet values are given below:

Time, min	Fe(II), mg/L	Fe(II), $C/C_0$	Fe(II), $\ln(C/C_0)$
0	5	1	0.00
8.3	2.0	0.4	-0.92
16.7	0.67	0.134	-2.01
24.8	0.32	0.064	-2.75
41.7	0.05	0.01	-4.61

2. Plot time (column 1) versus  $\ln(C/C_0)$  (column 4), and plot the best-fit regression line through the intercept at  $t = 0$  and  $\ln(C/C_0) = 0$ .

The slope of the line is  $-P_{O_2}k_{app}$  :

$$P_{O_2}k_{app} = 0.12 \text{ min}^{-1}$$

$$k_{app} = \left( \frac{0.12/\text{min}}{0.11 \text{ atm}} \right) \simeq 1.091/\text{min} \cdot \text{atm}$$

The oxidation of iron is relatively straightforward in normal, low-TOC groundwaters of low mineral content; however, high levels of TOC have been shown to complex with iron, which prevents its expeditious oxidation (Theis and Singer, 1974). As a practical matter, iron is the only constituent material that oxygen can be relied upon to accomplish removal by direct oxidation.

#### *Oxidation of manganese*

Aeration can also be used for the oxidation of Mn(II), but it has been found that the direct oxidation of Mn(II) is slow, even at elevated pH (Chen 1974; Morgan, 1967). As a result, phenomena other than direct oxidation probably occur when aeration is successful (e.g., biologically mediated oxidation), and unless these phenomena are well understood or there are successful projects of the same scale in the same vicinity with the same water quality, the engineer should avoid relying on these designs. The stoichiometric oxygen dose for the oxidation of Mn(II) is 0.29 mg  $O_2$ /mg  $Mn^{2+}$ .

#### *Oxidation of sulfide*

Aeration can be used to oxidize hydrogen sulfide, but it has been found that the direct oxidation of hydrogen sulfide with oxygen is very slow, even

at elevated pH (Chen 1974; Morgan, 1967). Chen and Morris (1972) did a study of the rate of sulfide oxidation by dissolved oxygen and found that the rate in a CMBR could be described by the empirical rate equation

$$-\left[\frac{d(\sum S^{2-})}{dt}\right]_{t=0} = k \left(\sum S^{2-}\right)_0^{1.34} [O_2]^{0.56} \quad (8-69)$$

where  $(\sum S^{2-})$  = total dissolved sulfide, mol/L

$t$  = time, h

$k$  = observed specific rate, (L/mol)<sup>0.9</sup> · h

$[O_2]$  = concentration of dissolved oxygen, mol/L

A complex reaction pathway was proposed, and the observed specific rate was shown to change significantly with pH. The authors showed that the reaction also requires an induction time. During the induction time, the concentrations of oxygen and sulfide remain unchanged. As a practical matter, this research and practical experience indicate that, unless the reaction between oxygen and sulfide is catalyzed or biologically mediated, its half-life is on the order of several days. Thus, oxidation of sulfide by oxygen alone is not practical in the typical treatment process time frame in a water treatment facility.

## Chlorine (Cl<sub>2</sub>)

Chlorine is the most commonly used compound for the disinfection of water in the United States. The use of chlorine for disinfection is examined in detail in Chap. 13. In the following discussion, the focus is on the use of chlorine as an oxidant.

### PHYSICAL AND CHEMICAL CHARACTERISTICS

Chlorine is a heavy greenish-yellow gas with a characteristic penetrating odor, corrosive and intensely irritating to the respiratory organs of all animals. Chlorine gas is easily liquefied. The physical characteristics of common oxidizing agents including chlorine are summarized in Table 8-5.

#### *Oxidation potential*

The reduction half reaction for chlorine at 25°C and its dissociation products hypochlorous acid and hypochlorite ion are given by the reactions

**Table 8-5**

Properties of common oxidizing agents: chlorine, chlorine dioxide, ozone, hydrogen peroxide, and potassium permanganate

Property	Unit	Chlorine, dioxide,		Ozone,	Hydrogen peroxide,		Potassium permanganate,
		Cl <sub>2</sub>	ClO <sub>2</sub>		O <sub>3</sub>	H <sub>2</sub> O <sub>2</sub>

*Predominance diagram for chlorine*

The chlorine predominance diagram for a total chlorine concentration of  $10^{-4}$  M is shown on Fig. 8-2. The details involved in the preparation of the diagram are given in Sec. 8-2.

**APPLICATION OF CHLORINE AS AN OXIDANT**

Chlorine can be an effective oxidant for some species, particularly sulfide, Fe(II), and Mn(II). Chlorine has also been used for the removal of taste and odor compounds. Occasionally, chlorine is used to remove ammonia.

*Oxidation of sulfide*

Under alkaline conditions, sulfide reacts rapidly with chlorine, and the following two reactions compete with each other:

Although research has been conducted on the oxidation of sulfide by chlorine (Black and Goodson, 1952; Chen, 1974; Powell and Lossberg, 1948), it has not been done in a way that allows more than a qualitative understanding of the chemistry involved. By the first reaction (Eq. 8-74), 2.1 mg  $\text{Cl}_2$  is required per milligram of  $\text{H}_2\text{S}$  removed. By the second reaction (Eq. 8-75), 8.4 mg  $\text{Cl}_2$  is required per milligram of  $\text{H}_2\text{S}$  removed. Both the kinetics and the stoichiometry of the reaction are influenced by the pH. Above pH 8, the chlorine requirement corresponds to Eq. 8-74. As the pH decreases from this point, the chlorine requirement increases until it approaches Eq. 8-75. Generally, the reaction of chlorine with sulfide is rapid, reaching completion in a few minutes.

*Oxidation of iron*

Oxidation of Fe(II) with chlorine is normally quite rapid following the stoichiometry shown below (approximately):

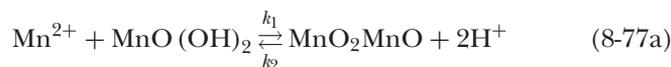

The stoichiometric chlorine dose for the oxidation of iron is 0.63 mg  $\text{Cl}_2$ /mg  $\text{Fe}^{2+}$ . The reaction is relatively rapid. Knocke (1990) has found that the reaction is generally completed in less than 15 min, even at low pH. Like the activity of oxygen, the oxidation of ferrous iron is accelerated by high pH and can be decelerated substantially by the presence of high levels of organic matter (Knocke, et al., 1992).

*Oxidation of manganese*

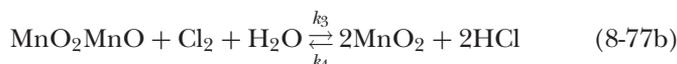

The oxidation of Mn(II) with free chlorine is more difficult than the oxidation of Fe(II). In solution, the reaction between chlorine and Mn(II) is too slow to be useful in water treatment unless the pH is elevated

above approximately 9. When chlorinated water is passed through a filter containing media coated with  $\text{MnO}_2$ , removal will occur by adsorption to the media, and the adsorbed Mn(II) will gradually be oxidized to  $\text{MnO}_2$  on the filter media surface. This behavior is analogous to the oxidation of Mn(II) by oxygen on  $\text{MnO}_2$  surfaces as demonstrated by Morgan (1967). Coffey et al. (1993) proposed the following steps in the oxidation process:

**Step 1:** Adsorption of Mn(II) on the  $\text{MnO}_2$  surface:

**Step 2:** Oxidation of the adsorbed species by chlorine:

Thus, chlorine is commonly used for manganese removal when filtration is available. Some time (on the order of months) is required for the filter media to become coated with the necessary  $\text{MnO}_2$  surface, but once the media is coated, manganese removal is fairly efficient and complete. During the acclimation period, the pH needs to be elevated to accelerate Mn(II) oxidation. Little work has been done on the kinetics of adsorption, but it is likely that the rate of adsorption may be the controlling factor when low effluent concentrations of Mn(II) are required.

#### *Oxidation of tastes and odors*

Given sufficient reaction time, free chlorine is also effective in the control of a wide variety of tastes and odors associated with drinking water, with sulfide odors being the most common, but also many fishy, grassy, and swampy odors. The earthy musty odors associated with geosmin and MIB are not removed with chlorine.

#### *Reactions of chlorine with ammonia*

The removal of ammonia with chlorine is called breakpoint chlorination. Breakpoint chlorination reactions are presented and discussed in Chap. 13. More common is the addition of ammonia to an existing free chlorine residual to stabilize the disinfectant residual and to arrest the formation of undesirable by-products.

One of the principal appeals of chlorine dioxide is that it can oxidize a variety of constituents without producing the trihalomethanes (THMs) and haloacetic acids (HAAs) associated with free chlorine. At the same time, both chlorite and chlorate ions are by-products of oxidation with chlorine dioxide, and regulations on these ions (see Chaps. 4 and 19) sometimes limit the dose of chlorine dioxide to concentration levels that cannot be used for oxidation.

## **Chlorine Dioxide ( $\text{ClO}_2$ )**

**PHYSICAL AND CHEMICAL CHARACTERISTICS**

Chlorine dioxide must be produced onsite because it is unstable at high concentrations. The physical characteristics of chlorine dioxide are summarized in Table 8-5; production methods are discussed in Chap. 13. The following issues must be considered with regard to handling, use, and storage: (1) chlorine dioxide is volatile (dimensionless Henry's constant is 0.0409 at 25°C, which is much larger than Henry's constant for chlorine, which is  $4.42 \times 10^{-5}$  at 25°C) and it can be stripped from aqueous solution if precautions against volatilization are not taken; (2) after it is generated and dissolved in water, chlorine dioxide is stable when it is not exposed to light or high temperatures; and (3) at high pH, chlorine dioxide disproportionates to form both chlorite ( $\text{ClO}_2^-$ ) and chlorate ( $\text{ClO}_3^-$ ), which are regulated by-products (see Chaps. 4 and 19).

*Oxidation potential*

The reduction half reaction for chlorine dioxide at 25°C is given by the reaction

*Formation of chlorite and chlorate*

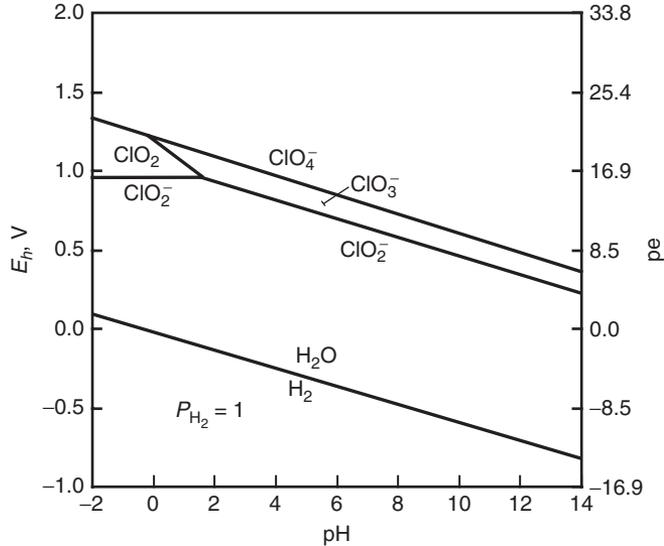

The formation of chlorite ( $\text{ClO}_2^-$ ) and chlorate ( $\text{ClO}_3^-$ ) is given by the reaction

*Predominance diagram for chlorine dioxide*

The chlorine dioxide predominance diagram for a total concentration of  $10^{-4}$  M is shown on Fig. 8-4. The lines plotted show the point at which the concentrations of the species are equal; consequently, the species that are indicated on the opposite side of the line are preferred for the particular  $E_H$  and pH value. For example, for pH values greater than 2, chlorine dioxide is unstable and forms either  $\text{ClO}_2^-$  or  $\text{ClO}_3^-$  depending on the  $E_H$  and pH value. The line for oxygen and water is not shown because it coincides with the chlorate line.

**APPLICATIONS OF CHLORINE DIOXIDE AS AN OXIDANT**

Relatively little has been published on the effectiveness of chlorine dioxide in oxidizing Fe(II) in drinking water, but it is likely that it can be effective when Fe(II) is not strongly complexed with NOM. Based on work with chlorine dioxide and Mn(II), it appears that the reaction is relatively rapid with the formation of colloidal particles of  $\text{MnO}_2$  (Knocke et al., 1988). The typical chlorine dioxide dose that has been reported for the

**Figure 8-4**

Predominance area diagram for chlorine dioxide system for total species concentration of  $10^{-4}$  mol/L.

oxidation of iron is 1.2 mg  $\text{ClO}_2$ /mg  $\text{Fe}^{2+}$ ; the corresponding dose for manganese is 2.5 mg  $\text{ClO}_2$ /mg  $\text{Mn}^{2+}$ . Little information is available on the oxidation of hydrogen sulfide via chlorine dioxide, although, once again, rapid oxidation seems likely. Chlorine dioxide will also remove many of the swampy, grassy, and fishy odors associated with drinking water, but like chlorine, it is of little use against the earthy musty odors associated with MIB and geosmin.

Hydrogen peroxide is one of the strongest oxidizing agents available. A metabolite of many microorganisms, hydrogen peroxide is decomposed by the same organisms to oxygen and water. Hydrogen peroxide is also produced by the action of sunlight on water. The use of hydrogen peroxide in the water field can be traced back to the early 1990s.

## Hydrogen Peroxide ( $\text{H}_2\text{O}_2$ )

### PROPERTIES AND CHEMICAL CHARACTERISTICS

Hydrogen peroxide is a nearly colorless liquid, with blue tinge, which may be solidified. It is soluble in water in all proportions. The physical properties of hydrogen peroxide are summarized in Table 8-5. Commercial solutions typically contain about 35, 50, or 75 percent hydrogen peroxide. In the absence of sunlight and exposure to foreign particles, concentrated solutions can be held for brief periods of time. Hydrogen peroxide becomes quite unstable, particularly in the presence of foreign particles such as dust. The concentrated solution can explode violently at temperatures above  $100^\circ\text{C}$ . Hydrogen peroxide is added to water as a dilute solution.

*Oxidation potential*

The half reaction for hydrogen peroxide at 25°C is

*Predominance diagram for hydrogen peroxide*

The predominance area diagram for a total hydrogen peroxide species concentration of  $10^{-4}$  mol/L is shown on Fig. 8-3. Hydrogen peroxide is preferred above the line and water is preferred below the line.

**APPLICATIONS OF HYDROGEN PEROXIDE AS AN OXIDANT**

One conventional application in water treatment for which hydrogen peroxide has been used successfully is in the oxidation of sulfides. Hydrogen peroxide has also been used for the removal of iron.

*Oxidation of sulfide*

The redox reaction for the oxidation of sulfide is

The stoichiometric hydrogen peroxide dose for the oxidation of sulfide is 1.0 mg  $\text{H}_2\text{O}_2$ /mg  $\text{H}_2\text{S}$ .

*Oxidation of iron*

The redox reaction for the oxidation of iron is

The stoichiometric hydrogen peroxide dose for the oxidation of iron is 0.30 mg  $\text{H}_2\text{O}_2$ /mg  $\text{Fe}^{2+}$ .

*Other oxidation applications*

Little information is available on the effectiveness of peroxide in oxidizing manganese. Based on the limited information that is available, it appears that hydrogen peroxide alone is not particularly effective at controlling tastes and odors. In advanced oxidation, hydrogen peroxide is an important precursor in processes that involve UV light and ozone, as discussed in Chap. 18.

**Ozone ( $\text{O}_3$ )**

The use of ozone as a conventional oxidant is discussed below. However, as discussed in Chap. 18, ozone will react with NOM and produce the hydroxyl radical and thus it can be argued that ozonation is an advanced oxidation process. Advanced oxidation processes involving ozone (including the production of the hydroxyl radical via reactions with NOM) are discussed in Chap. 18.

**PHYSICAL AND CHEMICAL CHARACTERISTICS**

Ozone is applied to water as a gas, which is generated onsite by passing dry compressed air or pure oxygen across an electrode (see Chap. 13). The physical properties of ozone are reported in Table 8-5.

*Oxidation potential*

The reduction half reaction for ozone at 25°C is

*Predominance area diagram for ozone*

The predominance area diagram for a total ozone concentration of  $10^{-4}$  mol/L is shown on Fig. 8-3. The point at which the concentrations of the species are equal corresponds to the lines that are plotted. Consequently, the species that are indicated on the opposite side of the line are preferred for the particular  $E_H$  and pH value. The line that separates the reactants ozone and oxygen clearly indicates that the hydroxyl radical is a much more powerful oxidant than ozone.

**APPLICATION OF OZONE AS AN OXIDANT**

Ozone is used in water treatment in a variety of applications, including (1) disinfection, (2) oxidation of iron and manganese, (3) oxidation of sulfides, (4) oxidation of taste and odor compounds, (5) oxidation of micropollutants, (6) removal of color, primarily through oxidation, (7) control of DBP precursors, and (8) the reduction of chlorine demand through oxidation. Because ozone is considered in Chap. 18, the following discussion is limited to the oxidation of iron, manganese, and sulfide; a brief mention of the oxidation of taste and odor compounds and NOM; and rate constants for ozone oxidation.

*Oxidation of iron and manganese*

The redox reactions for the oxidation of iron and manganese with ozone are as follows:

For iron

For manganese

The stoichiometric ozone dose for the oxidation of iron is 0.43 mg  $\text{O}_3$ /mg  $\text{Fe}^{2+}$ ; the corresponding stoichiometric dose for manganese is 0.88 mg  $\text{O}_3$ /mg  $\text{Mn}^{2+}$ . In both of the above reactions, alkalinity is consumed as a result of acid production. The amount of alkalinity consumed is 1.79 and 1.82 mg/L as  $\text{CaCO}_3$  per milligrams per liter of  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$

oxidized, respectively. Alkalinity is an important issue, especially where alum coagulation is involved, because both consume alkalinity. Ozone should be used with caution for the removal of Mn(II) because it converts Mn(II) to MnO<sub>2</sub> so rapidly that MnO<sub>2</sub> tends to clog ozone diffusers and the MnO<sub>2</sub> that forms in solution is of an extremely fine colloidal nature and can be difficult to remove in filtration.

#### *Oxidation of sulfide*

The redox reaction for the oxidation of sulfide with ozone is

Based on the above reaction, the required ozone dose for the oxidation of sulfide is 1.41 mg O<sub>3</sub>/mg H<sub>2</sub>S. In practice, it has been found that the required ozone dose will vary from 2.0 to 4.0 mg O<sub>3</sub>/mg H<sub>2</sub>S. Ozone dosages greater than the stoichiometric requirement occur because of the presence of other oxidizable constituents and because a portion of the sulfide is often converted to sulfate (SO<sub>4</sub><sup>2-</sup>) rather than elemental sulfur.

#### *Oxidation of taste and odor compounds*

Ozone has been found to be effective for the oxidation of taste and odor compounds in water. Typical ozone doses are in the range of 1 to 3 mg/L with a minimum contact time of 10 to 15 min. However, because the compounds that contribute to taste and odor are site specific, bench- and pilot-scale testing is usually required to establish the appropriate dose and the points of application. As discussed in Chap. 18, ozone can oxidize the taste and odor compounds geosmin and methyl isoborneol through the production of the hydroxyl radical.

#### *Oxidation of NOM*

In addition to the above uses, ozone reacts with NOM to form lower molecular weight polar compounds (e.g., aldehydes, organic acids, and ketones). Many polar compounds are biodegradable and are not believed to be harmful, but they can cause biofouling problems in the water distribution system. As a result, ozonated water can be followed by a biologically active filtration process, which sometimes includes GAC, to remove the biodegradable fraction.

#### *Rate constants for ozone oxidation*

The second-order rate constants for ozone, provided in the electronic Table E2 at the website listed in App. E, are useful in assessing possible reactions and their kinetics. However, NOM can also initiate the production of hydroxyl radicals, which is more important for the degradation of most compounds (Elovitz and von Gunten, 1999; Westerhoff et al., 1999), as

discussed in Chap. 18. The second-order rate constants for organics are highly dependent on the type of organic being oxidized. The reaction rate is high for the hydroxyl- or amine-substituted benzenes and low for aliphatics without nucleophilic sites. Most of the rate constants are too low to allow for the use of ozone in water treatment, unless initiators (e.g., NOM, organic compounds, UV, or hydrogen peroxide) are used to produce hydroxyl radicals, which react rapidly with organic compounds. Reactions that involve hydroxyl radicals are referred to as advanced oxidation processes (see Chap. 18).

Permanganate was first used for water treatment in 1910 in London but did not begin to grow in use until the 1960s, when it was applied successfully for taste and odor control. Since then, potassium permanganate has been accepted by the water industry as one of the most versatile oxidants available.

### Permanganate ( $\text{MnO}_4^-$ )

#### PHYSICAL AND CHEMICAL CHARACTERISTICS

As an oxidant, potassium permanganate is typically more expensive than chlorine and ozone, but for iron and manganese removal, it has been reported to be as efficient and may require considerably less equipment and capital investment. The physical properties of potassium permanganate are summarized in Table 8-5. Potassium permanganate can be purchased in bulk as granules and be added using a dry chemical feeder or as a concentrated solution.

#### *Oxidation potential*

Potassium permanganate will oxidize a wide variety of inorganic and organic compounds. Under acidic conditions the principal reduction half reactions are

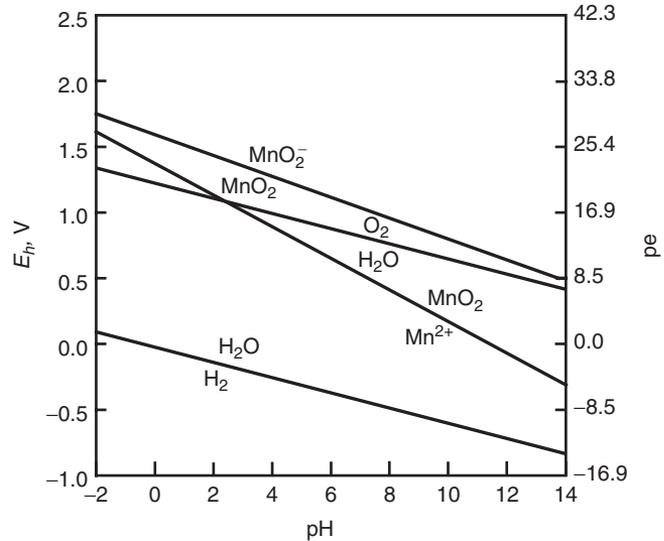

Under alkaline conditions the corresponding reduction half reaction is

#### *Predominance diagram for permanganate*

The predominance area diagram for a total permanganate species concentration of  $10^{-4}$  M is shown on Fig. 8-5. The lines that are plotted show the point at which the concentrations of the species are equal; consequently, the species shown on the opposite side of the line are preferred for the particular  $E_H$  and pH value. For example, the order required for increasing  $E_H$  potential to be thermodynamically favored is  $\text{Mn}^{2+}$ ,  $\text{MnO}_2$ , and  $\text{MnO}_4^-$ .

**Figure 8-5**

Predominance area diagram for permanganate system for total species concentration of  $10^{-4}$  mol/L.

#### APPLICATION OF POTASSIUM PERMANGANATE AS AN OXIDANT

Potassium permanganate is used in drinking water treatment for a variety of purposes. The principal applications involving its use as an oxidant include (1) oxidation of iron and manganese, (2) oxidation of taste and odor compounds, (3) control of nuisance organisms, and (4) control of the formation of THMs and other DBPs by oxidizing precursors and reducing the demand for other disinfectants.

##### *Oxidation of iron and manganese*

The principal use of potassium permanganate in water treatment is the oxidation of iron and manganese. The corresponding redox reactions are as follows:

For iron

For manganese

The stoichiometric potassium permanganate dose for the oxidation of iron is  $0.94 \text{ mg } KMnO_4/\text{mg } Fe^{2+}$ , and the corresponding dose for manganese is  $1.92 \text{ mg } KMnO_4/\text{mg } Mn^{2+}$ . In both of the above reactions alkalinity is consumed as a result of acid production. The amount of alkalinity consumed is 1.49 and 1.21 mg/L as  $CaCO_3$  per milligram per liter of  $Fe^{2+}$  and  $Mn^{2+}$ , respectively. Alkalinity is an important issue, especially where alum coagulation is involved because both consume alkalinity. The oxidation of manganese is considered in the following example.

### Example 8-8 Oxidation of Mn(II) with permanganate

Determine how much Mn(II) remains after 30 s of oxidation with permanganate in a CMBR. The initial concentrations of permanganate and Mn(II) are 1.5 times the stoichiometric requirement and 1 mg/L, respectively. Assume that the second-order rate constant is  $10^5$  L/mol · s.

#### Solution

- Calculate the initial concentration of permanganate using Eq. 8-91. Assume the initial concentrations of  $\text{Mn}^{2+}$  and  $\text{MnO}_4^{2-}$  are  $C_{A0}$  and  $C_{B0}$ , respectively:

$$C_{A0} = [\text{Mn}^{2+}]_0 = \frac{1 \times 10^{-3} \text{ g/L}}{54.938 \text{ g/mol}} = 1.82 \times 10^{-5} \text{ mol/L}$$

$$\begin{aligned} C_{B0} &= [\text{MnO}_4^-]_0 = 1.5 \times \frac{2}{3} \times [\text{Mn}^{2+}]_0 \\ &= 1.5 \times \frac{2}{3} \times (1.82 \times 10^{-5} \text{ mol/L}) \\ &= 1.82 \times 10^{-5} \text{ mol/L} \end{aligned}$$

- Calculate the remaining concentrations of Mn(II):
  - Write a mass balance for a CMBR, and develop the rate expression:

$$\frac{dC_A}{dt} = r_A = -kC_A C_B = -kC_A \left[ C_{B0} - \frac{2}{3} (C_{A0} - C_A) \right]$$

- Integrate the rate expression:

$$\frac{1}{C_{B0} - \frac{2}{3} C_{A0}} \int_{C_{A0}}^{C_A} \left[ \frac{dC_A}{C_A} - \frac{d \left[ C_{B0} - \frac{2}{3} (C_{A0} - C_A) \right]}{C_{B0} - \frac{2}{3} (C_{A0} - C_A)} \right] = - \int_0^t k dt$$

$$\frac{1}{C_{B0} - \frac{2}{3} C_{A0}} \ln \left( \frac{C_A}{C_{B0} - \frac{2}{3} (C_{A0} - C_A)} \times \frac{C_{B0}}{C_{A0}} \right) = -kt$$

$$\frac{C_A}{C_{B0} - \frac{2}{3} (C_{A0} - C_A)} = \frac{C_{A0}}{C_{B0}} \exp \left[ - \left( C_{B0} - \frac{2}{3} C_{A0} \right) kt \right]$$

c. Solve for Mn(II) concentration at  $t = 30$  s:

$$\frac{C_A}{1.82 \times 10^{-5} - \frac{2}{3}(1.82 \times 10^{-5} - C_A)}$$

$$= \exp\left(-0.333 \times 1.82 \times 10^{-5} \times 10^5 \times 30\right)$$

$$C_A = [\text{Mn}^{2+}] = 7.56 \times 10^{-14} \text{ M}$$

*Oxidation of taste and odor compounds*

The application of potassium permanganate is also quite common for the oxidation of the odorous compounds occasionally found in water. Typical dosages of potassium permanganate, which are site specific, vary from 0.25 to 20 mg/L. Potassium permanganate also seems to work fairly well for sulfide oxidation and for the removal of fishy/grassy odors that are produced by methyl sulfides. However, it does a poor job of removing geosmin and MIB.

*Importance of dosage control with permanganate*

Permanganate gives an easily detected pink color to water with overdoses in the 0.05-mg/L range. Due to this fact, the dose range is critical in avoiding consumer complaints. It is also important to remove unreacted permanganate because it will form black deposits in distribution systems and on plumbing fixtures. In addition, the manganese concentration in the final treated water may exceed the levels prescribed in the secondary regulations. A typical permanganate dose is on the order of 1 to 3 mg/L, and a contact time of at least 1 to 2 h is usually provided for the oxidation reaction to be complete. As exceptions, doses as high as 10 mg/L have been used without adverse effects and contact times of 10 to 15 min are sometimes adequate. To obtain longer contact times than would be available in their treatment plant basins, many utilities add  $\text{KMnO}_4$  to raw-water pipelines at the source. If excessive permanganate is used in the oxidation process, it will pass through the downstream filters and enter the distribution system. However, if the excess dose appears to be necessary to remove a target compound, raising the pH prior to solids separation will accelerate the kinetics of permanganate oxidation.

Settling out the excess permanganate in the sedimentation basin generally controls overdosing, which corresponds to the disappearance of permanganate's characteristic pink color. However, for plants without flocculation or sedimentation steps, such as in-line or direct-filtration plants, special monitoring equipment must be used to prevent permanganate from passing through the filters. Excess permanganate residual can sometimes

be removed by adding PAC after the oxidation step to avoid reducing the permanganate's efficiency.

## 8-4 Photolysis

---

Photolysis is a process by which photons are absorbed by compounds, and the energy released is used to drive light-induced oxidation or reduction processes. The rate at which a compound is photolyzed can be estimated from the rate at which the compound absorbs light and the quantum yield (photonic efficiency of the reaction). Estimating these rates is discussed in this section.

Usually, photons in the UV range (200 to 400 nm) are capable of providing enough energy to drive photolytic reactions. There are three major options for UV lamps: (1) low-pressure, low-intensity, (2) low-pressure, high-intensity (sometimes referred to as pulsed UV lamps), and (3) medium-pressure, high-intensity lamps. Low-pressure lamps emit all their energy at a wavelength of 254 nm. The medium-pressure lamps emit energy at several wavelengths. Additional discussion of UV lamp technologies is provided in Chap. 13.

In photolysis, the photons from a light source supply the energy required for a reaction to proceed. For a given photolytic reaction, a reaction occurs when an electron in the outer orbital absorbs a photon and forms an unstable compound that undergoes reaction or splits apart. The photonic energy that is required for such a reaction to proceed depends on the specific electron structure of a given compound, but basic thermodynamics can be used to estimate the minimum photonic energy that is required. The minimum energy for a given reaction may be calculated from the reaction potential. The free energy of the reaction and its electrochemical potential are related to each other as given by Faraday's law:

$$\Delta G_{\text{Rxn}}^{\circ} = -nFE_{\text{Rxn}}^{\circ} \quad (8-92)$$

where  $F$  = Faraday's constant, 96,500 C/eq  
 $n$  = number of photons, eq/mol  
 $\Delta G_{\text{Rxn}}^{\circ}$  = free energy of reaction, J/mol  
 $E_{\text{Rxn}}^{\circ}$  = reaction potential, V or J/C

The reaction potential can also be obtained from summary tables, such as the one in the electronic Table E1 at the website listed in App. E. Often, it is necessary to know the wavelength of light that is necessary for the photolysis reaction to occur. The energy required for the reaction to proceed can be calculated from the reaction potential as follows:

$$E = ne^{-}E_{\text{rxn}}^{\circ} \quad (8-93)$$

**Energy Required  
for Photolysis and  
Wavelength  
of Light**

where  $E$  = energy for photolysis reaction, J  
 $e^-$  = charge of an electron =  $1.602 \times 10^{-19}$  C

The frequency of light is related to the energy of a photon by Planck's constant, as shown in the expression

$$\nu = \frac{E}{h} \quad (8-94)$$

where  $\nu$  = frequency of light,  $s^{-1}$   
 $h$  = Planck's constant,  $6.62 \times 10^{-34}$  J · s

The wavelength of light is inversely related to the frequency, as shown in the expression

$$\lambda = \frac{c}{\nu} \quad (8-95)$$

where  $c$  = speed of light,  $3.00 \times 10^8$  m/s  
 $\lambda$  = wavelength of light, m

Because photonic energy is inversely related to the wavelength, the wavelength of light that is expressed in Eq. 8-95 represents the longest wavelength required to power the photolytic reaction.

### Example 8-9 Determining the longest wavelength of light required for photolysis of hydrogen peroxide

Advanced oxidation processes take advantage of the extreme reactivity of the hydroxyl radical. The hydroxyl radical and its behavior are discussed in Sec. 8-5. In one important advanced oxidation process, hydroxyl radicals are produced by causing UV light to act on hydrogen peroxide. The overall reaction is

The two half reactions for this overall equation can be combined to find the potential of this reaction (see the electronic Table E1 at the website listed in App. E, for half reactions):

Find the potential of the overall reaction. From the overall reaction potential, estimate the frequency and wavelength of the light that will best promote it. Note  $1 \text{ V} = 1 \text{ J/C}$ .

**Solution**

1. Calculate the potential of the overall reaction: Using the procedure for balancing redox reactions (see Sec. 8-2), the potential of the overall reaction can be determined from the potentials of the two half reactions:

$$E_{\text{Rxn}}^{\circ} = E_{\text{ox}}^{\circ} + E_{\text{red}}^{\circ} = -2.59 + 1.763 = -0.827 \text{ V}$$

2. Because  $\Delta G_{\text{Rxn}}^{\circ}$  is positive and  $E_{\text{Rxn}}^{\circ}$  is negative, the reaction requires energy in order to proceed. Calculate the energy required for the reaction using Eq. 8-93:

$$\begin{aligned} E &= ne^{-} E_{\text{rxn}}^{\circ} = (2) (1.602 \times 10^{-19} \text{ C}) (0.827 \text{ J/C}) \\ &= 2.65 \times 10^{-19} \text{ J} \end{aligned}$$

3. Calculate the frequency of the light using Eq. 8-94:

$$\nu = \frac{E}{h} = \frac{2.65 \times 10^{-19} \text{ J}}{6.62 \times 10^{-34} \text{ J} \cdot \text{s}} = 4.00 \times 10^{14} \text{ s}^{-1}$$

4. Calculate the wavelength of the light using Eq. 8-95:

$$\lambda = \frac{c}{\nu} = \frac{(3.00 \times 10^8 \text{ m/s})}{4.00 \times 10^{14} \text{ s}^{-1}} = 7.50 \times 10^{-7} \text{ m} = 750 \text{ nm}$$

**Comment**

This is the longest wavelength of light that can split hydrogen peroxide based on thermodynamics. Shorter wavelengths have higher frequency and higher energy as shown in Eqs. 8-94 and 8-95. However, application of light with shorter wavelengths does not guarantee that the reaction will proceed because the wavelength of light that will split hydrogen peroxide also depends on the electronic structure of the molecule's orbital. Based on experimental evidence, wavelengths much shorter than 750 nm are required to split hydrogen peroxide.

Photolysis generally takes place in circumstances where multiple solutes absorb light; however, to introduce the concepts involved in photolysis, the photolysis of a single absorbing solute will be examined first. As previously stated, photolysis occurs when an electron in the outer orbital absorbs a photon and forms an unstable compound that undergoes a chemical reaction. The photonic absorption efficiency may be calculated from the Beer–Lambert law, which is discussed below. The instability of the compound that absorbed a photon is determined from the quantum yield, as discussed below.

**Estimating  
Photolysis for  
Single Absorbing  
Solute**

**ABSORPTION OF UV LIGHT BY A COMPOUND IN AQUEOUS SOLUTION**

Lambert's law and Beer's law are two empirical laws used to describe light absorption in aqueous solution. When these laws are combined, the Beer–Lambert law (repeated here from Chap. 2) is used to relate the light intensity emerging from solution to the incident light intensity for a one-dimensional light source (e.g., Cartesian coordinates and a plate light source):

$$\log\left(\frac{I}{I_0}\right) = -\varepsilon(\lambda) Cx = -k(\lambda) x = -A(\lambda) \quad (8-96)$$

where

- $I$  = light intensity after passing through solution containing constituents of interest at wavelength  $\lambda$ , einstein/cm<sup>2</sup> · s
- $I_0$  = initial detector reading for blank (i.e., distilled water) after passing through solution of known depth (typically 1.0 cm) at wavelength  $\lambda$ , einstein/cm<sup>2</sup> · s
- $\varepsilon(\lambda)$  = base-10 extinction coefficient or molar absorptivity of light-absorbing solute at wavelength  $\lambda$ , L/mol · cm
- $\lambda$  = wavelength, nm
- $C$  = concentration of light-absorbing solute, mol/L
- $x$  = length of light path, cm
- $k(\lambda)$  = absorptivity (base 10), =  $\varepsilon(\lambda) C$ , cm<sup>-1</sup>
- $A(\lambda)$  = absorbance, =  $k(\lambda) x$ , dimensionless

The terms in Eq. 8-96 can be confusing because they may not be familiar and may be used differently in the literature than in this text. For instance, the term “absorbance” is often used to refer to both the absorbance  $A(\lambda)$  and the absorptivity  $k(\lambda)$ . While the two terms are not equivalent, their values are equal when the path length of absorption,  $x$ , is 1 cm. The unit of einstein is in recognition of the work Albert Einstein did to establish that light was comprised of particles now called photons. One mole of photons is referred to as one einstein. The extinction coefficient is the representation of the general phenomenon that, as the wavelength decreases, more energetic photons are absorbed; thus, the molar absorptivity of a light-absorbing solute increases. Values of the extinction coefficients at various wavelengths,  $\varepsilon(\lambda)$ , for several common compounds are summarized in the electronic Table E3 at the website listed in App. E.

**Example 8-10 Absorption of UV<sub>254</sub> by NDMA**

*N*-Nitrosodimethylamine (NDMA), an undesirable compound sometimes found in drinking water, can be removed by photolysis. Estimate the absorptivity of NDMA at a wavelength of 254 nm for both base e and base 10, assuming

NDMA is present at a concentration of 20 ng/L. The extinction coefficient of NDMA is 1974 L/mol · cm and the molecular weight is 74.09 g/mol.

### Solution

1. Calculate the concentration  $C$  in moles per liter:

$$C = \frac{20 \text{ ng/L}}{(74.09 \text{ g/mol})(10^9 \text{ ng/g})} = 2.7 \times 10^{-10} \text{ mol/L}$$

2. Convert  $\varepsilon(\lambda)$  (base 10) to  $\varepsilon'(\lambda)$  (base  $e$ ):

$$\varepsilon'(254) = \ln(10) \times \varepsilon(254) = 2.303 \times 1974 = 4546 \text{ L/mol} \cdot \text{cm}$$

3. Calculate base 10 absorptivity:

$$\begin{aligned} k(\lambda) &= \varepsilon(254) C = (1974 \text{ L/mol} \cdot \text{cm}) (2.7 \times 10^{-10} \text{ mol/L}) \\ &= 5.33 \times 10^{-7} \text{ cm}^{-1} \end{aligned}$$

4. Calculate base- $e$  absorptivity:

$$\begin{aligned} k'(\lambda) &= \varepsilon'(254) C = (4546 \text{ L/mol} \cdot \text{cm}) (2.7 \times 10^{-10} \text{ mol/L}) \\ &= 1.23 \times 10^{-6} \text{ cm}^{-1} \end{aligned}$$

### Comment

The absorptivity of NDMA is very low because NDMA is present at very low concentrations.

### RATE OF PHOTON ABSORPTION AND QUANTUM YIELD

As described earlier, the rate at which a compound is photolyzed depends on the rate of photon absorption and the fraction of adsorbed photons that results in a reaction. For a single compound, the rate at which photons are absorbed can be determined by differentiating the intensity of light over the distance the light travels, as shown in the following derivation. First, Eq. 8-96 is converted to base  $e$ :

$$\ln\left(\frac{I}{I_0}\right) = -\varepsilon'(\lambda) Cx \quad (8-97)$$

where  $\varepsilon'(\lambda)$  = base- $e$  extinction coefficient or molar absorptivity of light-absorbing solute at wavelength,  $\lambda = 2.303\varepsilon(\lambda)$ , L/mol · cm

Raising both sides of the equation to the  $e$  power and solving for  $I$  yields:

$$I = I_0 e^{-\varepsilon'(\lambda) Cx} \quad (8-98)$$

Differentiating with respect to distance yields the volumetric photon absorption rate  $I_a$ :

$$I_a = -\frac{dI}{dx} = \varepsilon'(\lambda) CI_0 e^{-\varepsilon'(\lambda)Cx} \quad (8-99)$$

where  $I_a$  = number of photons absorbed per volume of solution at particular point, einstein/cm<sup>3</sup> · s

The fraction of adsorbed photons that result in a photolysis reaction must be known to estimate the rate of photolysis of a particular compound. This fraction is called the quantum yield and depends on the type of compound and the wavelength. The quantum yield  $\phi(\lambda)$  is defined as the rate of photolysis divided by photon absorption rate as follows:

$$\phi(\lambda) = \frac{-r_R}{I_a} = \frac{\text{photolysis reaction rate}}{\text{photon absorption rate}} \quad (8-100)$$

where  $\phi(\lambda)$  = quantum yield at wavelength  $\lambda$ , mol/einstein  
 $r_R$  = reaction rate, mol/cm<sup>3</sup> · s

As a general rule, the quantum yield  $\phi(\lambda)$  increases as wavelength decreases (increasing photonic energy). Selected quantum yields at wavelength 254 nm are summarized in Table 8-6.

#### RATE OF PHOTOLYSIS IN A COMPLETELY MIXED FLOW REACTOR

For modeling a UV reactor in Cartesian coordinates, it is convenient to assume the light source to be a flat plate and that the photonic flux is in the  $x$  direction. The resulting light intensity is constant in the  $y$ - $z$  plane for a given  $x$  value and is illustrated on Fig. 8-6. Rearranging Eq. 8-100 and substituting Eq. 8-99 yields an expression that describes the reaction rate at a local point in the reactor

$$r_x = -\phi(\lambda) I_a = -\phi(\lambda) \varepsilon'(\lambda) CI_0 e^{-\varepsilon'(\lambda)Cx} \quad (8-101)$$

where  $r_x$  = photolysis rate at a point in reactor, mol/cm<sup>3</sup> · s  
 $x$  = distance from light source, cm

Because the contents of the reactor are mixed completely in the  $y$ - $z$  plane, the overall average photolysis rate in the reactor can be determined by integrating Eq. 8-100 over the path length of the light, as shown below:

$$r_{\text{avg}} = \frac{1}{b} \int_0^b r_x dx = -\frac{1}{b} \int_0^b \phi(\lambda) \varepsilon'(\lambda) CI_0 e^{-\varepsilon'(\lambda)Cx} dx \quad (8-102)$$

$$r_{\text{avg}} = -\frac{\phi(\lambda) I_0}{b} \left(1 - e^{-\varepsilon'(\lambda)Cb}\right) = -\phi(\lambda) P_{U-V} \left(1 - e^{-\varepsilon'(\lambda)Cb}\right) \quad (8-103)$$

where  $r_{\text{avg}}$  = average photolysis rate, mol/cm<sup>3</sup> · s  
 $b$  = effective light path length, cm  
 $P_{U-V} = I_0/b$  = photonic intensity per volume, einstein/cm<sup>3</sup> · s

**Table 8-6**  
Selected quantum yields

Compound	Primary Quantum Yield in Aqueous Phase, mol/einstein	Extinction Coefficient at 253.7 nm, (Base 10) L/mol · cm
NO <sub>3</sub> <sup>-</sup>	—	3.8

<sup>a</sup>330 nm.

<sup>b</sup>Independent of wavelength.

<sup>c</sup>Nowell and Hoigne (1992a).

<sup>d</sup>Nowell and Hoigne (1992b).

<sup>e</sup>Reisz et al. (2003).

<sup>f</sup>Gurol and Akata (1996).

<sup>g</sup>Cosson and Ernst (1994).

<sup>h</sup>Zika et al. (1984).

<sup>i</sup>Taku and Tanaka (2000).

<sup>j</sup>Mertens and von Sonntag (1995).

<sup>k</sup>Sharpless and Linden (2003).

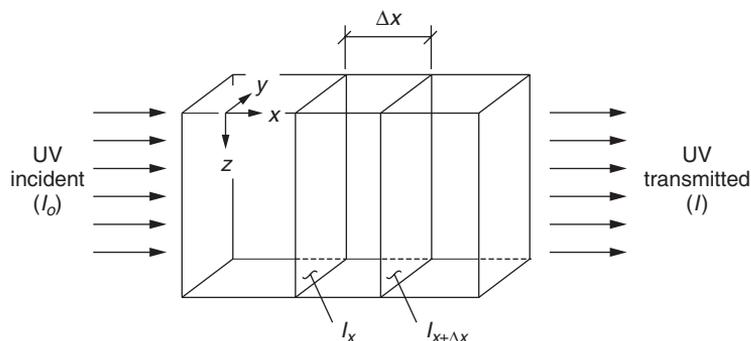

<sup>l</sup>Ho et al. (1996).

Photoreactors are designed in such a way that all the light remains within the reactor and is absorbed (e.g., using reflective surfaces). The effective path length is then much longer than the physical dimensions of the reactor, as the light bounces back and forth between reflective surfaces until all the light is adsorbed. When the path length  $b$  is sufficiently large, the exponent term in Eq. 8-103 approaches zero.

Accordingly, the average rate of reaction is given by the zero-order rate expression

$$r_{\text{avg}} = -\frac{\phi(\lambda) I_0}{b} = -\phi(\lambda) P_{\text{U-V}} \quad (8-104)$$

Thus, the reaction rate in a completely mixed, reflective reactor is independent of the concentration of compound being photolysed and depends only on two parameters: (1) the photonic energy per unit volume and (2) the quantum yield. This relationship is true regardless of the geometry of the light source and reactor as long as the solution is mixed completely. Most UV lamps are cylinders, but if all the light is absorbed, the photolysis rate is still given by Eq. 8-104.

**Figure 8-6**  
Definition sketch for light flux in one dimension.

#### DETERMINING QUANTUM YIELD IN A BENCH-SCALE COLLIMATED BEAM APPARATUS

Bench-scale experiments can be conducted in a collimated beam apparatus. A collimated beam apparatus is a device in which coherent light is produced that irradiates a Petri dish. The objective is to achieve uniform irradiation of a sample by using a one-dimensional light source and a shallow reactor.

If the reactor is sufficiently shallow, the distance from light source ( $x$  in Eq. 8-98) is small and the exponent term is approximately equal to one. Under these circumstances, Eq. 8-98 can be simplified to

$$I_a = \varepsilon'(\lambda) C I_0 \quad (8-105)$$

Multiplying the photon adsorption rate by the quantum yield (Eq. 8-100) yields the following expression for the average photolysis rate:

$$r_{avg} = -\phi(\lambda) \varepsilon'(\lambda) C I_0 \quad (8-106)$$

Applying a mass balance for a completely mixed batch reactor (the Petri dish) and solving for the concentration results in the following expression:

$$\frac{C}{C_0} = e^{-\phi(\lambda) I_0 \varepsilon'(\lambda) t} \quad (8-107)$$

The use of Eq. 8-107 to estimate the quantum yield from laboratory data is illustrated in Example 8-11.

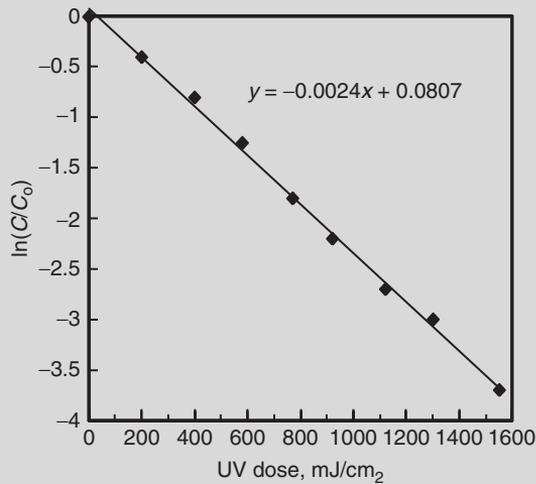

### Example 8-11 Estimation of the quantum yield from collimated beam experiments

Calculate the quantum yield of NDMA from the collimated beam data obtained from a bench-scale experiment using a low-pressure UV lamp. The molar absorption coefficient for NDMA at a wavelength of 253.7 nm is 1974 L/mol · cm (see Table 8-6).

Time, s	Time, min	UV dose, mJ/cm <sup>2</sup>	[NDMA], μM
0	0.0	0	1.00
180	3.0	200	0.67
350	5.8	400	0.45
420	7.0	580	0.29
600	10.0	770	0.17
800	13.3	920	0.11
950	15.8	1120	0.07
1100	18.3	1300	0.05
1250	20.8	1550	0.02

### Solution

- Plot the logarithm (base e) of the ratio of the concentration to the initial concentration of NDMA as a function of UV dose.

- Convert Eq. 8-107 to a linear form by taking the natural log of both sides of the equation:

$$\ln \left[ \frac{C}{C_0} \right] = -\phi_i(\lambda) \epsilon_i(\lambda) \ln(10) I_0 t$$

- Rearrange the equation given in step 2 to solve for  $\phi_i(\lambda)$ :

$$\phi_i(\lambda) = - \left[ \frac{\ln(C/C_0)}{I_0 t} \right] \left[ \frac{1}{\epsilon_i(\lambda) \ln(10)} \right]$$

It should be noted that the first term on the right side of the equations corresponds to the slope of the line in the plot created in step 1 above.

4. Substitute the slope of the line and the value of the extinction coefficient to determine the value for  $\phi_i(\lambda)$ :

$$\begin{aligned}\phi_i(\lambda) &= -(-0.0024 \text{ cm}^2/\text{mJ}) \left[ \frac{1}{(1974 \text{ L/mol} \cdot \text{cm}) \times 2.303} \right] \left[ \frac{\text{L}}{10^3 \text{ cm}^3} \right] \\ &= 5.28 \times 10^{-10} \text{ mol/mJ}\end{aligned}$$

5. Convert  $\phi_i(\lambda)$  to units of mol/einstein using the following expression

$$U_\lambda = \frac{A_v h c}{\lambda}$$

where  $U_\lambda$  = energy per einstein for photons of wavelength  $\lambda$ ,  
J/einstein

$A_v$  = Avagadro's number,  $6.02214 \times 10^{23}$  photons/einstein

$h$  = Planck's constant,  $6.62607 \times 10^{-34}$  J · s/photon

$c$  = speed of light,  $2.99792 \times 10^8$  m/s

$\lambda$  = wavelength of light, m

At 253.7 nm of wavelength,  $U_\lambda$  becomes 471,155 J/einstein

$$\begin{aligned}\phi_i(\lambda) &= (5.28 \times 10^{-10} \text{ mol/mJ})(U_\lambda) \\ &= (5.28 \times 10^{-10} \text{ mol/mJ})(471,155 \text{ J/einstein})(1000 \text{ mJ/J}) \\ &= 0.25\end{aligned}$$

### Comment

The estimated value is in good agreement with literature-reported experimental values.

### Photolysis in Presence of Multiple Absorbing Compounds

The principles of UV absorbance and photolysis have been examined for a single absorbing compound, and now these principles will be extended to cover the more common circumstance where a number of absorbing compounds are present in solution. An analogous extension of the same concepts can be employed to examine the performance of UV lamps emitting multiple wavelengths. Although this approach will be outlined, the details of that analysis are beyond the scope of this discussion. The

discussion of photolysis in the presence of multiple absorbing compounds will be on the basis of a single incident wavelength, which is the circumstance that occurs when low-pressure, low-intensity and low-pressure, high-intensity UV lamps are used.

#### ABSORPTION BY MULTIPLE COMPOUNDS

Functional groups or bonds on chemical compounds responsible for the absorption of light are referred to as *chromophores*. When more than one chromophore is present in a solution, their impact on the absorption of light is additive. As a result, the absorption of light as it passes through a solution containing several different compounds may be determined by summing the absorption that would result from each individual compound, as shown in the expression

$$\ln\left(\frac{I}{I_0}\right) = -\left[\sum \epsilon'(\lambda)_i C_i\right] x \quad (8-108)$$

where  $\epsilon'(\lambda)_i$  = extinction coefficient of compound  $i$  at wavelength  $\lambda$   
(base  $e$ ), L/mol · cm

$C_i$  = concentration of compound  $i$ , mol/L

#### ABSORPTION OF UV BY NOM

The extinction coefficient for NOM varies over a wide range and is typically site specific. Because the specific UV absorption ratio at 254 nm (SUVA, L/mg · m) is used frequently in estimating the potential for formation of disinfection by-products (see Chap. 19), SUVA data are widely available. The SUVA is the extinction coefficient expressed in L/mg · m and is related to absorptivity  $k(\lambda)$  and extinction coefficient  $\epsilon(254)$ , as shown in the equations

$$\text{SUVA} \left( \frac{\text{L}}{\text{mg C} \cdot \text{m}} \right) = \frac{k(254) \text{ cm}^{-1}}{(\text{DOC mg C / L})} \times \frac{100 \text{ cm}}{\text{m}} \quad (8-109)$$

$$\epsilon(254) \frac{\text{L}}{\text{mg} \cdot \text{cm}} = \frac{k(254) \text{ cm}^{-1}}{\text{DOC mg C / L}} \quad (8-110)$$

$$\text{SUVA} = \epsilon(254) \frac{\text{L}}{\text{mg} \cdot \text{cm}} \times 100 \frac{\text{cm}}{\text{m}} \quad (8-111)$$

The range of values and the average value for extinction coefficients for NOM at 254 nm that have been reported (Westerhoff et al., 1999) are 0.013 to 0.107 L/mg C · cm, which correspond to SUVA values between 1.3 and 10.7.

### Example 8-12 Estimating absorptivity $k(\lambda)$ of $UV_{254}$ of water sample

A potential raw-water source for drinking water is analyzed and found to contain the following constituents:

Constituent	Unit	Value
DOC	mg/L as C	3.0
Fe(II)	mg/L as Fe	0.3
Nitrate	mg/L as $NO_3^-$	5.5
SUVA	L/mg · m	2

Estimate the absorptivity (both base 10 and base e) of the water at a wavelength of 254 nm.

#### Solution

- Convert the constituent concentrations to moles per liter:

Constituent	Concentration		
	MW	mg/L	mol/L
Nitrate	62	5.5	$8.87 \times 10^{-5}$
DOC	—	3.0	—
Fe(II)	56	0.3	$0.54 \times 10^{-5}$
Water	18	$10^6$	55.6

- Calculate the extinction coefficient for DOC using Eq. 8-111:

$$\epsilon(254) = \frac{SUVA}{100} = 0.02 \text{ L/mg} \cdot \text{cm}$$

- Estimate the absorptivity.
  - Find the extinction coefficients for the other constituents using the data given in the electronic Table E3 at the website listed in App. E, and estimate the absorptivity of each constituent:

Constituent	Concentration,		
	C (mol/L)	$\epsilon(254)$	$\epsilon(254)C$
Nitrate	$8.87 \times 10^{-5}$	3.8	0.0003
DOC	3 (mg/L)	0.02	0.0600
Fe(II)	$0.54 \times 10^{-5}$	465	0.0025
Water	55.6	$6.1 \times 10^{-6}$	0.0003
			$\Sigma = 0.0631$

b. Sum the absorptivity of each component:

$$k(254) = \sum \varepsilon(254) C = 0.0631 \text{ cm}^{-1}$$

c. Convert to absorptivity base 10 to base e:

$$k'(254) = 2.303k(254) = 0.145 \text{ cm}^{-1}$$

### Comment

The absorptivity is dominated by the DOC, and the absorptivity of both the nitrate and the water itself is insignificant.

### RATE OF PHOTON ABSORPTION WITH MULTIPLE COMPOUNDS PRESENT

To determine the rate at which the target compound absorbs photons when multiple compounds are present, the photon absorption rate for the other compounds must also be determined. The absorption rate of all the species in a solution with  $n$  compounds present can be obtained by rearranging and differentiating Eq. 8-108 as follows:

$$I_a = -\frac{dI}{dx} = I_0 \left[ \sum_1^n \varepsilon'(\lambda)_i C_i \right] \exp \left[ -x \sum_1^n \varepsilon'(\lambda)_i C_i \right] \quad (8-112)$$

where  $\varepsilon'(\lambda)_i$  = extinction coefficient of compound  $i$  (base  $e$ ), L/mol · cm  
 $C_i$  = concentration of compound  $i$ , mol/L  
 $n$  = number of compounds, unitless  
 $x$  = length of light path, cm  
 $I_a$  = combined rate at which all  $n$  compounds are absorbing photons at wavelength  $\lambda$ , einstein/cm<sup>3</sup> · s  
 $I_0$  = irradiance entering the reactor, einstein/cm<sup>2</sup> · s

Thus, the relative rate at which each particular compound absorbs photons can be determined using the expression

$$I_{aj} = -\frac{dI_j}{dx} = I_0 \varepsilon'(\lambda)_j C_j \exp \left[ -x \sum_1^n \varepsilon'(\lambda)_i C_i \right] \quad (8-113)$$

where  $I_{aj}$  = rate at which compound  $j$  is absorbing photons, einstein/cm<sup>3</sup> · s  
 $I_j$  = light intensity after passing through solution containing compound  $j$  at wavelength  $\lambda$ , einstein/cm<sup>2</sup> · s  
 $\varepsilon'(\lambda)_j$  = extinction coefficient of compound  $j$  (base  $e$ ), L/mol · cm  
 $C_j$  = concentration of compound  $j$ , mol/L

**MODELING REACTOR PERFORMANCE**

Equation 8-113 can be combined with Eq. 8-101 to estimate the rate of photolysis for compound  $j$  at a point that is a distance  $x$  from the light source:

$$r_{x,j} = -\phi(\lambda)_j I_0 \varepsilon'(\lambda)_j C_j \exp \left[ -x \sum_1^n \varepsilon'(\lambda)_i C_i \right] \quad (8-114)$$

where  $r_{x,j}$  = photolysis rate of compound  $j$  at a point  $x$  in reactor,  
mol/cm<sup>3</sup> · s  
 $x$  = distance from light source, cm  
 $\phi(\lambda)_j$  = quantum yield of compound  $j$  at wavelength  $\lambda$ ,  
mol/einstein

The average rate of photolysis of compound  $j$  in a photoreactor with an optical path length  $b$  can be determined by substituting Eq. 8-114 in Eq. 8-102 and integrating to obtain the expression

$$\begin{aligned} r_{\text{avg},j} &= -\phi(\lambda)_j f_j \left( \frac{I_0}{b} \right) \left\{ 1 - \exp \left[ -b \sum_1^n \varepsilon'(\lambda)_i C_i \right] \right\} \\ &= -\phi(\lambda)_j f_j P_{\text{U-V}} \left\{ 1 - \exp \left[ -b \sum_1^n \varepsilon'(\lambda)_i C_i \right] \right\} \end{aligned} \quad (8-115)$$

where  $r_{\text{avg},j}$  = overall average photolysis rate of compound  $j$  in reactor,  
mol/cm<sup>3</sup> · s  
 $f_j$  = fraction of light absorbed by component  $j$ , dimensionless  
and calculated by the expression

$$f_j = \left[ \frac{\varepsilon'(\lambda)_j C_j}{\sum_{i=1}^n \varepsilon'(\lambda)_i C_i} \right] \quad (8-116)$$

Equation 8-115 becomes first order in component  $j$  if  $j$  absorbs only a fraction of the light. Many photoreactors are designed with reflective surfaces so that all the light emitted by the lamps is retained in the reactor. In these circumstances, Eq. 8-115 reduces to the form

$$r_{\text{avg},j} = -\phi(\lambda)_j f_j P_{\text{U-V}} \quad (8-117)$$

### Addressing Multiple Wavelengths

When medium-pressure lamps are used in the photooxidation process, the spectral distribution of the lamp must be considered. Usually, the incident UV light intensity is measured at specific wavelength intervals (e.g., 5 nm) within the effective UV radiation range. The UV light intensity can be assumed to be monochromatic within small wavelength increments. The quantum yield  $\phi(\lambda)$  and the extinction coefficient  $\varepsilon(\lambda)$  of an absorbing compound are dependent upon wavelength. Knowing the UV light intensities  $I_{01}, I_{02}, I_{03}, \dots, I_{0k}$  at every  $k$ th-wavelength band (represented as  $\lambda_1, \lambda_2,$

$\lambda_3, \dots, \lambda_k$ ) as well as the quantum yields  $\phi(\lambda_1), \phi(\lambda_2), \phi(\lambda_3), \dots, \phi(\lambda_k)$  and extinction coefficients  $\epsilon'(\lambda_1), \epsilon'(\lambda_2), \epsilon'(\lambda_3), \dots, \epsilon'(\lambda_k)$ , the following formula can be developed to estimate the photolysis rate:

$$r_{\text{avg}} = - \sum_{j=1}^k [\phi(\lambda_j) P_{\text{U-V},j} f(\lambda_j)] \quad (8-118)$$

where  $r_{\text{avg}}$  = overall average photolysis rate of an absorbing compound in a reactor with multiple wavelengths,  $\text{mol}/\text{cm}^3 \cdot \text{s}$

$\phi(\lambda_j)$  = quantum yield at wavelength  $\lambda_j$ ,  $\text{mol}/\text{einstein}$

$P_{\text{U-V},j}$  = photonic intensity per volume for wavelength  $j$ ,  $= I_{0j}/b$   
einstein/ $\text{cm}^3 \cdot \text{s}$

$f(\lambda_j)$  = fraction of light absorbed at wavelength  $\lambda_j$ , dimensionless

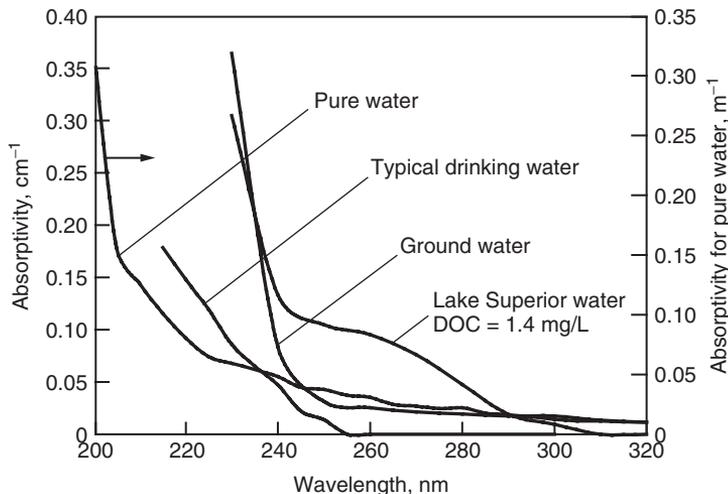

$k$  = number of wavelength, unitless

$b$  = optical path length, cm

The extinction coefficients for common inorganic species in water as a function of wavelength are reported in the electronic Table E3 at the website listed in App. E. The absorbances of several natural water resources are illustrated as a function of wavelength on Fig. 8-7.

Photolysis may be used to remove some organic compounds, notably NDMA and several oxidants and disinfectants, such as chlorine, chlorine dioxide, and combined chlorine and ozone. However, for the destruction of most organic compounds, photolysis is often more efficient when used in combination with hydrogen peroxide so that hydroxyl radicals can be produced. The use of photolysis with hydrogen peroxide oxidation is a form of advanced oxidation and is discussed in greater detail in Chap. 18.

### Application of Photolysis in Water Treatment

**Figure 8-7**

The UV absorbance of typical natural water and pure water (Lake Superior sample taken 9 km from the shore of Eagle Harbor, MI).

**CONVERTING LAMP POWER EINSTEIN UNITS**

In theory, the photons entering the reactor per unit volume of the reactor and time,  $P_{U-V}$  (einstein/L · s), can be determined using the expression

$$P_{U-V} = \frac{P \times \eta}{N_{av} \times V \times h\nu} \quad (8-119)$$

where  $P$  = lamp power, W  
 $h$  = Planck's constant,  $6.62 \times 10^{-34}$  J · s  
 $\eta$  = electrical efficiency (as a fraction), dimensionless  
 $N_{av}$  = Avogadro's number,  $6.023 \times 10^{23}$  molecules/mol  
 $V$  = reactor volume, L  
 $\nu$  = frequency of light,  $= c/\lambda$ ,  $s^{-1}$   
 $c$  = speed of light,  $3.00 \times 10^8$  m/s  
 $\lambda$  = wavelength of light, m

The following assumption was made to develop Eq. 8-119: There are no photon losses upon reflection off the reactor wall or through the exterior surface of sleeves that cover the lamps (precipitate builds up on the exterior surface because of the elevated temperature). Consequently, Eq. 8-119 represents the highest possible photonic intensity per volume. Performance of an actual photoreactor is much lower than would be expected by Eq. 8-119, partly due to light being absorbed and blocked by the precipitate that forms on the lamp sleeve and reactor walls.

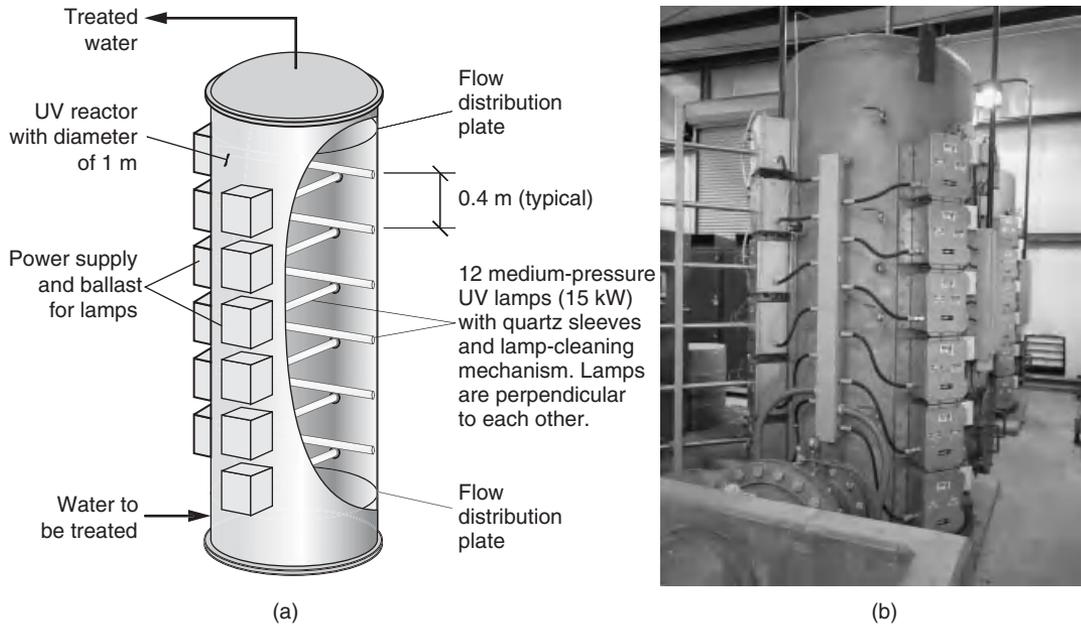

**PHOTOREACTOR DESIGN**

A typical UV photolysis reactor is a stainless steel column that contains UV lights in a criss-crossing pattern, as shown in the schematic on Fig. 8-8a and the photo on Fig. 8-8b. The approximate locations of the lamps are shown on the left, and the perpendicular arrangement is shown on the right of Fig. 8-8a. Most lamps are cylindrical in shape, and, in this design, they are arranged perpendicular to the direction of flow. The UV lamps are covered with quartz-insulating sleeves to allow the lamps to operate at the appropriate temperature. The elevated temperature of the lamp sleeves causes inorganic precipitates to form, which are removed on a routine basis by collars that move back and forth across the sleeves. Other options for photoreactors, including those that are used for disinfection, are discussed in Chap. 13.

The rate of destruction (for a single wavelength  $\lambda$ ) of a compound by photolysis may be described by Eq. 8-117. Equation 8-117 is expanded further in the expression

$$r_{avg,j} = -\phi(\lambda)_j f_j P_{U-V} = -\phi(\lambda)_j P_{U-V} \frac{\epsilon'(\lambda)_j C_j}{\sum_{i=1}^n \epsilon'(\lambda)_i C_i} \quad (8-120)$$

where  $r_{avg,j}$  = overall average photolysis rate of compound  $j$  in reactor, mol/L · s

**Figure 8-8**  
UV reactor used for advanced oxidation: (a) schematic and (b) photograph.

$\phi(\lambda)_j$  = quantum yield of compound  $j$  at wavelength  $\lambda$ ,  
mol/einstein

$f_j$  = fraction of light absorbed by compound  $j$ , dimensionless

$P_{U-V}$  = photonic intensity per unit volume, einstein/cm<sup>3</sup> · s

$\epsilon'(\lambda)_i$  = extinction coefficient of compound  $i$  (base  $e$ ), L/mol · cm

$\epsilon'(\lambda)_j$  = extinction coefficient of compound  $j$  (base  $e$ ), L/mol · cm

$C_i$  = concentration of compound  $i$ , mol/L

$C_j$  = concentration of compound  $j$ , mol/L

In most cases, the light absorption by the component that is targeted for removal is minor as compared to the light absorption by the background water matrix. For this situation, the rate law becomes pseudo-first order, as shown in the following expression:

$$r_{\text{avg},j} = k_j C_j \quad (8-121)$$

$$k_j = \phi(\lambda)_j P_{U-V} \frac{\epsilon'(\lambda)_j}{\sum_{i=1}^n \epsilon'(\lambda)_i C_i} \quad (8-122)$$

where  $k_j$  = pseudo-first-order rate coefficient, s<sup>-1</sup>

If all the chromophores in the water have been measured, then the pseudo-first-order rate coefficient can be estimated from that analysis. However, it is more accurate and easier to measure the absorptivity of the

water matrix. The pseudo-first-order rate coefficient of the water matrix can be determined by simplifying Eq. 8-122 as follows:

$$k_j = \phi(\lambda)_j P_{U-V} \frac{\epsilon'(\lambda)_j}{k'(\lambda)} \quad (8-123)$$

where  $k'(\lambda)$  = absorptivity of water matrix at wavelength (base  $e$ )  $\lambda$ ,  $\text{cm}^{-1}$

#### PERFORMANCE OF A COMPLETELY MIXED FLOW REACTOR

The mass balances for various ideal and nonideal reactors are discussed in Chap. 6. For a complete mixed flow reactor (CMFR), the following expression relates the effluent concentration to the influent concentration:

$$\frac{C_{j,e}}{C_{j,o}} = \frac{1}{1 + k_j \tau} \quad (8-124)$$

where  $C_{j,e}$  = effluent concentration of component  $j$ , mg/L  
 $C_{j,o}$  = influent concentration of component  $j$ , mg/L  
 $k_j$  = pseudo-first-order rate constant,  $\text{s}^{-1}$   
 $\tau$  = hydraulic detention time of photoreactor, =  $V/Q$ , s  
 $V$  = reactor volume, L  
 $Q$  = volumetric flow rate, L/s

#### PERFORMANCE OF PLUG FLOW REACTOR

For a plug flow reactor (PFR), the following expression relates the effluent concentration to the influent concentration:

$$\frac{C_{j,e}}{C_{j,o}} = e^{-k_j \tau} \quad (8-125)$$

where the terms are as defined above.

#### PERFORMANCE OF NONIDEAL REACTOR

Most reactors are not PFRs or CMFRs, and, as discussed in Chap. 6, tracer studies can be conducted on the reactors to determine the degree of nonideal mixing that occurs. Models that describe nonideal mixing may be fit to the tracer curve and then used to describe reactor performance. The TIS model and the DFM are two models that were discussed in Chap. 6 and are repeated here. The SFM may also be used to estimate reactor performance when a tracer curve is available, as discussed in Chap. 6.

##### *Tanks in series model*

The TIS model is used to describe nonideal mixing in a photoreactor by varying the number of tanks in series. The following expression

relates the effluent concentration to the influent concentration for the TIS model:

$$\frac{C_{j,e}}{C_{j,o}} = \frac{1}{(1 + k_j\tau/n)^n} \quad (8-126)$$

where  $n$  = number of tanks, unitless

Other terms are as defined previously.

#### *Dispersed flow model*

The nonideal mixing in a photoreactor may be described by the DFM using the Peclet number. The following expression relates the effluent concentration to the influent concentration for the DFM model:

$$\frac{C_{j,e}}{C_{j,o}} = \frac{4a \exp(\text{Pe}/2)}{(1+a)^2 \exp(a\text{Pe}/2) - (1-a^2) \exp(-a\text{Pe}/2)} \quad (8-127)$$

$$a = \sqrt{1 + \frac{4k_j\tau}{\text{Pe}}} \quad (8-128)$$

where  $\text{Pe} = vL/E$ , also known as the Peclet number, dimensionless

$v$  = average velocity of fluid, m/s

$L$  = reactor length, m

$E$  = dispersion coefficient,  $\text{m}^2/\text{s}$

Other terms are as defined previously.

### **Example 8-13 Removal of NDMA by photolysis**

The source water for a drinking water treatment plant in California contains 20 ng/L NDMA. The treatment objective for NDMA has been set at 2 ng/L. After considering various treatment options, UV photolysis has been chosen for NDMA removal. The commercial reactors being evaluated are 1 m in diameter and 3 m in height (water volume 2300 L). Each reactor has 12 lamps that use 15 kW per lamp. The lamps are 20 percent efficient; that is, 20 percent of the energy consumed by the lamp is produced as UV light at the relevant wavelength ( $15 \text{ kW} \times 20\% = 3 \text{ kW}$ ). From a previous tracer study it has been found that the reactor can be treated as four tanks in series. Estimate the flow rate that can be treated in this reactor. The extinction coefficient  $\epsilon(254)$  and quantum yield  $\phi(254)$  of NDMA can be found in Table 8-6. For calculation simplicity, assume there are no losses on the reactor walls, the lamp sleeves do not block any light, the UV light intensity

is monochromatic at 254 nm, and the water has exactly the same quality as the water used in Example 8-12:  $k'(\lambda) = 0.145 \text{ cm}^{-1}$ .

### Solution

1. Calculate the rate constant for NDMA:
  - a. Calculate the photonic intensity per volume,  $P_{U-V}$ :
    - i. Calculate the total lamp power:

$$P = (12 \text{ lamps} \times 15 \text{ kW/lamp}) = 180 \text{ kW}$$

- ii. Calculate the UV photonic intensity  $P_{U-V}$  using Eq. 8-115:

$$P_{U-V} = \frac{(180 \text{ kW})(10^3 \text{ W/kW})[(1 \text{ J/s})/1 \text{ W}](254 \times 10^{-9} \text{ m})(0.2)}{(6.023 \times 10^{23} \text{ photon/einstein})(6.62 \times 10^{-34} \text{ J} \cdot \text{s})(3.0 \times 10^8 \text{ m/s})(2300 \text{ L})}$$

$$= 3.32 \times 10^{-5} \text{ einstein/L} \cdot \text{s}$$

- ii. Calculate the rate constant for NDMA,  $k_{\text{NDMA}}$ :
        - i. From Table 8-6, the extinction coefficient of NDMA at 254 nm,  $\epsilon(254)$ , is 1974 L/mol · cm. Determine  $\epsilon'(254)$ :

$$\epsilon'(254) = 2.303\epsilon(254) = 2.303 \times 1974 = 4546 \text{ L/mol} \cdot \text{cm}$$

- ii. From Table 8-6, the quantum yield for NDMA,  $\phi(\lambda)_{\text{NDMA}}$ , is equal to 0.3 mol/einstein. Determine  $k_{\text{NDMA}}$  according to Eq. 8-119:

$$k_{\text{NDMA}} = \phi(\lambda)_{\text{NDMA}} P_{U-V} \frac{\epsilon'(\lambda)_{\text{NDMA}}}{k'\lambda}$$

$$= (0.3 \text{ mol/einstein}) (3.32 \times 10^{-5} \text{ einstein/L} \cdot \text{s})$$

$$\times \left( \frac{4546 \text{ L/mol} \cdot \text{cm}}{0.1451/\text{cm}} \right)$$

$$= 0.313 \text{ s}^{-1}$$

2. Calculate the flow rate that can be treated:
  - a. Calculate hydraulic detention time by rearranging Eq. 8-126 to solve for  $\tau$ . Rewriting Eq. 8-126 for four reactors in series whose contents are completely mixed with a first-order reaction yields

$$\frac{C_{\text{NDMA},e}}{C_{\text{NDMA},o}} = \frac{1}{(1 + k_{\text{NDMA}}\tau/4)^4}$$

Rearranging and solving for  $\tau$  give

$$\tau = \frac{4 \left[ (C_{\text{NDMA},o}/C_{\text{NDMA},e})^{1/4} - 1 \right]}{k_{\text{NDMA}}} = \frac{4 \left[ \left( \frac{20}{2} \right)^{1/4} - 1 \right]}{0.313 \text{ s}^{-1}}$$

$$= 9.95 \text{ s}$$

b. Calculate the flow rate:

$$Q = \frac{V}{\tau} = \frac{2300 \text{ L}}{9.95 \text{ s}} = 231 \text{ L/s}$$

#### ELECTRICAL EFFICIENCY PER ORDER OF CONTAMINANT DESTRUCTION

Photolytic reactions require a significant amount of electrical energy and the associated costs are significant. Consequently, it is important to compare process efficiency on the basis of electrical usage per amount of compound destruction. One such measure is the electrical efficiency per log order (EE/O) of compound destruction (Bolton and Carter, 1994). The definition of EE/O is the electrical energy (in kWh) required to reduce the concentration of a pollutant by one order of magnitude for 1000 U.S. gallons (3785 L) of water, and it may be calculated using the following equations for batch and flowing systems, respectively:

$$\text{EE/O} = \frac{P \times t}{V \times \log(C_i/C_f)} \quad (8-129)$$

$$\text{EE/O} = \frac{P}{Q \times \log(C_i/C_f)} \quad (8-130)$$

where EE/O = electrical efficiency per log order reduction,  
kWh/m<sup>3</sup> = 3.785 kWh/10<sup>3</sup> gal

$P$  = lamp power output, kW

$t$  = irradiation time, h

$V$  = reactor volume, m<sup>3</sup>

$C_i$  = initial concentration, mg/L

$C_f$  = final concentration, mg/L

$Q$  = water flow rate, m<sup>3</sup>/h

For a flow-through system, the power input can be divided by the EE/O to obtain an estimate of the flow rate that can be treated in a given reactor and achieve one order-of-magnitude reduction in concentration.

A theoretical basis for EE/O for a flowing system may be derived from the photolysis model for a PFR and a pseudo-first-order reaction. However, it must be recognized that using a photolysis model will yield the most optimistic (i.e., smallest) value of EE/O because photons are absorbed by the reactor walls and blocked by precipitate that builds up on the lamp sleeves, which is not accounted for in the models. The theoretical value for EE/O is referred to as EE/O<sub>min</sub>. Substituting Eq. 8-123 into Eq. 8-125 yields the expression

$$\frac{C_{j,e}}{C_{j,o}} = \exp \left[ -\phi(\lambda)_j P_{U-V} \frac{\epsilon'(\lambda)_j}{k'(\lambda)} \tau \right] \quad (8-131)$$

where  $C_{j,e}$  = effluent concentration of compound  $j$ , mg/L  
 $C_{j,o}$  = influent concentration of compound  $j$ , mg/L  
 $\phi(\lambda)_j$  = quantum yield of compound  $j$  at wavelength  $\lambda$ ,  
 mol/einstein  
 $P_{U-V}$  = photonic intensity per unit volume, einstein/cm<sup>3</sup> · s  
 $\epsilon'(\lambda)_j$  = extinction coefficient of compound  $j$  (base  $e$ ), L/mol · cm  
 $k'(\lambda)$  = absorptivity of water matrix at wavelength (base  $e$ )  $\lambda$ ,  
 cm<sup>-1</sup>  
 $\tau$  = hydraulic detention time, s

Equation 8-131 can be rearranged after substituting in the definition of the hydraulic detention time to the form

$$\frac{k'(\lambda)}{2.303\epsilon'(\lambda)_j \phi(\lambda)_j} = \frac{VP_{U-V}}{2.303Q \ln(C_{j,o}/C_{j,e})} = \frac{VP_{U-V}}{\log(C_{j,o}/C_{j,e})} \quad (8-132)$$

The left side of Eq. 8-132 is equal to the moles of photons per volume (einstein/L) that are required to reduce the concentration of the contaminant by one order of magnitude. Finally, it can be shown that the EE/O<sub>min</sub> is related to the quantum yield and the fraction of the light that is absorbed by the targeted component as follows:

$$EE/O_{\min} = \frac{N_{av} h \nu k'(\lambda)}{2.303 \eta \epsilon'(\lambda)_j \phi(\lambda)_j} \quad (8-133)$$

where EE/O<sub>min</sub> = minimum electrical efficiency per order,  
 J/L = 0.00105 kWh/10<sup>3</sup> gal  
 $N_{av}$  = Avogadro's number, 6.023 × 10<sup>23</sup> molecules/mol  
 $h$  = Planck's constant, 6.62 × 10<sup>-34</sup> J · s  
 $\nu$  = frequency of light, s<sup>-1</sup>  
 $\eta$  = electrical efficiency of lamps, dimensionless

Other terms are as defined above.

Based on Eq. 8-133, the EE/O<sub>min</sub> is independent of the light intensity and the concentration of the contaminant and inversely depends upon

the extinction coefficient and quantum yield of the targeted compound. In real-world applications the actual EE/O is a multiple of  $EE/O_{\min}$ , but it is independent of light intensity and the concentration of the target component. Consequently, EE/O is a convenient measure because it can be used to quickly estimate the energy that is required to reduce the contaminant concentration by one order of magnitude.

### Example 8-14 Calculation of EE/O

Estimate the minimum EE/O for NDMA for a lamp efficiency of 0.2 in a PFR. Compare this value to the EE/O that would be calculated for Example 8-13. Calculate EE/O values in units of kWh/m<sup>3</sup> and kWh/10<sup>3</sup> gal.

#### Solution

- Calculate the EE/O for Example 8-13 (4 CMFRs in series):
  - In units of kWh/m<sup>3</sup>:

$$\begin{aligned} EE/O &= \frac{P}{Q \log(C_i/C_f)} \\ &= \frac{180 \text{ kW} \times (10^3 \text{ L/m}^3)}{(231 \text{ L/s}) [\log(20 \text{ ng/L})/(2 \text{ ng/L})] (3600 \text{ s/h})} \\ &= 0.216 \text{ kWh/m}^3 \end{aligned}$$

- In units of kWh/1000 gal:

$$\begin{aligned} EE/O &= \frac{0.216 \text{ kWh/m}^3}{264.2 \text{ gal/m}^3} \times \frac{10^3 \text{ gal}}{10^3 \text{ gal}} \\ &= 0.818 \text{ kWh/10}^3 \text{ gal} \end{aligned}$$

- Calculate the minimum EE/O for a PFR using Eq. 8-95:
  - Calculate the frequency of light:

$$\nu = \frac{c}{\lambda} = \frac{3 \times 10^8 \text{ m/s}}{254 \times 10^{-9} \text{ m}} = 1.18 \times 10^{15} \text{ s}^{-1}$$

- From Example 8-13:

$$k'(\lambda) = 0.145 \text{ cm}^{-1}$$

$$\epsilon'(\lambda)_j = 4546 \text{ L/mol} \cdot \text{cm}$$

$$\phi(\lambda)_j = 0.3 \text{ molecules/photon}$$

c. Calculate minimum EE/O using Eq. 8-133:

$$\begin{aligned} EE/O_{\min} &= \frac{N_{av} h \nu k'(\lambda)}{\eta \varepsilon'(\lambda)_j \phi(\lambda)_j \times 2.303} \\ &= \frac{(6.023 \times 10^{23} \text{ molecules/mol}) (6.62 \times 10^{-34} \text{ J} \cdot \text{s/photon}) (1.18 \times 10^{15} \text{ s}^{-1}) (0.145 \text{ cm}^{-1})}{0.2 \times (4546 \text{ L/mol} \cdot \text{cm}) (0.3 \text{ molecules/photon}) \times 2.303} \\ &= 109 \text{ J/L} \end{aligned}$$

i. In units of kWh/m<sup>3</sup>:

$$EE/O_{\min} = \frac{(109 \text{ J/L}) [1 \text{ W/(J/s)}] (10^3 \text{ L/m}^3)}{(3600 \text{ s/h}) (10^3 \text{ W/kW})} = 0.0303 \text{ kWh/m}^3$$

ii. In units of kWh/10<sup>3</sup> gal:

$$\begin{aligned} EE/O_{\min} &= \frac{0.0303 \text{ kWh/m}^3}{264.2 \text{ gal/m}^3} \times \frac{10^3 \text{ gal}}{10^3 \text{ gal}} \\ &= 0.115 \text{ kWh/10}^3 \text{ gal} \end{aligned}$$

### Comment

The EE/O for the existing reactor is reasonable for reducing the NDMA concentration from 20 to 2 ng/L, considering the energy required. The EE/O value of 109 J/L (0.115 kWh/10<sup>3</sup> gal) is the EE/O<sub>min</sub> for a PFR, which is much lower than 0.818 kWh/10<sup>3</sup> gal, the value obtained for actual mixing conditions in the reactor (represented by four tanks in series). For a PFR, an effluent concentration of 0.2 ng/L can be obtained by doubling the energy input from 0.115 kWh/10<sup>3</sup> gal to 0.230 kWh/10<sup>3</sup> gal because photolysis is a pseudo-first-order reaction in this case. The value of the EE/O concept is demonstrated by the ease with which the energy required for a lower effluent concentration can be determined.

## Problems and Discussion Topics

- 8-1 What oxidants are used most frequently in water treatment? What are the principal applications of these oxidants? What oxidants are employed most commonly for taste and odor control?
- 8-2 One problem associated with H<sub>2</sub>S removal using oxidation is the formation of polysulfides when H<sub>2</sub>S concentration is higher than

- 1 mg/L. What measures can be taken to avoid the formation of polysulfides?
- 8-3 Discuss the reason that permanganate, chlorine dioxide, free chlorine, ozone, and hydrogen peroxide are unable to oxidize iron in many waters and how to assess the feasibility of using chemical oxidation for iron removal?
- 8-4 Balance the oxidation–reduction reaction for the oxidation of benzene ( $C_6H_6$ ) using (a) hydrogen peroxide and (b) ozone.
- 8-5 Balance the oxidation–reduction reaction for the oxidation of *tert*-butyl methyl ether (MTBE)  $[(CH_3)_3COCH_3]$  using (a) hydrogen peroxide and (b) ozone.
- 8-6 Determine whether chlorine or ozone is the more powerful oxidant from a consideration of free energy and reduction potential.
- 8-7 Determine the oxidation potential for converting chloride ( $Cl^-$ ) to chlorate ( $ClO_3^-$ ) from (a) the chlorine dioxide/chloride reaction, (b) the chlorine dioxide/chlorite reaction, and (c) the chlorate/chlorite reaction.
- 8-8 Calculate the equilibrium constant and  $\Delta G_{Rxn}^\circ$  for the oxidation of Mn(II) to manganese oxide by dissolved oxygen. What oxygen concentrations are needed for pH values of 6.0, 7.0, and 8.0 such that the reaction is thermodynamically favorable? *Given:*  $[Mn^{2+}] = 10^{-6}$  M and the temperature is 298 K.
- 8-9 Manganese [Mn(II)] is soluble in water and is present in many groundwaters because insoluble forms (e.g.,  $MnO_2$ ) that are contained in minerals are reduced to soluble forms. The initial reactant concentrations are as follows: potassium permanganate ( $KMnO_4$ ), 8 mg/L;  $Mn^{2+}$ , 2 mg/L. Permanganate is sometimes used to remove  $Mn^{2+}$  and the half reactions are

- Balance the overall redox reaction. Which reaction is the oxidation reaction? Which is the reduction reaction? Identify the electron acceptor and donor as well as the reductant and the oxidant.
- Calculate the equilibrium constant.
- Calculate the equilibrium  $Mn^{2+}$  concentration when the pH is 7 and the concentration of potassium permanganate is 1 mg/L.
- Obtain expressions for permanganate and  $MnO_2$  concentrations in terms of  $Mn^{2+}$  concentration.
- Plot the free energy as a function of the conversion of  $Mn^{2+}$  from 0.01 to 0.999.

*Hint:* Use the stoichiometric table to determine all reacting species as a function of  $X_a$  and then eliminate  $X_a$  by using the final concentration,  $C_a$ . After substituting  $C_a$  back into the expressions, the permanganate and  $\text{MnO}_2$  concentrations can be obtained in terms of the final concentration of  $\text{Mn}^{2+}$ .

- 8-10 Can hydrogen sulfide be oxidized using hydrogen peroxide for the following conditions:  $[\text{H}_2\text{S}] = 10^{-2}$  M,  $[\text{H}_2\text{O}_2] = 10^{-12}$  M,  $[\text{Cl}^-] = 1$  M,  $P_{\text{CO}_2} = 1$  atm, and pH 7?
- 8-11 Can nitrate ( $\text{NO}_3^-$ ) be reduced to nitrogen gas ( $\text{N}_2$ ) under aerobic conditions? For this problem, assume the following conditions are applicable for aerobic fresh water:  $[\text{NO}_3^-] = 10^{-2}$  M,  $P_{\text{N}_2} = 1$  atm,  $[\text{H}^+] = 10^{-7}$  M, and  $[\text{O}_2(\text{aq})] = 8.24$  mg/L ( $2.58 \times 10^{-4}$  M) at  $25^\circ\text{C}$ .
- 8-12 Is it thermodynamically possible to form bromate ( $\text{BrO}_3^-$ ) from bromide ( $\text{Br}^-$ ) using hydroxyl radicals ( $\text{HO}\cdot$ ) for the following conditions? Also, determine whether it is possible to form bromate concentrations in excess of  $10$   $\mu\text{g/L}$ , which is its maximum contaminant level.

$$[\text{HO}\cdot] = 10^{-11} \text{ M} \quad \text{Br}^- = 0.3 \text{ mg/L} \quad \text{BrO}_3^- = 10 \mu\text{g/L}$$

- 8-13 Calculate the equilibrium concentrations of  $\text{HOCl}$  and  $\text{Cl}_2(\text{aq})$  in solution for a chlorine addition of  $4$  mg/L at  $25^\circ\text{C}$ . Assume that the pH is  $6.0$  and does not change and that the  $\text{HOCl}$  does not disassociate into  $\text{H}^+$  and  $\text{OCl}^-$ . Express the chlorine concentrations in terms of milligrams per liter of  $\text{Cl}_2$ .
- 8-14 Chlorine has a unitless Henry's law constant of  $0.480$  at  $25^\circ\text{C}$  and a reduction potential of  $1.390$  V when it is a gaseous reactant. Calculate the reduction potential when it is present as an aqueous reactant as shown in the reaction

- 8-15 Rank the following oxidants according to redox potential: oxygen, chlorine, chlorine dioxide, potassium permanganate, ozone, hydroxyl radical, and hydrogen peroxide. What is the general trend typically observed with respect to oxidation rate for these oxidants?
- 8-16 Bench-scale tests have been used to develop a value of the apparent rate constant ( $K_{\text{app}}$ ) for a particular well water in the presence

of oxygen. The results are shown below. Assuming that the partial pressure of oxygen is maintained at 0.1 atm during the tests, determine  $K_{app}$ .

Time, min	Fe(II), mg/L
0	5
5.1	3
10.2	1.8
15.3	1
25.8	0.4
40.6	0.08

- 8-17 How much Mn(II) remains after 5, 10, 20, and 30 s of oxidation with chlorine dioxide? The initial concentrations of chlorine dioxide and Mn(II) are 1.5 times the stoichiometric requirement and 1.5 mg/L, respectively. Assume that the second-order rate constant is  $5 \times 10^4 \text{ L/mol} \cdot \text{s}$ .

- 8-18 How much Fe(II) remains after 10 and 30 s of oxidation with permanganate? The initial concentration of permanganate and Fe(II) are 1.5 times the stoichiometric requirement and 1 mg/L, respectively. Assume that the second-order rate constant is  $10^5 \text{ M}^{-1} \text{ s}^{-1}$ .
- 8-19 Estimate the absorptivity of ozone at a wavelength of 254 nm for both base  $e$  and base 10, assuming ozone is present at a concentration of 0.50 mg/L. The extinction coefficient of ozone is  $3300 \text{ L/mol} \cdot \text{cm}$  and the molecular weight of ozone is 48.0 g/mol.
- 8-20 A potential raw-water source for drinking water is analyzed and found to contain the constituents given below. Using the given values, estimate the absorptivity (both base 10 and base  $e$ ) of the water at a wavelength of 254 nm.

Constituent	Unit	Value	$\epsilon(254) \text{ L/mol} \cdot \text{cm}$
TOC	mg/L as C	2.0	
water	mol/L		$6.1 \times 10^{-6}$
Fe(II)	mg/L as Fe	1.3	466
Nitrate	mg/L as $\text{NO}_3^-$	3.0	3.4
SUVA	L/mg $\cdot$ m	3.0	

- 8-21 The source water for a drinking water treatment plant in California contains 50 ng/L NDMA. The treatment objective for NDMA has

been set at 2 ng/L. After considering various treatment options, UV photolysis has been chosen for NDMA removal. The commercial reactors being evaluated are 1 m in diameter and 3 m in height (water volume 2300 L). Each reactor has 15 lamps that use 15 kW per lamp. The lamps are 30 percent efficient; that is, 30 percent of the energy consumed by the lamp is produced as UV light at the relevant wavelength ( $15 \text{ kW} \times 0.30 = 4.5 \text{ kW}$ ). A previous dye study has shown that the reactor can be modeled as three tanks in series. Estimate the flow rate that can be treated in this reactor. The extinction coefficient  $\epsilon(254)$  and quantum yield  $\phi(254)$  for NDMA can be found in Table 8-6. For calculation simplicity, assume there are no losses on the reactor walls, the lamp sleeves do not block any light, the UV light intensity is monochromatic at 254 nm, and the water has exactly the same quality as the water used in Example 8-12:  $k'(\lambda) = 0.145 \text{ cm}^{-1}$ .

- 8-22 Calculate the EE/O for NDMA in Problem 8-21. Compare this value to the EE/O estimated in a PFR with the same lamp efficiency as Problem 8-21. Calculate the EE/O values in units of kWh/m<sup>3</sup> and kWh/10<sup>3</sup> gal.
- 8-23 Calculate the half-life and time to convert 95 percent of the hypochlorous acid to hypobromous acid. The initial concentrations of HOCl and Br<sup>-</sup> are 2 mg/L as chlorine ( $2.82 \times 10^{-5} \text{ mol/L}$ ) and 0.3 g/L, respectively. Assume that the second-order rate constant is  $2.95 \times 10^3 \text{ L/mol} \cdot \text{s}$ .

## Terminology for Coagulation and Flocculation

<b>Term</b>	<b>Definition</b>
Coagulation	Addition of a chemical to water with the objective of destabilizing particles so they aggregate or forming a precipitate that will sweep particles from solution or adsorb dissolved constituents.
Coagulant aid	Chemicals (typically synthetic polymers) added to water to enhance the coagulation process.
Counterions	Ions of opposite charge to the surface charge of particles.
Critical coagulation concentration (CCC)	Concentration of coagulant that reduces the electric double layer to the point where flocculation can occur.
Destabilization	Process of eliminating the surface charge on a particle so that flocculation can occur.
Electric double layer (EDL)	Electrostatic potential surrounding a charged particle in solution, consisting of a layer of counterions adsorbed directly to the surface and a diffuse layer of ions forming a cloud of charge around the particle.
Enhanced coagulation	Coagulation process with the objective of removing natural organic matter, typically for minimizing the formation of disinfection by-products (see Sec 9-5).
Enmeshment or sweep floc	Entrapment or capture of particles by amorphous precipitates that form when a coagulant is added to water.
Flocculation	Aggregation of destabilized particles into larger masses that are easier to remove from water than the original particles.
Flocculant aid	Organic polymers used to enhance settleability and filterability of floc particles.

<b>Term</b>	<b>Definition</b>
Inorganic metal coagulant	Metal salts such as aluminum sulfate and ferric chloride that will hydrolyze, forming mononuclear and polynuclear species of varying charge. When added in excess, metal coagulants form chemical precipitates.
Jar test	Procedure to study effect of coagulant addition to water; used to determine required doses and operating conditions for effective coagulation and flocculation.
Stable particle suspension	Suspension of particles that will stay in solution indefinitely; stable particles have a surface charge that causes them to repel each other and prevent aggregation into larger particles that would settle on their own.
Synthetic organic coagulant	High-molecular-weight (typically $10^4$ to $10^7$ g/mol) organic molecules that can carry positive (cationic), negative (anionic), or neutral (nonionic) charge.
Zeta potential	Measurement of the charge at the shear plane of particles, used as a relative measure of particle surface charge.

Natural surface waters contain inorganic and organic particles. Inorganic particulate constituents, including clay, silt, and mineral oxides, typically enter surface water by natural erosion processes. Organic particles may include viruses, bacteria, algae, protozoan cysts and oocysts, as well as detritus litter that have fallen into the water source. In addition, surface waters will contain very fine colloidal and dissolved organic constituents such as humic acids, a product of decay and leaching of organic debris. Particulate and dissolved organic matter is often identified as natural organic matter (NOM).

Removal of particles is required because they can (1) reduce the clarity of water to unacceptable levels (i.e., cause turbidity) as well as impart color to water (aesthetic reasons), (2) be infectious agents (e.g., viruses, bacteria, and protozoa), and (3) have toxic compounds adsorbed to their external surfaces. The removal of dissolved NOM is of importance because many of the constituents that comprise dissolved NOM are precursors to the formation of disinfection by-products (see Chap. 19) when chlorine is used for disinfection. NOM can also impart color to the water.

The most common method used to remove particulate matter and a portion of the dissolved NOM from surface waters is by sedimentation and/or filtration following the conditioning of the water by coagulation and flocculation, the subject of this chapter. Thus, the purpose of this chapter is to present the chemical and physical basis for the phenomena occurring in

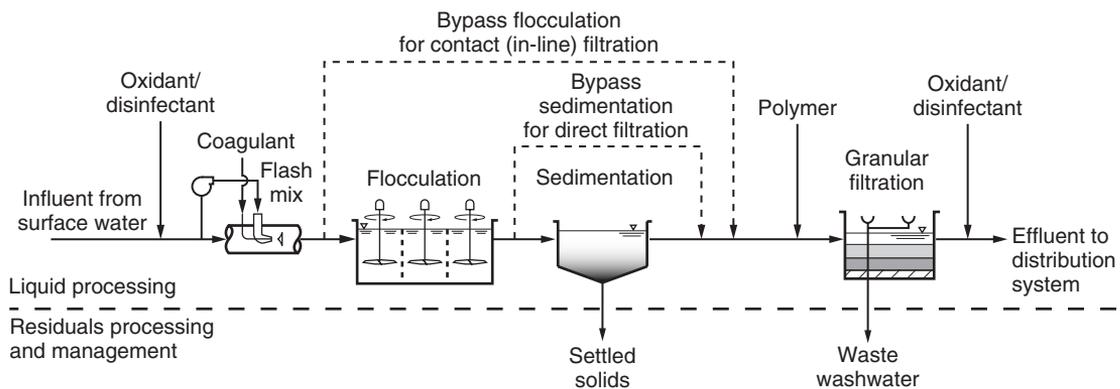

the coagulation and flocculation processes. Specific topics include (1) the role of coagulation and flocculation processes in water treatment, (2) stability of particles in water, (3) coagulation theory, (4) coagulation practice, (5) coagulation of dissolved and organic constituents, (6) flocculation theory, and (7) flocculation practice.

## 9-1 Role of Coagulation and Flocculation Processes in Water Treatment

The importance of the coagulation and flocculation processes in water treatment can be appreciated by reviewing the process flow diagrams illustrated on Fig. 9-1. As used in this book, *coagulation* involves the addition of a chemical coagulant or coagulants for the purpose of conditioning the suspended, colloidal, and dissolved matter for subsequent processing by flocculation or to create conditions that will allow for the subsequent removal of particulate and dissolved matter. *Flocculation* is the aggregation of destabilized particles (particles from which the electrical surface charge has been reduced) and precipitation products formed by the addition of coagulants into larger particles known as flocculant particles or, more commonly, “floc.” The aggregated floc can then be removed by gravity sedimentation and/or filtration. Coagulation and flocculation can also be differentiated on the basis of the time required for each of the processes. Coagulation typically occurs in less than 10 s, whereas flocculation occurs over a period of 20 to 45 min. An overview of the coagulation and flocculation processes is provided below.

### Coagulation Process

The objective of the coagulation process depends on the source of the water and the nature of the suspended, colloidal, and dissolved organic

**Figure 9-1**

Typical water treatment process flow diagram employing coagulation (chemical mixing) with conventional treatment, direct filtration, or contact filtration.

constituents. Coagulation by the addition of the hydrolyzing chemicals such as alum and iron salts and/or organic polymers can involve

1. Destabilization of small suspended and colloidal particulate matter
2. Adsorption and/or reaction of portions of the colloidal and dissolved NOM to particles
3. Creation of flocculant particles that will sweep through the water to be treated, enmeshing small suspended, colloidal, and dissolved material as they settle

Coagulants such as alum, ferric chloride, and ferric sulfate hydrolyze rapidly when mixed with the water to be treated. As these chemicals hydrolyze, they form insoluble precipitates that destabilize particles by adsorbing to the surface of the particles and neutralizing the charge (thus reducing the repulsive forces) and/or forming bridges between them. Natural or synthetic organic polyelectrolytes (polymers with multiple charge-conferring functional groups) are also used for particle destabilization. Because of the many competing reactions, the theory of chemical coagulation is complex. Thus, the simplified reactions presented in this and other textbooks to describe the various coagulation processes can only be considered approximations, as the reactions may not necessarily proceed as indicated (Letterman et al., 1999).

The purpose of flocculation is to produce particles, by means of aggregation, that can be removed by subsequent particle separation procedures such as gravity sedimentation and/or filtration. Two general types of flocculation can be identified: (1) microflocculation (also known as perikinetic flocculation) in which particle aggregation is brought about by the random thermal motion of fluid molecules (known as Brownian motion) and (2) macroflocculation (also known as orthokinetic flocculation) in which particle aggregation is brought about by inducing velocity gradients and mixing in the fluid containing the particles to be flocculated. Another form of macroflocculation is brought about by differential settling in which large particles overtake small particles to form larger particles.

## Flocculation Process

When it comes to the practical design of coagulation and flocculation facilities, designers must consider four process issues: (1) the type and concentration of coagulants and flocculant aids, (2) the mixing intensity and the method used to disperse chemicals into the water for destabilization, (3) the mixing intensity and time for flocculation, and (4) the selection of the liquid–solid separation process (e.g., sedimentation, flotation, and granular filtration). With the exception of sedimentation and flotation (considered in Chap. 10) and filtration (considered in Chaps. 11 and 12), these subjects are addressed in the subsequent sections of this chapter.

## Practical Design Issues

## 9-2 Stability of Particles in Water

---

The particles in water may, for practical purposes, be classified as suspended and colloidal, according to particle size. Because small suspended and colloidal particles and dissolved constituents will not settle in a reasonable period of time, chemicals must be used to help remove these particles. The physical characteristics of particles found in water including particle size, number, distribution, and shape have been discussed previously in Chap. 2, Sec 2-3.

To appreciate the role of chemical coagulants and flocculant aids, it is important to understand particle solvent interactions and the electrical properties of the colloidal particles found in water. These subjects along with the nature of particle stability and the compression of the electrical double layer are considered in this section.

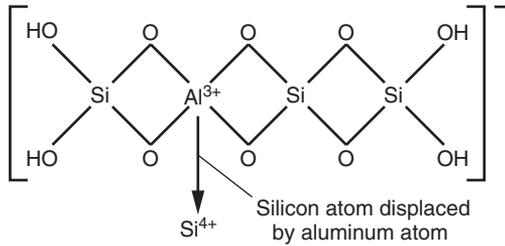

### Particle–Solvent Interactions

Particles in natural water can be classified as hydrophobic (water repelling) and hydrophilic (water attracting). Hydrophobic particulates have a well-defined interface between the water and solid phases and have a low affinity for water molecules. In addition, hydrophobic particles are thermodynamically unstable and will aggregate irreversibly over time.

Hydrophilic particles such as clays, metal oxides, proteins, or humic acids have polar or ionized surface functional groups. Many inorganic particulates in natural waters, including hydrated metal oxides (iron or aluminum oxides), silica ( $\text{SiO}_2$ ), and asbestos fibers, are hydrophilic because water molecules will bind to the polar or ionized surface functional groups (Stumm and Morgan, 1996). Many organic particulates are also hydrophilic and include a wide diversity of biocolloids (humic acids, viruses) and suspended living or dead microorganisms (bacteria, protozoa, algae). Because biocolloids can adsorb on the surfaces of inorganic particulates, the particles in natural waters often exhibit heterogeneous surface properties. Some particulate suspensions such as humic or fulvic acids can be reversibly aggregated because of their hydrogen bonding tendencies.

### Electrical Properties of Particles

The principal electrical property of fine particulate matter suspended in water is surface charge, which contributes to relative stability, causing particles to remain in suspension without aggregating for long periods of time. The particulate suspensions are thermodynamically unstable and, given sufficient time, colloids and fine particles will flocculate and settle. However, this process is not economically feasible because it is very slow. A review of the causes of particulate stability will provide an understanding of the techniques that can be used to destabilize particulates, which are discussed in the following section.

**Figure 9-2**

Charge acquisition through isomorphous substitution of Al for Si.

### ORIGIN OF PARTICLE SURFACE CHARGE

Most particulates have complex surface chemistry and surface charges may arise from several sources. Surface charge arises in four principal ways, as discussed below (Stumm and Morgan, 1996).

#### *Isomorphous replacement (crystal imperfections)*

Under geological conditions, metals in metal oxide minerals can be replaced by metal atoms with lower valence, and this will impart a negative charge to the crystal material. An example where an aluminum atom replaced a silicon atom in a clay particle is shown on Fig. 9-2. This process, known as isomorphous replacement, produces negative charges on the surface of clay particles (van Olphen, 1963).

#### *Structural imperfections*

In clay and similar mineral particles, imperfections that occur in the formation of the crystal and broken bonds on the crystal edge can lead to the development of surface charges.

#### *Preferential adsorption of specific ions*

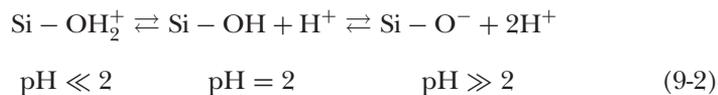

Particles adsorb NOM (e.g., fulvic acid), and these large macromolecules typically have a negative charge because they contain carboxylic acid groups:

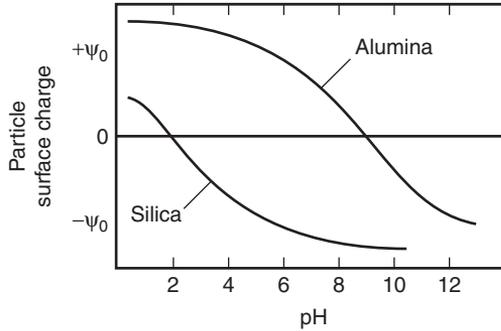

Consequently, particle surfaces that have adsorbed NOM will be negatively charged for pH values greater than  $\sim 5$ .

#### *Ionization of inorganic groups on particulate surfaces*

Many mineral surfaces contain surface functional groups (e.g., hydroxyl) and their charge depends on pH. For example, silica has hydroxyl groups on its exterior surface, and these can accept or donate protons as shown here:

**Figure 9-3**  
Variation in particle charge with pH.

The zero point of charge, as shown on Fig. 9-3, for silica is at pH 2, whereas the zero point of charge for alumina is about pH 9. The pH corresponding to a surface charge of zero is defined as the *zero point of charge* (ZPC). Above the ZPC the surface charge will be negative (anionic), and below the ZPC the charge will be positive (cationic). The ZPC for other particles that commonly occur in water are listed in Table 9-1. When examining Table 9-1, it is important to realize that many of the measurements that are reported are in low-ionic-strength waters (i.e., distilled water); consequently, the reported  $\text{pH}_{\text{zpc}}$  values are higher than is observed in natural waters.

**Table 9-1**

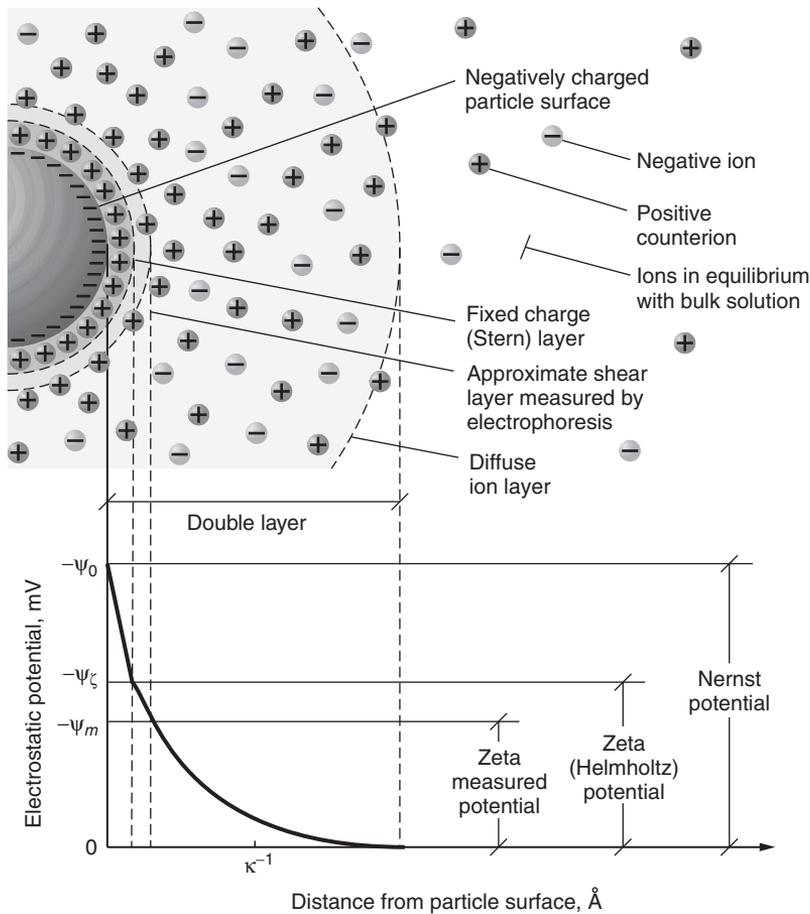

Surface characteristics of inorganic and organic particulates commonly found in natural waters

Type of Particle	Zero Point of Charge, $\text{pH}_{\text{zpc}}$
Inorganic	
$\text{Al}(\text{OH})_3$ (amorphous)	7.5–8.5
$\text{Al}_2\text{O}_3$	9.1
$\text{CuO}_3$	9.5
$\text{Fe}(\text{OH})_3$ (amorphous)	8.5
$\text{MgO}$	12.4
$\text{MnO}_2$	2–4.5
$\text{SiO}_2$	2–3.5
Clays	
Kaolinite	3.3–4.6
Montmorillonite	2.5
Asbestos	
Chrysotile	10–12
Crocidolite	5–6
$\text{CaCO}_3$	8–9
$\text{Ca}_5(\text{PO}_4)_3\text{OH}$	6–7
$\text{FePO}_4$	3
$\text{AlPO}_4$	4
Organic	
Algae	3–5
Bacteria	2–4
Humic acid	3
Oil droplets	2–5

**ELECTRICAL DOUBLE LAYER**

In natural waters, negatively charged particulates accumulate positive counterions on and near the particle's surface to satisfy electroneutrality. As shown on Fig. 9-4, a layer of cations will bind tightly to the surface of a negatively charged particle to form a fixed adsorption layer. This adsorbed layer of cations, bound to the particle surface by electrostatic and adsorption forces, is about 5 Å thick and is known as the *Helmholtz layer* (also known as the *Stern layer* after Stern, who proposed the model shown on Fig. 9-4). Beyond the Helmholtz layer, a net negative charge and electric field is present that attracts an excess of cations (over the bulk solution concentration) and repels anions, neither of which are in a fixed position. These cations and anions move about under the influence of diffusion (caused by collisions with solvent molecules), and the excess concentration of cations extends out into solution until all the surface charge and electric potential is eliminated and electroneutrality is satisfied.

**Figure 9-4**  
Structure of the electrical double layer. The potential measured at the shear plane is known as the zeta potential. The shear plane typically occurs in diffuse layer.

The layer of cations and anions that extends from the Helmholtz layer to the bulk solution where the charge is zero and electroneutrality is satisfied is known as the diffuse layer. Taken together the adsorbed (Helmholtz) and diffuse layer are known as the *electric double layer* (EDL). Depending on the solution characteristics, the EDL can extend up to 300 Å into the solution (Kruyt, 1952). It is interesting to note that the double-layer model proposed by Stern (see Fig. 9-4) is a combination of the earlier models proposed by Helmholtz–Perrin and Gouy–Chapman. In fact, the diffuse layer is often identified as the *Gouy–Chapman diffuse layer* (Voyutsky, 1978).

#### MEASUREMENT OF SURFACE CHARGE

The electrical properties of highly dispersed particle systems having a solid dispersed phase and a liquid dispersion medium can be defined in terms of four phenomena: (1) *electrophoresis*, (2) *electroosmosis*, (3) *sedimentation potential* (also known as the *Dorn effect*), and (4) *streaming potential*. Collectively these four phenomena, described in Table 9-2, are known as *electrokinetic phenomena* because they involve the movement of particles (or a liquid) when a potential gradient is applied or the formation of the potential

**Table 9-2**  
Description and application of electrochemical phenomena

Phenomena	Description	Application in Water Treatment
Electrophoresis, discovered by R. Reuss, circa 1808	Refers to the movement of charged particles relative to a stationary liquid subject to an applied electrical field. The particles move along the lines of the electrical field.	Used to assess the destabilization of particles subject to the addition of coagulant chemicals. Also used in laboratory studies to isolate new proteins and other organic molecules.
Electroosmosis, discovered by R. Reuss, circa 1808	Refers to the movement of liquid relative to a stationary charged surface (e.g., a porous plug) subject to an applied electrical field.	
Streaming potential, discovered by G. Quincke, circa 1859	Refers to the creation of a potential gradient when liquid is made to flow along a stationary charged surface (e.g., when forced through a porous plug). The charges from the particles are carried along with the fluid.	Used to assess the destabilization of particles subject to the addition of coagulant chemicals. Online instruments are now available that can be used to control chemical addition in water treatment.
Sedimentation potential, discovered by Dorn, circa 1878	Refers to the creation of a potential gradient when charged particles move (e.g., settling) relative to a stationary liquid medium. Sedimentation potential is the opposite of electrophoresis.	

Source: Adapted from Voyutsky (1978) and Shaw (1966).

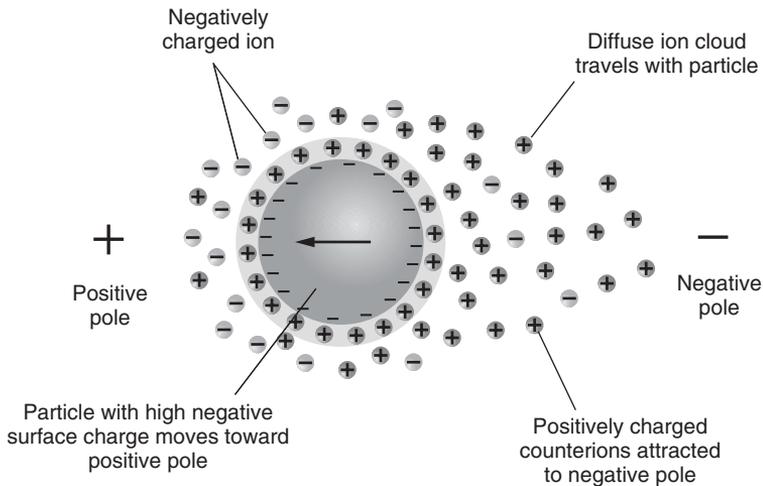

gradient when particles (or liquid) move. It should be noted that these aforementioned electrical phenomena are caused by the opposite charge of the particle (solid) and liquid. Although there is no direct measure of the electrical field surrounding a particle or method to determine when particles have been destabilized from the addition of coagulants, the surface charge on a particle can be measured indirectly using one of the four electrokinetic phenomena (Voyutsky, 1978).

### ZETA POTENTIAL

When a charged particle is subjected to an electric field between two electrodes, a negatively charged particle will migrate toward the positive electrode, as shown on Fig. 9-5, and vice versa. This movement is termed *electrophoresis*. It should be noted that when a particle moves in an electrical field some portion of the water near the surface of the particle moves with it, which gives rise to the shear plane, as shown on Fig. 9-4. Typically, as shown on Fig. 9-4, the actual shear plane lies in the diffuse layer to the right of the theoretical fixed shear plane defined by the Helmholtz layer. The electrical potential between the actual shear plane and the bulk solution is what is measured by electrophoretic measurements. This potential is called the *zeta potential* or the electrical potential and is given by the expression

$$Z = \frac{v^0 k_z \mu}{\epsilon \epsilon_0} \quad (9-3)$$

where  $Z$  = zeta potential, V  
 $v^0$  = electrophoretic mobility,  $(\mu\text{m/s})/(\text{V/cm})$   
 $= v_E/E$   
 $v_E$  = electrophoretic velocity of migrating particle,  $\mu\text{m/s}$  (also reported as  $\text{nm/s}$  and  $\text{mm/s}$ )

**Figure 9-5**  
 Schematic illustration of electrophoresis in which a charged particle moves in an electrical field, dragging with it a cloud of ions.

$$\begin{aligned}
 E &= \text{electrical field at particle, V/cm} \\
 k_z &= \text{constant that is } 4\pi \text{ or } 6\pi \\
 \mu &= \text{dynamic viscosity of water, N} \cdot \text{s/m}^2 \\
 \epsilon &= \text{permittivity relative to a vacuum (}\epsilon \text{ for water is 78.54, unitless)} \\
 \epsilon_0 &= \text{permittivity in a vacuum, } 8.854188 \times 10^{-12} \text{ C}^2/\text{J} \cdot \text{m (note} \\
 &\quad \text{that } \text{C}^2/\text{J} \cdot \text{m is equivalent to } \text{N/V}^2\text{)}
 \end{aligned}$$

Typical values for the electrophoretic mobility for particles in natural waters vary from about  $-2$  to  $+2$  ( $\mu\text{m/s})/(\text{V/cm})$ . The constant  $k_z$  is used to account for the shape of the particle. The value of  $4\pi$  appears in the derivation put forth by Smoluchowski and applies if the extent of the diffuse layer is small relative to the curvature of the particle. The value of  $6\pi$  is used when the particle is much smaller than the thickness of the double layer (Kissa, 1999).

For example, if the value of the constant is  $4\pi$  and the electrical mobility is  $0.5$  ( $\mu\text{m/s})/(\text{V/cm})$ , the value of the zeta potential at  $25^\circ\text{C}$  is  $80.4$  mV as given below:

$$\begin{aligned}
 Z &= \frac{(0.5 \mu\text{m} \cdot \text{cm/s} \cdot \text{V})(4\pi)(0.890 \times 10^{-3} \text{N} \cdot \text{s/m}^2)(1 \text{m}/10^6 \mu\text{m})(1 \text{m}/10^2 \text{cm})}{(78.54)(8.854188 \times 10^{-12} \text{C}^2/\text{J} \cdot \text{m})} \\
 &= 80.4 \text{ mV}
 \end{aligned}$$

Empirically, when the absolute value of the zeta potential is reduced below approximately  $20$  mV, rapid flocculation occurs (Kruyt, 1952). The zeta potential will vary with the size and shape of the particle, with the number of charges on the particle, with the strength of the electric field, and with the nature of the ions in the diffuse layer.

## Particle Stability

The stability of particles in natural waters depends on a balance between (1) the repulsive electrostatic force and (2) the attractive force known as the van der Waals force.

### REPULSIVE ELECTROSTATIC FORCES

The principal mechanism controlling the stability of hydrophobic and hydrophilic particles is electrostatic repulsion. Electrostatic repulsion occurs, as discussed above, because particles in water have a net negative surface charge. The magnitude of the electrostatic force will depend on the charge of the particle and the solution characteristics.

### VAN DER WAALS ATTRACTIVE FORCE

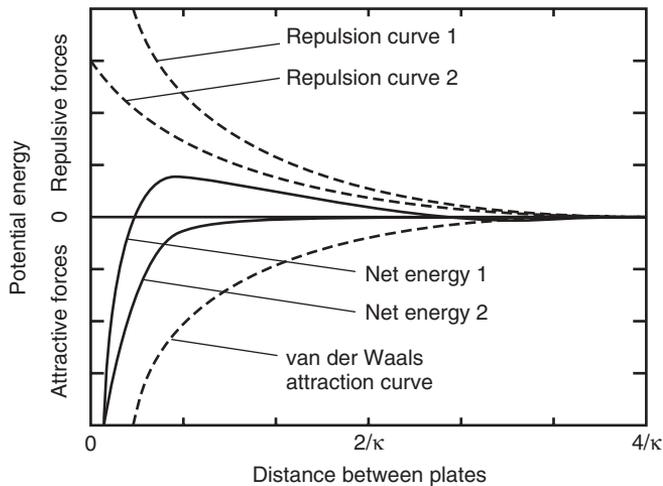

Van der Waals forces originate from magnetic and electronic resonance that occurs when two particles approach one another. This resonance is caused by electrons in atoms on the particle surface, which develop a strong attractive force between the particles when these electrons orient themselves in such a way as to induce synergistic electric and magnetic

fields. Van der Waals forces are proportional to the polarizability of the particle surfaces. Van der Waals attractive forces ( $< \sim 20$  kJ/mol) are strong enough to overcome electrostatic repulsion, but they are unable to do so because electrostatic repulsive forces and the EDL extend further into solution than do the van der Waals forces. As a result, an energy barrier is formed that must be overcome for flocculation to occur and coagulants are added to reduce the repulsive force, which allows for rapid flocculation.

#### PARTICLE-PARTICLE INTERACTIONS

Particle-particle interactions are extremely important in bringing about aggregation by means of Brownian motion. The theory of particle-particle interaction is based on the interaction of the repulsive and attractive forces on two charged particles as they are brought closer and closer together. The theory, first worked out by Derjaguin, later improved upon together with Landau, and subsequently extended by Verwey and Overbeek, is known as the DLVO theory after the scientists who developed it (Derjaguin and Landau, 1941; Verwey and Overbeek, 1948).

A conceptual diagram of the DLVO model is provided on Fig. 9-6, in which the interaction between two particles represented by flat plates with similar charge is illustrated. As shown on Fig. 9-6, the two principal forces involved are the forces of repulsion due to the electrical properties of the charged plates and the van der Waals forces of attraction. Two cases are illustrated on Fig. 9-6 with respect to the forces of repulsion. In the first case, the repulsive force extends far into solution. In the second case, the extent of the repulsive force is reduced considerably. The net total energy shown by the solid lines on Fig. 9-6 is the difference between the forces of repulsion and attraction. For case 1, the forces of attraction will predominate at very short and long distances. The net energy curve for

**Figure 9-6**  
Attractive and repulsive potential energy that result when two particles are brought together.

condition 1 contains a repulsive maximum that must be overcome if the particles are to be held together by the van der Waals force of attraction. Although floc particles can form at long distances as shown by the net energy curve for case 1, the net force holding these particles together is weak and the floc particles that are formed can be ruptured easily. In case 2, there is no energy barrier to overcome. Clearly, if colloidal particles are to be flocculated by microfloculation, the repulsive force must be reduced as shown in case 2. With the addition of a coagulant, which reduces the extent of the electrical double layer, rapid flocculation can occur.

### Compression of the Electrical Double Layer

It has been observed that, if the electrical double layer is compressed, particles in water will come together as a result of Brownian motion and remain attached due to van der Waals forces of attraction, as discussed above. As the ionic strength of a solution is increased, the extent of the double layer decreases, which in turn reduces the zeta potential. The thickness of the double layer and the effects of ionic strength and electrolyte addition on the compression of the double layer are described below.

#### DOUBLE-LAYER THICKNESS

The thickness of the electrical diffuse layer as a function of the ionic strength and electrolyte is given in Table 9-3. The thickness of the diffuse layer may be calculated using the following equation (Gouy, 1910):

$$\kappa^{-1} = 10^{10} \left[ \frac{(2)(1000) e^2 N_A I}{\epsilon \epsilon_0 k T} \right]^{-1/2} \quad (9-4)$$

where  $\kappa^{-1}$  = double-layer thickness, Å  
 $10^{10}$  = length conversion, Å / m  
 $1000$  = volume conversion, L/m<sup>3</sup>

**Table 9-3**

Thickness of electrical double layer (EDL) as function of ionic strength and valence at 25°C

Molarity	z <sup>+</sup> : z <sup>-</sup>	I, mol/L	$\kappa$ , cm <sup>-1</sup>	1/ $\kappa$ , Å
0.001	1:1	0.001	1.04 × 10 <sup>6</sup>	96.2
	2:2	0.004	2.08 × 10 <sup>6</sup>	48.1
	3:3	0.009	3.12 × 10 <sup>6</sup>	32.1
0.01	1:1	0.01	3.29 × 10 <sup>6</sup>	30.4
	2:2	0.04	6.57 × 10 <sup>6</sup>	15.2
	3:3	0.09	9.86 × 10 <sup>6</sup>	10.1
0.1	1:1	0.1	1.04 × 10 <sup>7</sup>	9.6
	2:2	0.4	2.08 × 10 <sup>7</sup>	4.8
	3:3	0.9	3.12 × 10 <sup>7</sup>	3.2

- $e$  = electron charge,  $1.60219 \times 10^{-19}$  C  
 $N_A$  = Avagadro's number,  $6.02205 \times 10^{23}$ /mol  
 $I$  = ionic strength,  $\frac{1}{2} \sum z^2 M$ , mol/L  
 $z$  = magnitude of positive or negative charge on ion  
 $M$  = molar concentration of cationic or anionic species, mol/L  
 $\epsilon$  = permittivity relative to a vacuum ( $\epsilon$  for water is 78.54, unitless)  
 $\epsilon_0$  = permittivity in a vacuum,  $8.854188 \times 10^{-12}$  C<sup>2</sup>/J · m  
 $k$  = Boltzmann constant,  $1.38066 \times 10^{-23}$  J/K  
 $T$  = absolute temperature, K ( $273 + ^\circ\text{C}$ )

The relationship given in Eq. 9-4 is not actually the double-layer thickness but is related to how far out into the solution the repulsive force will reach. It is approximately equal to the distance at which the electrical potential is 37 percent of the value at the particle surface. However, it is still important to know the EDL thickness because it provides insight into the particle stability and the coagulation process.

#### EFFECT OF IONIC STRENGTH

Of the many factors that affect double-layer thickness, ionic strength is perhaps the most important. As reported in Table 9-3, the EDL thickness shrinks dramatically with increasing ionic strength and valance. According to the DLVO theory, van der Waals forces extend out into solution about 10 Å; consequently, if the double layer is smaller than this, a rapidly flocculating suspension is formed. While it is possible to reduce the thickness of the EDL by increasing the ionic strength, this is not a practical method for destabilizing particles in drinking water treatment because the required ionic strengths are greater than are considered acceptable in potable water. It is interesting to note that ionic strength can be used to explain why particles are stable in freshwater (low ionic strength but high electrical repulsive forces) and flocculate rapidly in salt water (high ionic strength but low electrical repulsive forces). Determination of the thickness of the double layer as function of the ionic strength is illustrated in Example 9-1.

#### EFFECT OF COUNTERIONS

If the charge on the counterions in solution is altered, the thickness of the EDL will be reduced, as illustrated in Table 9-3. The ionic concentration that results in the reduction of the EDL to the point where flocculation occurs is defined as the critical coagulation concentration (CCC) and will depend on the type of particulate as well as the dissolved ions. According to the DLVO theory, the CCC is inversely proportional to the sixth power of the charge on the ion. Thus, the CCC values for mono-, di-, and trivalent ions are in the ratio of 1:  $\frac{1}{2}^6$ :  $\frac{1}{3}^6$ , or 100: 1.6: 0.14 percent, assuming that the electrolytes do not adsorb or precipitate. The above relationship is known as the Schultz-Hardy rule, which was originally observed in the 1880s

### Example 9-1 Determination of thickness of electrical double layer

Verify that the values in Table 9-3 are correct for 0.001 M solutions of monovalent and divalent ions using Eq. 9-4.

#### Solution

1. Determine the ionic strength  $I$  for a molarity of 0.001 for chemical constituents with a charge of 1 and 2.

a. Determine the ionic strength for  $Z = +1$  and  $-1$ :

$$I = \frac{1}{2} \sum Z^2 M = \frac{1}{2} \sum (+1)^2 (0.001) + (-1)^2 (0.001) = 0.001 \text{ mol/L}$$

b. Determine the ionic strength for  $Z = +2$  and  $-2$ :

$$I = \frac{1}{2} \sum Z^2 M = \frac{1}{2} \sum (+2)^2 (0.001) + (-2)^2 (0.001) = 0.004 \text{ mol/L}$$

2. Substitute known terms in Eq. 9-4 and solve for  $1/\kappa$ :

a. For  $M = 0.001$ ,  $Z = +1, -1$ , and  $I = 0.001 \text{ mol/L}$ ,

$$\kappa^{-1} = (10^{10} \text{ \AA/m})$$

$$\times \left[ \frac{(2)(1000 \text{ L/m}^3)(1.60219 \times 10^{-19} \text{ C})^2 (6.02205 \times 10^{23} \text{ mol}^{-1})(0.001 \text{ mol/L})}{(78.54)(8.854188 \times 10^{-12} \text{ C}^2/\text{J} \cdot \text{m})(1.38066 \times 10^{-23} \text{ J/K})(273 + 25 \text{ K})} \right]^{-1/2}$$

$$= 96.2 \text{ \AA}$$

b. For  $M = 0.001$ ,  $Z = +2, -2$ , and  $I = 0.004 \text{ mol/L}$ ,

$$\kappa^{-1} = (10^{10} \text{ \AA/m})$$

$$\times \left[ \frac{(2)(1000 \text{ L/m}^3)(1.60219 \times 10^{-19} \text{ C})^2 (6.02205 \times 10^{23} \text{ mol}^{-1})(0.004 \text{ mol/L})}{(78.54)(8.854188 \times 10^{-12} \text{ C}^2/\text{J} \cdot \text{m})(1.38066 \times 10^{-23} \text{ J/K})(273 + 25 \text{ K})} \right]^{-1/2}$$

$$= 48.1 \text{ \AA}$$

#### Comment

The above computation illustrates the importance of the charge of the ionic species, as reported in Table 9-3.

Kruyt, 1952). Thus, if 3000 mg/L of NaCl will produce rapid flocculation of hydrophobic particulates, then 47 mg/L of CaCl<sub>2</sub> will achieve similar results. It should also be noted that if multivalent ions comprise the fixed layer next to a negatively charged particle, the EDL will be reduced significantly and the CCC value would be much lower than predicted by the theory (for the Schultz–Hardy rule).

## 9-3 Coagulation Theory

---

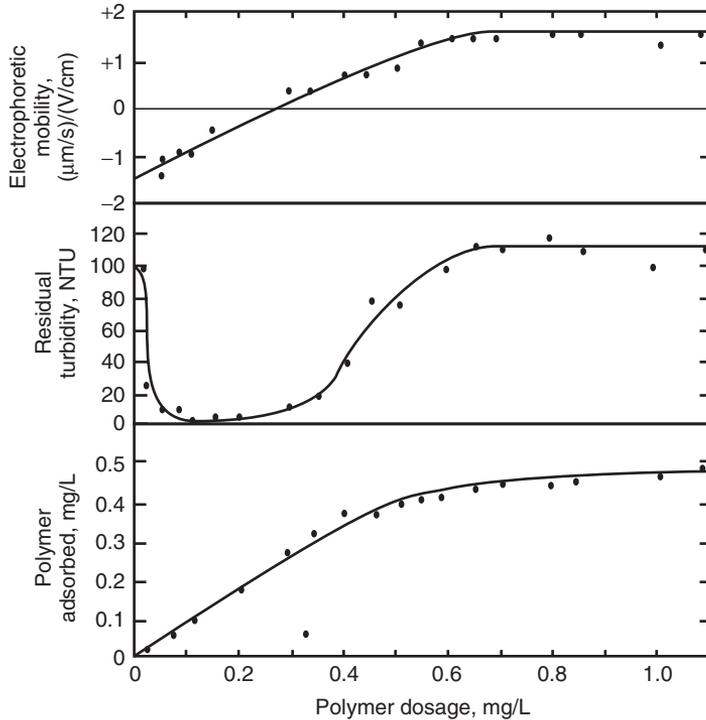

The electrical properties of particles were considered in the previous section. Coagulation, as described in Sec. 9-1, is the process used to destabilize the particles found in waters so that they may be removed by subsequent separation processes. The purpose of this section is to introduce the principal coagulation mechanisms responsible for particle destabilization and removal. Coagulation practice including the principal chemicals used for coagulation in water treatment and jar testing is presented and discussed in Sec. 9-4.

Mechanisms that can be exploited to achieve particulate destabilization include (1) compression of the electrical double layer, (2) adsorption and charge neutralization, (3) adsorption and interparticle bridging, and (4) enmeshment in a precipitate, or “sweep floc.” While these mechanisms are discussed separately here, it will become apparent that each one has certain pitfalls, and this is the reason that destabilization strategies exploit several mechanisms simultaneously. It should also be noted that compression of the electrical double layer, discussed in the previous section, is also considered a coagulation mechanism but is not discussed here because increasing the ionic strength is not practiced in water treatment.

Particulates can be destabilized by adsorption of oppositely charged ions or polymers. Most particulates in natural waters are negatively charged (clays, humic acids, bacteria) in the neutral pH range (pH 6 to 8); consequently, hydrolyzed metal salts, prehydrolyzed metal salts, and cationic organic polymers can be used to destabilize particles through charge neutralization. Cationic organic polymers can be used as primary coagulants, but they are most often used in conjunction with inorganic coagulants to form particle bridges, as discussed below. Generally, the optimum coagulant dose occurs when the particle surface is only partially covered (less than 50 percent). Polymers of high charge density and low to moderate molecular weights (10,000 to 100,000) are believed to be adsorbed on negatively charged particles as a patch on the surface and do not extend much from the surface. The optimum dose appears to increase in proportion to the surface area concentration of the particulates.

When the proper amount of polymer has adsorbed, the charge is neutralized and the particle will flocculate. When too much polymer has

### **Adsorption and Charge Neutralization**

**Figure 9-7**

Destabilization of a kaolinite clay suspension with cationic polymer No. 4. Initial clay concentration = 73.2 mg/L. (Adapted from Black et al., 1966.)

been added, the particles will attain a positive charge and become stable once again. This phenomenon is demonstrated by the classical experiments of Black et al. (1966), which are shown on Fig. 9-7. For polymer dosages up to 0.7 mg/L, the electrophoretic mobility becomes more positive and the amount adsorbed increases. Higher dosages cause charge reversal, particle stability, and a higher residual turbidity. Cationic polymers and polyaluminum chloride (PACl) are said to exhibit stoichiometry because a certain amount of charge exists on the particle suspension surface, and when the precise amount of coagulant is added, a rapidly flocculating suspension is created.

### Adsorption and Interparticle Bridging

Polymer bridging is complex and has not been adequately described analytically. Schematically, polymer chains adsorb on particle surfaces at one or more sites along the polymer chain as a result of (1) coulombic (charge–charge) interactions, (2) dipole interaction, (3) hydrogen bonding, and (4) van der Waals forces of attraction (Hunter, 2001). The rest of the polymer may remain extended into the solution and adsorb on available surface sites of other particles, thus creating a “bridge” between particle surfaces. If the extended polymer cannot find vacant sites on the surface of other particulates, no bridging will occur. Thus, there

is an optimum degree of coverage or extent of polymer adsorption at which the rate of aggregation will be a maximum. Polymer bridging is an adsorption phenomenon; consequently, the optimum coagulant dose will generally be proportional to the concentration of particulates present. Adsorption and interparticle bridging occur with nonionic polymers and high-molecular-weight (MW  $10^5$  to  $10^7$ ), low-surface-charge polymers. High-molecular-weight cationic polymers have a high charge density to neutralize surface charge.

#### REACTION MECHANISMS FOR POLYMERS

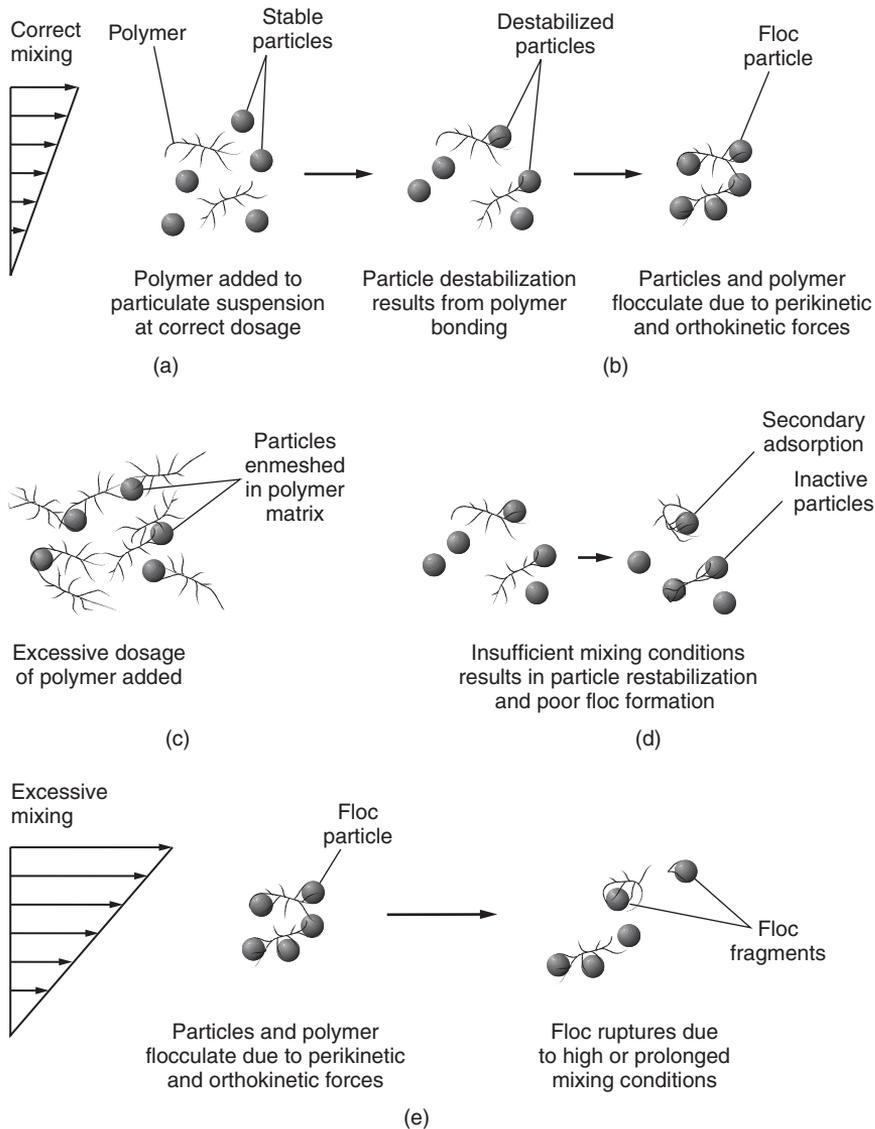

A schematic of the reaction mechanisms for polymers is shown on Fig. 9-8. At the optimum dosage of polymer shown in reaction (a), the particles are destabilized and can subsequently flocculate, as shown in reaction (b). If the particle concentration is very low or if adequate mixing does not allow flocculation, then nonadsorbed ends of the polymers will eventually adsorb on the destabilized particle, causing it to restabilize, as shown in reaction (c). If too much polymer is added, all adsorption sites will be taken up and the particle will not flocculate, as shown in reaction (d). If the particles are mixed for too long or too intensively, they will break up, as shown in reaction (e).

#### POLYMER SELECTION

Because polymer–solution interactions are complex, polymer selection is based on empirical testing. In general, though, anionic polymers have been shown to be effective flocculant aids, while nonionic polymers have been effective as filter aids. Polymer selection for sludge conditioning is dependent on sludge properties, polymer properties, and the mixing environment (O'Brien and Novak, 1977). Polymer bridging is the dominant mechanism in sludge conditioning, and thus polymer molecular weight is the dominant property of interest. For each system, the optimum polymer dose, mixing conditions, and pH must be determined empirically.

When high enough dosages are used, aluminum and iron form insoluble precipitates and particulate matter becomes entrapped in the amorphous precipitates. This type of destabilization has been described as *precipitation and enmeshment* or *sweep floc* (Packham, 1965; Stumm and O'Melia, 1968). Although the molecular events leading to sweep floc have not been defined clearly, the steps for iron and aluminum salts at lower coagulant dosages are as follows: (1) hydrolysis and polymerization of metal ions, (2) adsorption of hydrolysis products at the interface, and (3) charge neutralization. At high dosages, it is likely that nucleation of the precipitate occurs on the surface of particulates, leading to the growth of an amorphous precipitate with the entrapment of particles in this amorphous structure. This mechanism predominates in water treatment applications where pH values are generally maintained between pH 6 and 8, and aluminum or iron salts are used at

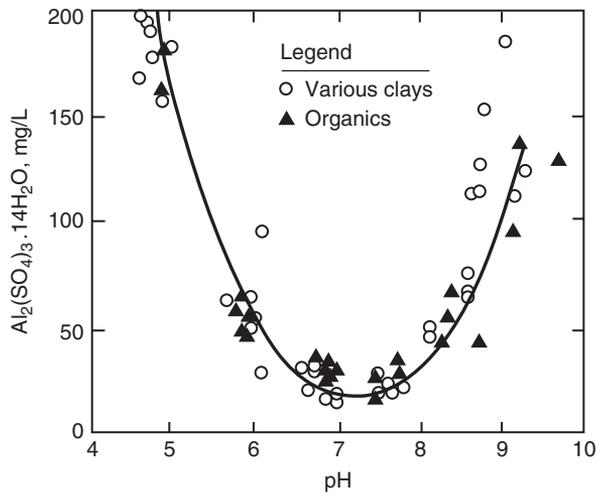

### Precipitation and Enmeshment

**Figure 9-8**

Schematic representation of the bridging model for the destabilization of particles by polymers. (Adapted from O'Melia, 1972.)

concentrations exceeding saturation with respect to the amorphous metal hydroxide solid that is formed.

One interesting finding regarding sweep floc is that, in general, the sweep floc mechanism does not depend on the type of particle, and, thus, the same dosage of coagulant is required for sweep floc formation regardless of the type of particles that may be present (in the absence of

**Figure 9-9**

Coagulation of various types of clays and organics, which supports hypothesis that sweep floc is not influenced by type of particles present: (○) clays and (▲) organics. (Adapted from Packman, 1962.)

NOM). The dosage of alum required to reduce the turbidity of a variety of particles is displayed on Fig. 9-9. Although the dosage does not depend on the type of particles, it does depend on the pH, as expected. However, a caveat that should be mentioned is that the coagulant demand exerted by NOM is not reflected on Fig. 9-9. Thus, the concentration of hydrolyzing metal salts that is required for sweep floc will depend on the type and concentration of NOM, which unfortunately is site specific. The effects of NOM on coagulation practice are considered in Sec. 9-5.

## 9-4 Coagulation Practice

Selection of the type and dose of coagulant depends on the characteristics of the coagulant, the concentration and type of particulates, concentration and characteristics of NOM, water temperature, and water quality. At present, the interdependence of these five elements is only understood qualitatively, and prediction of the optimum coagulant combination from characteristics of the particulates and the water quality is not yet possible. The purpose of this section is to introduce coagulation practice, including the types of inorganic and organic coagulants and coagulant aids used, and alternative techniques used to reduce coagulant dosages.

Inorganic coagulants, coagulant aids, and the chemicals used for alkalinity and pH adjustment are summarized in Table 9-4. Of the chemicals listed in Table 9-4, the principal inorganic coagulants used in water treatment are salts of aluminum and ferric ions and prehydrolyzed salts of these metals. These hydrolyzable metal cations are readily available as sulfate or

### Inorganic Metallic Coagulants

**Table 9-4**

Common inorganic coagulants, coagulant aids, and pH and alkalinity adjusting chemicals used in water treatment

Classification	Chemical Formula	Molecular Weight, g/mol	Application
Coagulants			
Aluminum sulfate	$\text{Al}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}$	594.4	Primary coagulant
Sodium aluminate	$\text{Na}_2\text{Al}_2\text{O}_4$	163.9	Used with alum; provides alkalinity and pH control
Aluminum chloride	$\text{AlCl}_3$	160.3	Used in blends with organic polymers
Polyaluminum chloride (PACl) <sup>a</sup>	$\text{Al}_a(\text{OH})_b(\text{Cl})_c(\text{SO}_4)_d$	Variable	Primary coagulant
Polyaluminum sulfate (PAS) <sup>b</sup>	$\text{Al}_a(\text{OH})_b(\text{Cl})_c(\text{SO}_4)_d$	Variable	Primary coagulant, produced onsite
Polyiron chloride <sup>c</sup>	$\text{Fe}_a(\text{OH})_b(\text{Cl})_c(\text{SO}_4)_d$	Variable	Primary coagulant, produced onsite
Ferric chloride	$\text{FeCl}_3$	162.2	Primary coagulant
Ferric sulfate	$\text{Fe}_2(\text{SO}_4)_3$	400.0	Primary coagulant
Coagulant aids			
Activated silica	$\text{SiO}_2$	60.0	Coagulant aid used with alum during cold winter months
Sodium silicate	$\text{Na}_2\text{O}(\text{SiO}_2)_{3-25}$	242–1562	Coagulant aid, produced onsite
Bentonite	$\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$	258	Used to provide nucleation sites for enhanced coagulation
Alkalinity and pH adjustment			
Calcium hydroxide	$\text{Ca}(\text{OH})_2$	56.1 as CaO	Used to provide alkalinity and adjust pH
Sodium hydroxide	$\text{NaOH}$	40.0	Used to provide alkalinity and adjust pH
Soda ash	$\text{Na}_2\text{CO}_3$	106.0	Used to provide alkalinity and adjust pH

<sup>a</sup>Prehydrolyzed metal salts made from aluminum chloride.

<sup>b</sup>Prehydrolyzed metal salts made from aluminum sulfate.

<sup>c</sup>Prehydrolyzed metal salts made from iron chloride.

chloride salts in both liquid and solid (dry) forms. In the United States, the predominant water treatment coagulant is aluminum sulfate, or “alum,” sold in a hydrated form as  $\text{Al}_2(\text{SO}_4)_3 \cdot x\text{H}_2\text{O}$ , where  $x$  is usually 14 because it is the least expensive coagulant. The action, solubility, and application of these coagulants are considered in the following discussion.

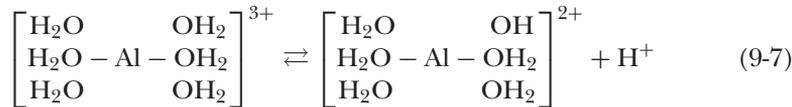

#### ACTION OF ALUM AND IRON SALTS

When ferric or aluminum ions are added to water, a number of parallel and sequential reactions occur. Initially, when a salt of Al(III) and Fe(III)

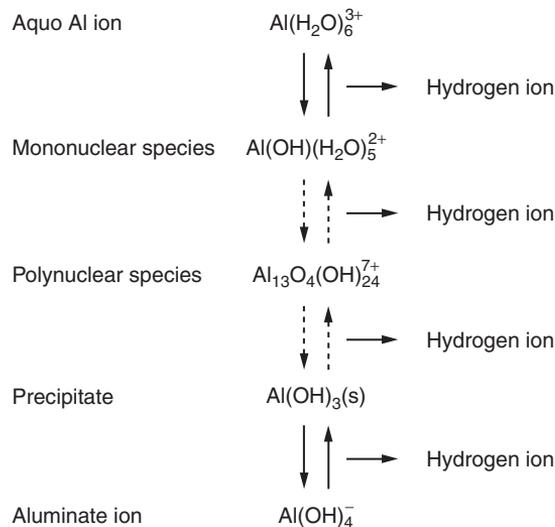

is added to water, it will dissociate to yield trivalent  $\text{Al}^{3+}$  and  $\text{Fe}^{3+}$  ions, as given below:

The trivalent ions of  $\text{Al}^{3+}$  and  $\text{Fe}^{3+}$  then hydrate to form the aquometal complexes  $\text{Al}(\text{H}_2\text{O})_6^{3+}$  and  $\text{Fe}(\text{H}_2\text{O})_6^{3+}$ , as shown on the left-hand side of Eq. 9-7. As shown, the metal ion (aluminum in this case) has a coordination number of 6 and six water molecules orient themselves around the metal ion:

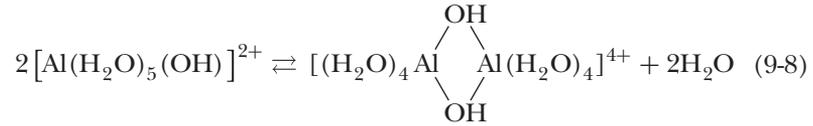

These aquometal complexes then pass through a series of hydrolytic reactions, as illustrated on the right-hand side of Eq. 9-8, which give rise to the formation of a variety of soluble mononuclear (one aluminum ion) and polynuclear (several aluminum ions) species, as illustrated on Fig. 9-10. The mononuclear species— $\text{Al}(\text{H}_2\text{O})_5(\text{OH})^{2+}$  [or just  $\text{Al}(\text{OH})^{2+}$ ] and  $\text{Al}(\text{H}_2\text{O})_4(\text{OH})_2^+$  [or just  $\text{Al}(\text{OH})_2^+$ —are among the many species formed. Similarly, iron forms a variety of soluble species, including mononuclear species (one iron ion) such as  $\text{Fe}(\text{H}_2\text{O})_5(\text{OH})^{2+}$  [or just  $\text{Fe}(\text{OH})^{2+}$ ] and  $\text{Fe}(\text{H}_2\text{O})_4(\text{OH})_2^+$  [or just  $\text{Fe}(\text{OH})_2^+$ ].

**Figure 9-10**

Aluminum hydrolysis products. The dashed lines are used to denote an unknown sequence of reactions. (Adapted from Letterman, 1981)

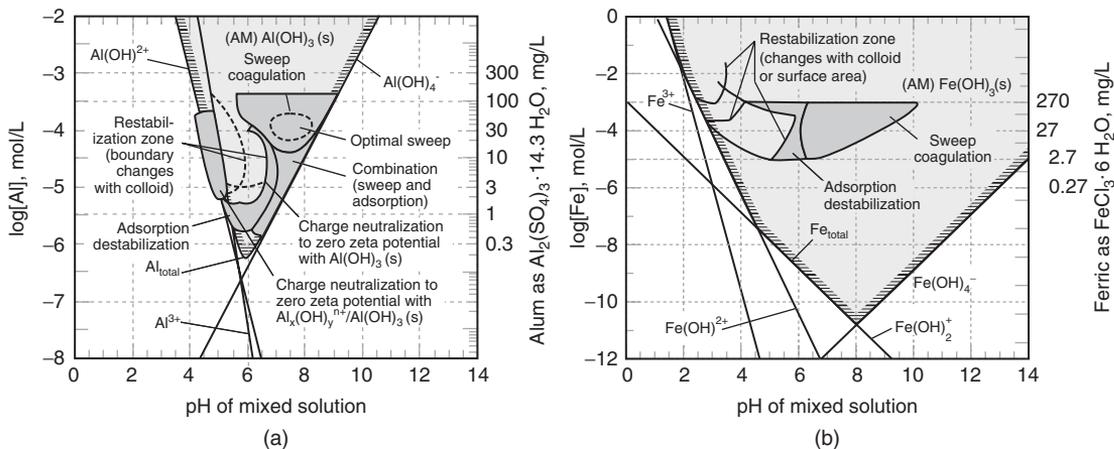

Polynuclear species such as  $\text{Al}_{18}(\text{OH})_{20}^{4+}$  form via hydroxyl bridges. For example, a hydroxyl bridge for two aluminum atoms is shown below:

It should be noted that all of these mononuclear and polynuclear species can interact with the particles in water, depending on the characteristics of the water and the number of particles. Unfortunately, it is difficult to control and know which mononuclear and polynuclear species are operative. As will be discussed later, this uncertainty gave rise to the development of prehydrolyzed metal salt coagulants.

#### SOLUBILITY OF METAL SALTS

The solubility of the various alum [Al(III)] and iron [Fe(III)] species are illustrated on Figs. 9-11a and 9-11b, respectively, in which the log molar concentrations have been plotted versus pH. The equilibrium diagrams shown on Figs. 9-11a and 9-11b were created using equilibrium constants for the major hydrolysis reactions that have been estimated after approximately 1 h of reaction time (upper limit of coagulation/flocculation detention times). Accordingly, the composition of aluminum and iron species in contact with the freshly precipitated hydroxide (amorphous) is illustrated on Figs. 9-11a and 9-11b. In preparing these diagrams, only the mononuclear species for

**Figure 9-11**

Solubility diagram for (a) Al(III) and (b) Fe(III) at 25°C. Only the mononuclear species have been plotted. The metal species are assumed to be in equilibrium with the amorphous precipitated solid phase. Typical operating ranges for coagulants: (a) alum and (b) iron. (Adapted from Amirtharajah and Mills, 1982)

**Table 9-5**

Reactions and associated equilibrium constants for aluminum and iron species in equilibrium with amorphous aluminum hydroxide and ferric hydroxide

Reaction	Acid Equilibrium Constants		
	Equilibrium Constant	Range, log K	Used for Fig. 9-11
Aluminum, Al(III)			
$\text{Al(OH)}_3(\text{s}) + 3\text{H}^+ \rightarrow \text{Al}^{3+} + 3\text{H}_2\text{O}$	$K_{s0}$	9.0–10.8	10.8
$\text{Al(OH)}_3(\text{s}) + 2\text{H}^+ \rightarrow \text{Al(OH)}^{2+} + 2\text{H}_2\text{O}$	$K_{s1}$	4.0–5.8	5.8
$\text{Al(OH)}_3(\text{s}) + \text{H}^+ \rightarrow \text{Al(OH)}_2^+ + \text{H}_2\text{O}$	$K_{s2}$	0.7–1.5	0.7
$\text{Al(OH)}_3(\text{s}) \rightarrow \text{Al(OH)}_3^0$	$K_{s3}$	–4.2 to –6.1	–6.1
$\text{Al(OH)}_3(\text{s}) + \text{H}_2\text{O} \rightarrow \text{Al(OH)}_4^- + \text{H}^+$	$K_{s4}$	–7.7 to –12.5	–11.9
Species not considered: $\text{Al}_2(\text{OH})_2^{4+}$ , $\text{Al}_8(\text{OH})_{20}^{4+}$ , $\text{Al}_{13}\text{O}_4(\text{OH})_{24}^{7+}$ , $\text{Al}_{14}(\text{OH})_{32}^{10+}$			
Iron, Fe(III)

$\text{Fe(OH)}_3(\text{s}) + \text{H}_2\text{O} \rightarrow \text{Fe(OH)}_4^- + \text{H}^+$	$K_{s4}$	–16.709 to –19	–18.4
Species not considered: $\text{Fe}_2(\text{OH})_2^{4+}$ , $\text{Fe}_3(\text{OH})_4^{5+}$			

Source: Benefield et al. (1982), McMurry and Fay (2003), Morel and Hering (1993), Nordstrom and May (1989a, b), Pankow (1991), Snoeyink and Jenkins (1980), Sawyer et al. (2002), and Stumm and Morgan (1981).

alum and iron have been plotted. The various mononuclear species for alum and iron are given in Table 9-5, along with the corresponding range of acid solubility products reported in the literature and the values used to prepare Figs. 9-11a and 9-11b. The approximate total concentration of residual soluble alum (see Fig. 9-11a) and iron (see Fig. 9-11b) in solution after precipitation is identified by the solid line. Aluminum hydroxide and ferric hydroxide are precipitated within the shaded areas, and polynuclear and polymeric species are formed outside of the shaded areas at higher and lower pH values. It should also be noted that the structure of the precipitated iron is far more compact and inert as compared to the amorphous nature of precipitated aluminum.

In most water treatment applications for removal of turbidity, disinfection by-product precursors (NOM), and color, the pH during coagulation ranges between 6 and 8. The lower limit is imposed to prevent accelerated corrosion rates that occur at pH values below pH 6. The regions shown on Figs. 9-11a and 9-11b correspond to the operating pH and dosage ranges that are normally used in water treatment when alum and iron are used

in the sweep floc mode of operation. The operating region for aluminum hydroxide precipitation is in a pH range of 5.5 to about 7.7, with minimum solubility occurring at a pH of about 6.2 at 25°C, and from about 5 to 8.5 for iron precipitation, with minimum solubility occurring at a pH of 8.0. The importance of pH in controlling the concentration of soluble metal species that will pass through the treatment process is illustrated on Figs. 9-11a and 9-11b. The effect of temperature on the solubility products for aluminum is also illustrated on Fig. 9-11a. As shown, the point of minimum solubility for alum shifts with temperature, which has a significant impact on the operation of water treatment plants where alum is used as the coagulant. Comparing the solubility of alum and ferric species, the ferric species are more insoluble than aluminum species and are also insoluble over a wider pH range. Thus, ferric ion is often the coagulant of choice to aid destabilization in the lime-softening process, which is carried out at higher pH values (pH 9).

#### STOICHIOMETRY OF METAL ION COAGULANTS

The overall stoichiometric reactions for aluminum and ferric ion in the formation of hydroxide precipitates are given by Eqs. 9-9 and 9-10. As shown, each mole of trivalent ion will produce 1 mole of the metal hydroxide and 3 moles of hydrogen ions:

The “am” subscripts in Eqs. 9-9 and 9-10 refer to amorphous solids (hours old), which have a much higher solubility product than crystalline precipitates.

When alum is added to water and aluminum hydroxide precipitates, the overall reaction is

Similarly, the overall reactions for ferric chloride and ferric sulfate are as follows:

Ferric chloride:

Ferric sulfate:

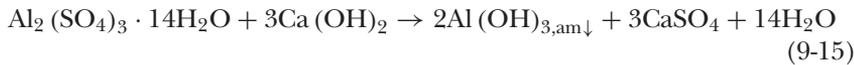

After  $\text{Al}(\text{OH})_3$  or  $\text{Fe}(\text{OH})_3$  precipitates, the species remaining in water are the same as if  $\text{H}_2\text{SO}_4$  or  $\text{HCl}$  had been added to the water. Thus, adding alum or ferric is like adding a strong acid. A strong acid will lower the pH and consume alkalinity. Alkalinity is the acid-neutralizing capacity of water and is consumed on an equivalent basis; that is, 1 meq/L of alum or ferric

will consume 1 meq/L of alkalinity. Since alkalinity buffers water against changes in pH, the change in pH following coagulant addition depends on the initial alkalinity. If the natural alkalinity of the water is not sufficient to buffer the pH, it may be necessary to add alkalinity to the water to keep the pH from dropping too low. Alkalinity can be added in the form of caustic soda (NaOH), lime [Ca(OH)<sub>2</sub>], or soda ash (Na<sub>2</sub>CO<sub>3</sub>). In many water plants, caustic soda is often used because it is easy to handle and the required dosage is relatively small. The reaction for alum with caustic soda is

The corresponding reaction for lime is given by the expression

Coagulants are typically purchased in a concentrated liquid form. Calculating coagulant doses can be confusing because the stock chemical concentration is often reported in percent by weight and the density of the stock solution will be significantly heavier than water. In addition, the extent of hydration of the alum or ferric will vary or be unknown in the stock solution, which affects the formula weight of the chemical. To get around this issue, chemical manufacturers will sometimes report the concentration of the coagulant as a different formula entirely, for example, stock alum concentration is often reported as percent as Al<sub>2</sub>O<sub>3</sub>, even though the chemical present is Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> · xH<sub>2</sub>O. Ferric chloride may be reported with or without waters of hydration (i.e., FeCl<sub>3</sub> · 6H<sub>2</sub>O or FeCl<sub>3</sub>) or as soluble iron (Fe<sup>3+</sup>). To calculate doses accurately, the density and chemical formula used by the chemical manufacturer to report the concentration must be known. The application of these principles and the above equations is illustrated in Example 9-2. Note that the sludge produced during coagulation consists of both the precipitate formed in the reactions shown above and the solids that were present in the source water. Example 21-2 in Chap. 21 demonstrates the procedure for calculating the amount of sludge produced considering both components.

### Example 9-2 Calculation of coagulant doses, alkalinity consumption, and precipitate formation

A chemical supplier reports the concentration of stock alum chemical as 8.37 percent as Al<sub>2</sub>O<sub>3</sub> with a specific gravity of 1.32. For the stock chemical, calculate (a) the molarity of Al<sup>3+</sup> and (b) the alum concentration if reported as g/L Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> · 14H<sub>2</sub>O. Also, for a 30-mg/L alum dose applied to a

treatment plant with a capacity of 43,200 m<sup>3</sup>/d (0.5 m<sup>3</sup>/s), calculate (c) the chemical feed rate in L/min, (d) the alkalinity consumed (expressed as mg/L as CaCO<sub>3</sub>), (e) the amount of precipitate produced in mg/L and kg/day, and (f) the amount of NaOH that would need to be added to counteract the consumption of alkalinity by alum.

### Solution

1. Calculate the formula weights (FW) for Al<sub>2</sub>O<sub>3</sub>, Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> · 14H<sub>2</sub>O, Al(OH)<sub>3</sub>, and NaOH, given molecular weights: Al = 27, O = 16, H = 1, S = 32, and Na = 23 g/mol.

$$\text{FW: Al}_2\text{O}_3 = 2(27) + 3(16) = 102 \text{ g/mol}$$

$$\text{FW: Al}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O} = 2(27) + 3(32) + 26(16) + 28(1) = 594 \text{ g/mol}$$

$$\text{FW: Al(OH)}_3 = 27 + 3(16) + 3(1) = 78 \text{ g/mol}$$

$$\text{FW: NaOH} = 23 + 16 + 1 = 40 \text{ g/mol}$$

2. Calculate the molar concentration of Al<sup>3+</sup> in the stock alum chemical.
  - a. Calculate the density of stock chemical:

$$\rho_{\text{stock}} = 1.32 \text{ (1 kg/L)} = 1.32 \text{ kg/L}$$

- b. Calculate the concentration of alum in the stock chemical as mg/L Al<sub>2</sub>O<sub>3</sub>:

$$C_{\text{stock}} = 0.0837 \text{ (1.32 kg/L)} \left(10^3 \text{ g/kg}\right) = 110.5 \text{ g/L Al}_2\text{O}_3$$

- c. Calculate the molar concentration of Al<sup>3+</sup> in the stock alum chemical:

$$[\text{Al}^{3+}] = 110.5 \text{ g/L Al}_2\text{O}_3 \left( \frac{\text{mol Al}_2\text{O}_3}{102 \text{ g Al}_2\text{O}_3} \right) \left( \frac{2 \text{ mol Al}^{3+}}{\text{mol Al}_2\text{O}_3} \right) = 2.17 \text{ mol/L}$$

3. Calculate the stock alum concentration if reported as g/L Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> · 14H<sub>2</sub>O.

$$C_{\text{stock}} = 110.5 \text{ g/L Al}_2\text{O}_3 \left( \frac{594 \text{ g/mol alum}}{102 \text{ g/mol Al}_2\text{O}_3} \right) = 643.5 \text{ g/L alum}$$

4. Calculate the chemical feed rate.  
By mass balance:

$$C_{\text{stock}} Q_{\text{feed}} = C_{\text{process}} Q_{\text{process}}$$

$$Q_{\text{feed}} = \frac{C_{\text{process}} Q_{\text{process}}}{C_{\text{stock}}} = \frac{(30 \text{ mg/L}) (43,200 \text{ m}^3/\text{d}) (10^3 \text{ L/m}^3)}{643.5 \text{ g/L} (10^3 \text{ mg/g}) (1440 \text{ min/d})} = 1.40 \text{ L/min}$$

5. Calculate the alkalinity consumed using Eq. 9-11:

$$\begin{aligned} \text{Alk} &= [30 \text{ mg/L alum}] \left( \frac{1 \text{ mmol alum}}{594 \text{ mg alum}} \right) \left( \frac{3 \text{ mmol SO}_4^{2-}}{\text{mmol alum}} \right) \left( \frac{2 \text{ meq SO}_4^{2-}}{\text{mmol SO}_4^{2-}} \right) \\ &\quad \times \left( \frac{1 \text{ meq alk}}{\text{meq SO}_4^{2-}} \right) \left( \frac{50 \text{ mg CaCO}_3}{\text{meq alk}} \right) = 15 \text{ mg/L as CaCO}_3 \end{aligned}$$

6. Calculate the precipitate formed using Eq. 9-11:

$$\begin{aligned} [\text{Al(OH)}_3] &= [30 \text{ mg/L alum}] \left( \frac{1 \text{ mmol alum}}{594 \text{ mg alum}} \right) \left[ \frac{2 \text{ mmol Al(OH)}_3}{\text{mmol alum}} \right] \left[ \frac{78 \text{ mg Al(OH)}_3}{\text{mmol Al(OH)}_3} \right] \\ &= 7.88 \text{ mg/L Al(OH)}_3 \\ [\text{Al(OH)}_3] &= \frac{(7.88 \text{ mg/L}) (43,200 \text{ m}^3/\text{d}) (10^3 \text{ L/m}^3)}{(10^6 \text{ mg/kg})} = 340 \text{ kg/d} \end{aligned}$$

7. Calculate the NaOH dose required to counteract the alkalinity consumption using Eq. 9-14:

$$\begin{aligned} [\text{NaOH}] &= [30 \text{ mg/L alum}] \left( \frac{1 \text{ mmol alum}}{594 \text{ mg alum}} \right) \left( \frac{6 \text{ mmol NaOH}}{\text{mmol alum}} \right) \left( \frac{40 \text{ mg NaOH}}{\text{mmol NaOH}} \right) \\ &= 12.1 \text{ mg/L NaOH} \end{aligned}$$

### Comment

The sludge produced by coagulation has two components the precipitate formed by the reactions shown above and the particles from the raw water. Calculation of the total amount of sludge produced during coagulation considering both components is illustrated in Example 21-2.

### APPLICATION OF METAL SALTS IN WATER TREATMENT

Because of the sequence of reactions that follow the addition of alum or iron salts, as discussed above and illustrated on Fig. 9-10, it is not possible to predict a priori the performance of a coagulation process. Consequently, jar testing is typically used for coagulant/coagulant aid screening, and these results must be evaluated in the full-scale operation. Nevertheless, it is useful to review some general aspects of coagulation practice, including (1) the operating regions for the alum and iron, (2) interactions with other constituents in water, (3) typical dosages, and (4) the importance of initial blending when using metal salts. As noted in Chap. 6, blending is a mixing process to combine two liquid streams to achieve a specified level of uniformity. Guidance on the use of coagulants is provided in Table 9-6. Additional effects of NOM on the coagulation process are considered in Sec. 9-5.

**Table 9-6**  
Application guidance for Al(III) and Fe(III) as coagulants and prehydrolyzed metal coagulants used in water treatment

Water Quality Parameter	Coagulant	
	Alum(III)	Fe(III)
Turbidity	For low-turbidity waters (i.e., low particle concentration), sweep floc will be required.	For low-turbidity waters (i.e., low particle concentration), sweep floc will be required. Medium-basicity PACIs (40–50%) are suitable for cold waters with low turbidity.
Alkalinity	High alkalinity values make pH adjustment for optimum coagulation more difficult. If sufficient alkalinity is not present, soluble aluminum is formed, which can result in postfloculation in downstream processes. Supplemental alkalinity should be added before coagulant.	Although high alkalinity values make pH adjustment for optimum coagulation more difficult, its impact on coagulation using Fe is less than Al.
pH	The optimum pH range is between 5.5 and 7.7 but will fluctuate seasonally (see Fig. 9-11). Typically, the optimum pH will be nearer 6 in the summer and 7 in the colder winter months. Higher pH levels often correspond to periods of algal growth, which in turn will affect the coagulant dose.	The optimum pH range is from 5 to 8.5 or more (see Fig. 9-11).  PACIs are less sensitive to pH. Can be used over the pH range of 4.5–9.5.

NOM	The removal of NOM will normally control the coagulant dose. Removal of NOM tends to increase as pH is reduced. Removal of up to 70% has been achieved.	The removal of NOM will normally control the coagulant dose. Removal of NOM tends to increase as the pH is reduced. Removals of up to 70% have been achieved. Low-basicity PACls (up to 20%) are suitable for waters high in color and total organic carbon.
Temperature	Temperature affects solubility products. Floc formed in colder water tends to be weaker.	Floc formed in colder water tends to be weaker.
Mixing	Hydrolysis reactions are very fast. Mixing times should be less than 1 s and preferably less than 0.5 s.	Hydrolysis reactions are very fast. Mixing times should be less than 1 s and preferably less than 0.5 s.
		Because the PACl is prehydrolyzed, the initial blending time is somewhat less critical.

**OPERATING REGIONS FOR METAL SALTS**

Because the chemistry of the various reactions discussed above is so complex, there is no complete theory to explain the action of hydrolyzed metal ions. To qualitatively describe the application of alum as a function of pH, taking into account the action of alum as described above, Amirtharajah and Mills (1982) developed the diagrams shown on Fig. 9-11. It is important to note that the generalized information represented on Fig. 9-11 does not reflect the effects of NOM on the dosages of coagulant required. The approximate regions in which the different phenomena associated with particle removal in conventional sedimentation and filtration applications are plotted as a function of the alum dose and the pH of the treated effluent after alum has been added. For example, optimum particle removal by sweep floc occurs in the pH range of 7 to 8 with an alum dose of 20 to 60 mg/L. With proper pH control it is possible to operate with extremely low alum dosages.

*Interactions with other constituents in water*

As with all cations in water, hydrolysis products of aluminum and iron react with various ligands (e.g.,  $\text{SO}_4^{2-}$ , NOM,  $\text{F}^-$ ,  $\text{PO}_4^{3-}$ ) forming both soluble and insoluble products that will influence the quantity or dose of the coagulant required to achieve a desired level of particle destabilization. Thus, the optimum dose of a coagulant depends strongly on the particular water chemistry and the types of particles.

*Typical dosages*

A typical dosage of alum ranges from 10 to 150 mg/L, depending on raw-water quality and turbidity. Typical dosages of ferric sulfate [ $\text{Fe}_2(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$ ] and ferric chloride ( $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ ) range from 10 to 250 mg/L and 5 to 150 mg/L, respectively, depending on raw-water quality and turbidity. Ferric chloride is more commonly used than ferric sulfate and comes as a liquid.

*Importance of initial mixing with metal salts*

The rapid initial mixing (known as blending) of the metal salts in water treatment is extremely important. The sequence of reactions shown on Fig. 9-10 occurs rather rapidly (Rubin and Kovac, 1974). For example, at a pH of 4, half of the  $\text{Al}^{3+}$  hydrolyzes to  $\text{Al}(\text{OH})^{2+}$  within  $10^{-5}$  s (Base and Mesmer, 1976). Hudson and Wolfner (1967) noted that "coagulants hydrolyze and begin to polymerize in a fraction of second after being added to water." Hahn and Stumm (1968), studying the coagulation of silica dispersions with Al(III), reported that the time required for the formation of mono- and polynuclear hydroxide species was on the order of  $10^{-3}$  s, and the time of formation for the polymer species was on the order of  $10^{-2}$  s. The importance of initial and rapid mixing is also discussed by Amirtharajah and Mills (1982) and Vrale and Jorden (1971).

Clearly, based on the literature and actual field evaluations, the instantaneous rapid and intense mixing of metal salts is of critical importance, especially where the metal salts are to be used as coagulants to lower the surface charge of the colloidal particles. It should be noted that, although achieving extremely low blending times in large treatment plants is often difficult, low blending times can be achieved by using multiple mixers. Typical blending times for various chemicals are reported in Table 6-10 in Sec. 6-10, where the subject of mixing is considered in detail.

From the previous discussion of the use of alum and iron salts, it is clear that it is difficult to control the metal species formed, especially at low dosages. The unpredictability associated with alum and iron salts led to the development of prehydrolyzed metal salts. Prehydrolyzed metal salts are prepared by reacting alum or ferric with various salts (e.g., chloride, sulfate) and water and hydroxide under controlled mixing conditions. Several advantages of preformed aluminum metal salts include the following: (1) lower dosages may be required for effective coagulation (on the basis of  $\text{Al}^{3+}$ ) for cases where NOM does not dictate the coagulant dosage at neutral or slightly acidic conditions, (2) flocs tend to be tougher and denser (although flocculation aids are still necessary in many cases), and (3) the performance of prehydrolyzed alum salts is less temperature dependent as compared to unmodified alum salts. General guidance on the application of prehydrolyzed metal salts is given in Table 9-6.

## Prehydrolyzed Metal Salts

### CHEMICAL COMPOSITION

The commercial prehydrolyzed alum salts, commonly known as PACl, have the following overall formula:  $\text{Al}_a(\text{OH})_b(\text{Cl})_c(\text{SO}_4)_d$ . Although many formulations do not contain any sulfate; the presence of sulfate ions helps to stabilize the aluminum polymers and keep them from precipitating. These polymers can be more effective than those formed by simply adding aluminum salts to solution because the larger cationic polymers can be formed by increasing the hydroxide-to-aluminum ratio ( $R = \text{OH}/\text{Al}$ , see following basicity discussion), which can lead to enhanced charge neutralization. Another benefit is that, as the polymer becomes larger, it becomes more crystalline, compact, and dense. However, as the value of  $R$  increases, the polymers become less stable and may begin to precipitate, which can cause a problem in the storage of PACl.

### BASICITY

As given by Eqs. 9-9 and 9-10, when metal salts such as alum and iron hydrolyze, hydrogen ions are released, which will react with the alkalinity of the water. In the formulation of PACl coagulants, some of the acid that would have been released is neutralized with base ( $\text{OH}^-$ ) when the coagulant is manufactured. The degree to which the hydrogen ions that would be released by hydrolysis are preneutralized is known as the basicity

of the product and is given by the following relationship for prehydrolyzed metal salts that do not contain oxygen:

$$\text{Basicity, \%} = \frac{[\text{OH}]}{[\text{M}] Z_M} \times 100 \quad (9-16)$$

where  $[\text{OH}]/[\text{M}]$  = molar ratio of hydroxide bound to metal ion  
 $Z_M$  = charge on metal species

For example, the basicity of the PACl  $\text{Al}_2(\text{OH})_4\text{Cl}_2$  is 66.7 percent  $\{[4/(3 \times 2)] \times 100\}$ . It should be noted that, if oxygen is included in the formulation, the basicity of the compound will increase by the effect of the oxygen. For example, the basicity for the compound  $\text{Al}_13\text{O}_4(\text{OH})_{24}$  is 82.1 percent  $\{[24 + (4 \times 2)]/(13 \times 3)] \times 100\}$ . In effect, each mole of oxygen will neutralize 2 moles of hydrogen. Most prehydrolyzed alum products have an OH/Al ratio of 0.45 to 2.5, which corresponds to basicity values of 15  $[(0.45/3) \times 100]$  and 83.3  $[(2.5/3) \times 100]$  percent.

## Organic Polymers

Organic polymers are long-chain molecules consisting of repeating chemical units with a structure designed to provide distinctive physicochemical properties. The chemical units usually have an ionic functional group that imparts an electrical charge to the polymer chain. Hence, organic polymers are often termed *polyelectrolytes*. Organic polymers have two principal uses in water treatment: (1) as a coagulant for the destabilization of particles and (2) as a filter aid to promote the formation of larger and more shear-resistant flocs. While destabilization occurs primarily through charge neutralization, nonionic and anionic polymers can be used to form a bridge between particles. Organic polymers are not generally used as primary coagulants and are often used after the particles have been destabilized to some degree with metal coagulants. Polymers are broadly classified as being natural or synthetic in origin. Because of their greater use in water treatment, the synthetic polymers are discussed first.

### SYNTHETIC ORGANIC POLYMERS

Generally, synthetic organic polymers are much cheaper than those made from natural sources and consequently are used more often in the United States than natural organic polymers. The principal synthetic organic polymers used for water treatment are summarized in Table 9-7. Synthetic organic polymers are made either by homopolymerization of the monomer or by copolymerization of two monomers. Polymer synthesis can be manipulated to produce polymers of varying size (molecular weight), charge groups, number of charge groups per polymer chain (charge density), and varying structure (linear or branched). A typical example is the production of polyacrylamide in which the monomer, acrylamide, homopolymerizes under appropriate conditions to form the polymer. Polyacrylamide carries no ionic charge and is referred to as a *nonionic* polymer. Subsequent

**Table 9-7**

Typical organic coagulants used in water treatment

Type	Charge	Molecular Weight, g/mole	Common Applications	Typical Examples <sup>a</sup>	Other Examples
Anionic	Negative	$10^4 - 10^7$	Coagulant aid, filter aid, flocculant aid, sludge conditioning	Hydrolyzed polyacrylamides $\left[ \begin{array}{c} \text{CH}_2 - \text{CH} \\   \\ \text{C} = \text{O} \\   \\ \text{NH}_2 \end{array} \right]_x \left[ \begin{array}{c} \text{CH}_2 - \text{CH} \\   \\ \text{C} = \text{O} \\   \\ \text{O} - \text{Na}^+ \end{array} \right]_y$	Hydrolyzed polyacrylamides, polyacrylamides, polyacrylates, polyacrylic acid, polystyrene sulfonate
Cationic	Positive	$10^4 - 10^6$	Primary coagulant, turbidity and color removal	Epichlorohydrin dimethylamine (epi-DMA) $\left[ \begin{array}{c} \text{CH}_3 \quad \text{Cl}^- \\   \quad   \\ \text{N}^+ - \text{CH}_2 - \text{CH}_2 \\   \quad   \\ \text{CH}_3 \quad \text{CH} \\   \quad   \\ \text{OH} \end{array} \right]_x$	Aminomethyl polyacrylamide, polyalkylene, polyamines, polyethylenimine
			Sludge conditioning	Polydiallyldimethyl ammonium chloride (poly-DADMAC) $\left[ \begin{array}{c} \text{CH} - \text{CH} \\   \quad   \\ \text{CH}_2 \quad \text{CH}_2 \\   \quad   \\ \text{N}^+ \quad \text{Cl}^- \\   \quad   \\ \text{CH}_3 \quad \text{CH}_3 \end{array} \right]_x \left[ \begin{array}{c} \text{CH} - \text{CH} \\   \quad   \\ \text{CH}_2 \quad \text{CH}_2 \\   \quad   \\ \text{N}^+ \quad \text{Cl}^- \\   \quad   \\ \text{CH}_3 \quad \text{CH}_3 \end{array} \right]_y$	Polydimethyl aminomethyl polyacrylamide, polyvinylbenzyl, trimethyl ammonium chloride
Nonionic	Neutral	$10^5 - 10^7$	Coagulant aid, filter aid, filter conditioning	Polyacrylamides $\left[ \begin{array}{c} \text{CH}_2 - \text{CH} \\   \\ \text{C} = \text{O} \\   \\ \text{NH}_2 \end{array} \right]_x$	Polyacrylamides, polyethylene oxide
Others	Variable	Variable	—	Sodium alginate	Alginate, dextran, guar gum, starch derivatives

<sup>a</sup>Number of monomer molecules in polymer designated by x and y.

hydrolysis of polyacrylamide under basic conditions produces a polymer with *anionic* charges. Thus, the number of anionic groups, in this case a carboxyl group, can be controlled, providing anionic polymers of different molecular weights and charge density. The third type of polymer has a *cationic* or positive charge group incorporated in the polymer chain, usually by a copolymerization process.

#### APPLICATION OF POLYMERS

Since their introduction in the early 1950s, the use of organic polyelectrolytes such as poly diallyl-dimethyl ammonium chloride (poly-DADMAC) and epichlorohydrin dimethylamine (epi-DMA) (see Table 9-7) has gained widespread use for water treatment in the United States. The MW ranges from  $10^4$  to  $10^5$  and the basic polymer units are shown in Table 9-7.

##### *Cationic polymers*

In water treatment applications, cationic organic polymers are generally designed to be water soluble, to adsorb on or react rapidly with particulates, and to possess a chemical structure suitable for the intended use. When used as primary coagulants, cationic polymers, in contrast to aluminum or ferric ions, do not produce large floc volumes because organic coagulants can be effective at much lower coagulant dosages than inorganic coagulants. However, sludge from organic coagulants is usually denser and stickier than sludge from inorganic coagulants. Consequently, cationic organic coagulants are not suitable for every type of separation process.

It should be noted that, because organic coagulants do not always produce the same water quality as is obtained with metallic ion coagulants, cationic organic polymers are rarely used alone except for direct filtration. Furthermore, if cationic organic polymers are used alone, they are ineffective in removing dissolved substances (e.g., NOM, As, F). It is common to use cationic organic polymers and metallic ion coagulants together. The main advantage of the combined usage is that the dosage of metallic ion coagulants can be reduced by 40 to 80 percent. The lower metallic ion coagulant dosage in turn reduces sludge and alkalinity consumption. With lower alkalinity consumption, the pH will not be depressed as much, which can improve metallic ion coagulation.

##### *Polymer dosages*

Because of the complex interactions between polymers and particulates and the uncertain influence of water quality on these interactions, polymer selection is empirical. The typical dosage rates for sedimentation are on the order of 1 to 10 mg/L for DADMAC and epi-DMA. Low dosages of high-molecular-weight nonionic polymers (0.005 to 0.05 mg/L) are often added before granular filtration and to the backwash water to improve filter performance. Incorrect dosing can cause mudball formation in the filters, which are not usually broken apart during normal backwashing operations.

### *Impact of solution parameters*

Solution parameters will also impact polymer dose. If the polymer charge density depends on pH, as with nonquaternized polyamines (see Table 9-7), then the optimum polymer dose will vary with pH, generally decreasing as the pH decreases [the charge on secondary and tertiary amines depends on pH because the amine group will tend to protonate at lower pH values (less than 6) and will remain uncharged at neutral pH]. The charge density of quaternized polymers such as poly-DADMAC are only slightly affected by pH. Changes in ionic strength and composition do not appear to affect polymer dose strongly over typical ranges encountered in water treatment (TDS between 50 and 500 mg/L).

### **MIXING OF POLYMERS**

Most polymers are available in liquid form and can be used without a preparation stage, but they must be injected directly following in-line dilution. Successful use of polymers in water treatment requires adequate dispersion of the polymer to promote more uniform polymer adsorption. Jar testing, as described in the previous section, may be used to assess the effect of mixing.

### **NATURAL POLYMERS**

Sodium alginate is a natural organic polymer extracted from brown seaweed. The polymeric structure of sodium alginate is comprised of mannuronic acid and glucuronic acid and the molecular weight is on the order of  $10^4$  to  $2 \times 10^5$  (Degrémont, 2007). Sodium alginate is particularly effective as a flocculant aid with ferric salts, and good results have also been obtained with aluminum salts, with typical dosages ranging from 0.5 and 2 mg/L. Chitosan, another natural organic, is obtained from chitin shells (crab, lobster, etc.). Natural starches are also classified as natural polymers. Starches can be obtained from a number of sources, including potatoes, tapioca, or plant seed extracts. Starches are branched and nonlinear glucopyranose polymers, which are sometimes partially broken down with  $\text{OH}^-$  or derivatized to form carboxy-ethyl-dextrose. Starches are used in concentrations of 1 to 10 mg/L, preferably together with aluminum salts.

A variety of chemicals and additives known as *coagulant aids* and *flocculant aids*, used to enhance coagulation and flocculation processes, are described below. Some of the commonly used inorganic coagulant aids are given in Table 9-4. Polymers used as flocculant aids are given in Table 9-7.

### **COAGULANT AIDS**

Coagulant aids, typically insoluble particulate materials, are added to enhance the coagulation process. Clay (bentonite, kaolinite), sodium silicate, pure precipitated calcium carbonate, diatomite, powdered activated

carbon (used as an adsorbent), and fine sand have all been used as coagulation aids. Coagulant aids are often added to waters that contain low concentrations of particles to form nucleating sites for the formation of larger flocs. Coagulant aids are used in conjunction with inorganic coagulants, organic polyelectrolytes, or both. Because the density of these particles is higher than that of most floc particles, the settling velocities of flocculated particles is increased.

#### FLOCCULANT AIDS

Uncharged and negatively charged organic polymers that were discussed in the previous section are used as flocculant aids as opposed to primary coagulants. As previously discussed, the main advantage of using flocculant aids is that a stronger floc is formed. Flocculant aids are added after the coagulants are added and the particles are already destabilized. The time required for destabilization depends on water temperature and the type of particles; consequently, jar tests have to be conducted. The important factors that need to be evaluated in jars and full-scale implementation are floc strength, size, and settling rate. It should be noted that improper dosing of flocculant aids can cause mudballs to form in gravity filters that are not easily eliminated by backwashing.

Activated silica is an important inorganic flocculant aid that is used in combination with alum and can be effective in cold water. It is usually stored as sodium silicate, which is soluble at high pH. Usually, the concentrated sodium silicate is partially neutralized (usually with sulfuric acid) prior to use and then added immediately to the water. In some instances, aluminosilicate is used where alum is the primary coagulant because the acidity of the alum can be used to activate the silica, and this will produce aluminum hydroxide floc and the  $\text{SiO}_2$  flocculant aid. A typical dosage is from 0.5 to 4 mg/L as  $\text{SiO}_2$ .

### Jar Testing for Coagulant Evaluation

Because of the many competing reactions and mechanisms that are operative in the coagulation process, the selection of coagulants and dosage is typically determined empirically using bench-scale and pilot-scale studies. The standard bench-scale testing procedure for determining coagulant doses and types is the “jar test” procedure. Developed originally by Langelier (1921) and refined over the years (see Black et al., 1957; Tekippe and Ham, 1970), jar testing permits rapid evaluation of a range of coagulant types and doses. A modern jar test apparatus is shown on Fig. 9-12. As shown on Fig. 9-12, the apparatus consists of six batch reactors, each equipped with a paddle mixer. Square-shaped jars are used to avoid vortex flow, which can occur if circular beakers are used.

#### JAR TEST PROCEDURE

The purpose of the jar test is to simulate, to the extent possible, the expected or desired conditions in the coagulation–flocculation facilities. Standard

**Figure 9-12**

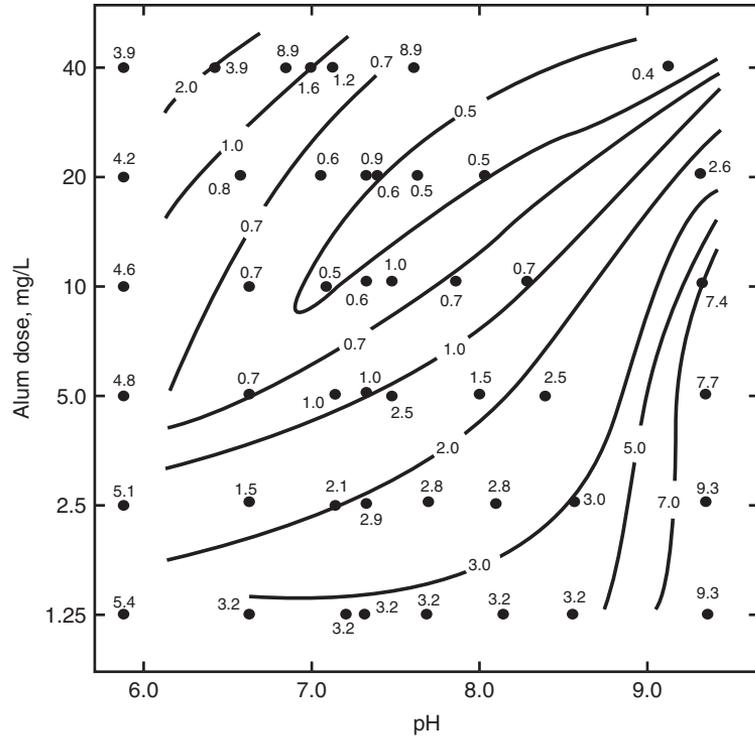

Jar test apparatus. Note use of square containers to limit the formation of vortex flow in which the particles rotate in the same position relative to each other.

jar testing procedures are available in Kawamura (2000), ASTM (2008), and AWWA (2011). Generally, the test consists of a rapid-mix phase (blending) with simple batch addition of the coagulant or coagulants followed by a slow-mix period to simulate flocculation. Flocs are allowed to settle and samples are taken from the supernatant. These parameters should be measured as part of the jar test routine: (1) turbidity or suspended solids removal; (2) NOM removal as measured by dissolved organic carbon (DOC) or a surrogate measure of dissolved NOM, such as UV at 254 nm; (3) residual dissolved coagulant concentrations of Fe or Al coagulants; and (4) sludge volume that is produced. If direct filtration is to be used, the filterability should be evaluated using a filterability test. The filterability is evaluated by filtering the mixed suspension through a 5- or 8- $\mu\text{m}$  laboratory filter to simulate a granular medium filter.

The results of a series of jar tests to determine the optimum alum dose and pH for turbidity removal for given water are summarized on Fig. 9-13. As shown on Fig. 9-13, the optimum alum dose and pH would be approximately 8 mg/L and 7, respectively, because the turbidity is minimized under these conditions. However, it must be emphasized that the raw-water particle concentration and NOM vary with water quality, and thus the optimum coagulant dosage also changes as the water quality changes.

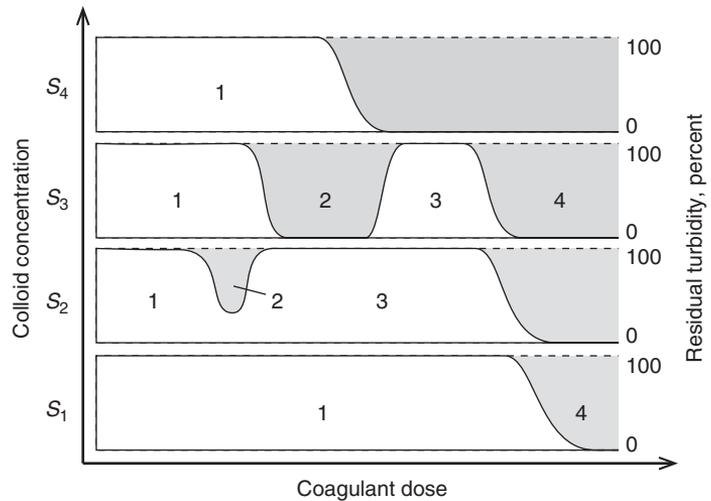

#### **ANALYSIS OF COAGULATION PROCESS USING JAR TEST PROCEDURE**

A conceptual diagram in which the residual turbidity from jar tests conducted for waters with different particle concentrations is illustrated on Fig. 9-14. The diagram on Fig. 9-14 applies to a limited pH range for the two coagulants: for alum, it is pH  $\sim$ 5.5 and for Fe it is pH  $\sim$ 5. If the pH

**Figure 9-13**

Turbidity topogram as function of pH and alum dosage. (Adapted from Trussell, 1978.) Points shown on the plot represent turbidity values and the isopleths represent constant turbidity at the value denoted on the isopleth.

**Figure 9-14**

Simulated residual turbidity remaining after jar tests as a function of particle and coagulant concentration for Al(III) or Fe(III) salts at constant pH. (Adapted from O'Melia, 1972.)

is higher, then no cationic metal ion species would be formed for charge neutralization. Furthermore, the impact of NOM on the coagulant dose has not been considered.

*Water with low concentration of particles*

For the lowest particle concentration,  $S_1$ , particles are removed by sweep flocculation (precipitation) because the concentration is too low for them to flocculate and settle. These particles are also destabilized by the hydrolysis products of the coagulant. The particle concentration  $S_1$  may be a good candidate for direct filtration or dissolved air flotation for liquid–solid separation.

*Water with moderate concentration of particles*

At a slightly higher particle concentration,  $S_2$ , some flocculation and settling occurs in zone 2, in which adsorption and charge neutralization occur. However, the concentration is too low for effective flocculation and a high degree of turbidity removal is not possible. Further, if more coagulant is added, the particles stabilize with a positive charge and the turbidity increases, as shown in zone 3. However, as the coagulant dosage is increased even further, sweep flocculation is again observed but at a lower coagulant concentration than for a particle concentration  $S_1$  because the particle concentration is higher, which allows for more effective flocculation and settling at a lower coagulant dosage.

*Water with high concentration of particles*

At a higher particle concentration,  $S_3$ , all four zones can clearly be found. Nearly complete removal by charge neutralization occurs in zone 2 and the particles stabilize at higher coagulant dosages. Sweep flocculation occurs in zone 4, and it occurs at lower coagulant dosages than for particle concentration  $S_2$  or  $S_1$ . Sweep flocculation occurs because a substantial portion of the floc volume comes from the particles, and this allows for effective flocculation at lower coagulant dosages.

*Water with very high concentration of particles*

For the highest particle concentration,  $S_4$ , the sweep floc and charge neutralization regions merge because the coagulant concentration required to neutralize the charges on the particles coincides with the onset of precipitation. Another noteworthy effect is that zone 2 starts at successively higher coagulant dosages as the particle concentration increases. As a result, the charge neutralization region is said to exhibit stoichiometry.

*Analysis of results*

By examining these results, it can be said that the addition of clays, such as bentonite, may be an effective coagulant aid for particle concentration  $S_2$  or

$S_1$ , if sedimentation is used for liquid–solid separation, because they would increase the floc volume, reduce the coagulant dosage, and increase the settling velocity. Jar testing and cost analysis would have to be conducted to examine the economic benefits that may result from such a strategy.

### **Alternative Techniques to Reduce Coagulant Dose**

In addition to the use of cationic polymers, several techniques have been evaluated to reduce the coagulant dose, including (1) preozonation and (2) the use of selective ion exchange resins, as discussed below.

#### **COAGULANT REDUCTION THROUGH USE OF OZONATION**

It has been reported that preozonation can be used to improve NOM removal in some instances; however, the results have proven to be quite variable.

For high DOC concentrations, the optimum coagulant dosage is dictated by the required DOC removal, and ozone dosages in the range of 0.1 to 2.0 mg/L do not appear to improve DOC or turbidity removal. In fact, ozonation at higher dosages (i.e., >2 mg/L) can be deleterious to DOC and turbidity removal for high DOC concentrations when using alum coagulation. It is likely that ozonation leads to the formation of more polar and reactive functional groups (e.g., carboxylic acid groups) in the DOC, and these react with aluminum hydroxide surfaces, increasing the coagulant demand.

At low DOC concentrations, there is some evidence that preozonation can reduce the required alum dosage. In this case, preozonation appears to affect adsorption of the DOC onto the particles in a beneficial way without increasing the reactive functional groups that in turn increase the coagulant demand. Although preozonation may be beneficial for low-DOC waters (especially when using direct filtration), it is likely that these situations will rarely occur, and it is better to coagulate and remove NOM before ozonating because this will reduce the ozone dose used for other purposes, such as disinfection.

The impact of ozonation on coagulant dosage using organic polymers is also quite variable. At high DOC levels and low to moderate turbidity, low dosages of ozone appear to improve DOC or turbidity removal and lower the coagulant dosage. Unfortunately, the DOC reduction decreases as ozone dose increases. It is likely that ozonation degrades the DOC into smaller polar compounds that cannot interact with most organic polymers and cannot be removed. Also, there are fewer large DOC molecules remaining to interact with the organic polymer. Because of the variable effects that have been reported, if preozonation is to be used, bench-scale and/or pilot plant testing will be required.

Additional information on ozonation, including equipment for ozone generation and ozone contactors, is presented in Chap. 13.

**COAGULANT REDUCTION THROUGH USE OF ION EXCHANGE RESINS**

Another approach that has been developed to reduce the coagulant dose involves the use of an ion exchange resin to remove the DOC (i.e., NOM) before the coagulant is added. The principal resin used for DOC removal, known as the MIEX DOC resin, was developed in Australia for use in water treatment. The specially developed resin beads, about 180  $\mu\text{m}$  in diameter, contain a magnetized component within their structure such that the resin beads act as weak individual magnets. Thus, in a sedimentation tank the magnetized resin beads readily aggregate and settle rapidly. The MIEX process is described in more detail in Chap. 16.

## 9-5 Coagulation of Dissolved Constituents

---

While the original objective of coagulation was to remove suspended particles from water, it can also be useful in removing natural organic matter and some dissolved inorganic constituents. This section discusses the impact of natural organic matter on the coagulation process and the removal of dissolved constituents by coagulation, including the process known as enhanced coagulation.

Natural organic matter (NOM), as described in Chap. 2, is the term used to describe the complex matrix of organics originating from natural sources that are present in all water bodies. Hydrophilic in nature, the constituents that comprise NOM (e.g., low-molecular-weight acids, amino acids, proteins and polysaccharides, fulvic and humic acids) have a wide range of molecular weights. In the literature, the concentration of NOM in water has been measured as total organic carbon (TOC), DOC, and  $\text{UV}_{254}$  absorbance. Dissolved organic carbon is the fraction of TOC remaining in solution after filtering the water through a 0.45- $\mu\text{m}$  filter. The particulate fraction of NOM is easily removed from water following coagulation because particulate NOM is destabilized in the same way that inorganic particles are destabilized. The dissolved fraction of NOM, however, also interacts with coagulants and can complicate efforts to determine the correct coagulant dose for turbidity removal.

It has been observed that dissolved NOM reacts or binds with metal ion coagulants, and some evidence suggests that the coagulant dosages at many, if not most, operating plants are determined by the dissolved NOM–metal ion interactions and not particle–metal ion interactions (O'Melia et al., 1999). No quantitative relationships about coagulant dosages for turbidity removal have been developed because solution conditions that affect dosage and effectiveness of coagulants—such as pH, hardness, and temperature—also affect the speciation of NOM. However, qualitatively, as pH increases, NOM becomes more ionized because the carboxyl groups lose protons, and the positive charge on metal coagulants will decrease.

**Effects of NOM  
on Coagulation  
for Turbidity  
Removal**

Consequently, higher coagulant dosages will be required at higher pH values. At neutral pH, the amount of positively charged coagulant (Al or Fe) species decreases with increasing temperature and a higher coagulant dosage may be required.

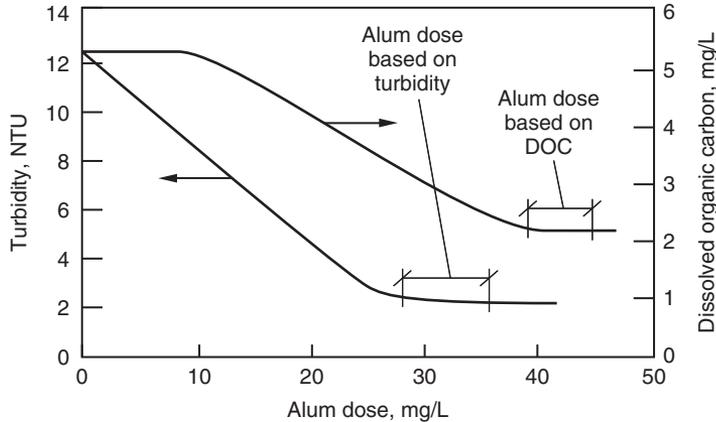

### Enhanced Coagulation

As discussed in Chap. 19, disinfection by-products (DBPs) are formed as a result of chemical reactions between chlorine and NOM. While trihalomethanes (THMs) and haloacetic acids (HAAs) are the primary DBPs that form during chlorination, the DBP regulations in the United States recognize that MCLs for specific DBPs may not address the total risk associated with adding chlorine to water containing NOM. Consequently, the regulations include a treatment technique that requires the removal of NOM prior to disinfection under certain conditions. The process of performing coagulation for the purpose of achieving specified removal of DBP precursors (NOM) is known as *enhanced coagulation*. The treatment technique uses a TOC removal requirement because TOC is a practical measure for the amount of NOM in water. The TOC removal requirements range from 15 to 50 percent removal depending on the raw water TOC and alkalinity at the specific site. Utilities can meet the treatment technique without practicing enhanced coagulation by meeting one of several alternate compliance criteria, which depend on factors such as raw or finished water TOC concentrations, specific UV absorbance (SUVA) values, disinfectant usage, and other factors. Specific requirements associated with enhanced coagulation are described in the Stage 1 D/DBP Rule (U.S. EPA, 1998) and the Enhanced Coagulation Guidance Manual (U.S. EPA, 1999).

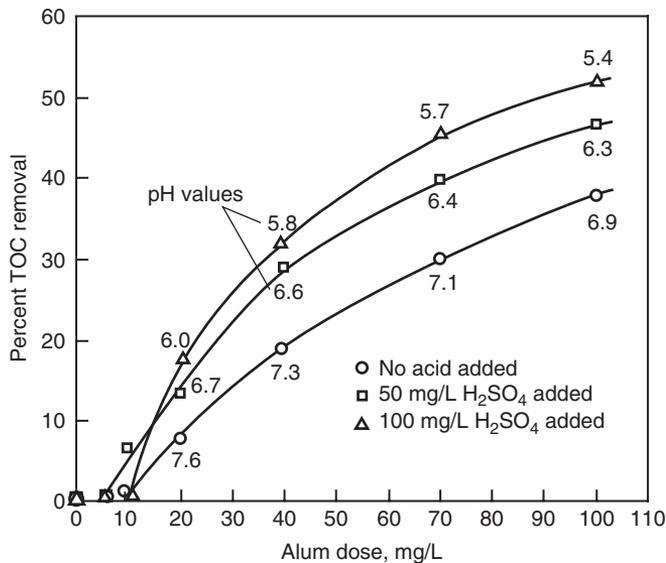

Coagulation tends to preferentially remove the higher-MW, more hydrophobic fractions of NOM (White, et al. 1997). Fortunately, the portion of NOM preferentially removed by enhanced coagulation tends to correspond to the fraction that preferentially forms DBPs; the hydrophobic fraction of NOM typically forms more DBPs than the hydrophilic fraction (Kavanaugh, 1978).

The dose required to achieve enhanced coagulation is typically higher than the dose for turbidity removal. Typical results from flocculation and sedimentation jar tests are shown on Fig. 9-15. As shown on Fig. 9-15, when turbidity and DOC removals are plotted as a function of coagulant dose, the DOC coagulant demand and the required degree of DOC removal for enhanced coagulation, not turbidity, will usually dictate the coagulant dosage. Of the metal salts and prehydrolyzed metal salts, the most effective for the removal of NOM is typically iron, followed by alum and PACl (see Table 9-6).

The previous section noted that the solubility of coagulants is dependent on pH; the minimum solubility of alum precipitate is around a pH of 6.3 at 25°C. As a result, the optimum NOM removal with alum is at a pH ranging from 5.5 to 6.5, depending on the water temperature and total dissolved solids (TDS) concentration. Removal of NOM with alum can also

**Figure 9-15**

Residual turbidity and dissolved organic matter as function of alum dose.

**Figure 9-16**

Removal of NOM with alum in bench-scale jar tests (data from of the Elsinore Valley Municipal Water District). (Untreated water quality: Temperature = 20°C, TOC = 9 mg/L, alkalinity = 160 mg/L as CaCO<sub>3</sub>, turbidity = 3.8 NTU.)

occur at higher pH values, but higher alum doses are required to meet the same NOM removal that can be achieved at optimum pH. In instances of high-pH conditions at the point of coagulation, acid addition to lower the pH can help improve NOM removal.

The impact of pH on NOM removal is shown on Fig. 9-16. In this study, three scenarios of NOM removal with alum from a natural water sample were investigated in bench-scale jar tests. The three scenarios were (1) without preaddition of sulfuric acid, (2) with preaddition of 50 mg/L sulfuric acid, and (3) with preaddition of 100 mg/L sulfuric acid. Without acid addition to this water, an alum dose of about 90 mg/L was required

to achieve 35 percent reduction in the TOC concentration (resulting in a settled-water pH of about 7.0). With the addition of 50 mg/L sulfuric acid, the alum dose required to achieve the same TOC reduction was about 60 mg/L (with a settled-water pH of about 6.5), a 33 percent reduction in coagulant usage.

Using pH adjustment for NOM removal has a number of consequences that need to be considered before pH adjustment is adopted by a water treatment plant. These consequences include:

- A lower alum dose, which will reduce the amount of sludge produced at the plant.
- A lower settled-water pH, which will require a substantially higher dose of an alkaline chemical (such as lime or sodium hydroxide) to raise the pH of the finished water to acceptable levels (in the range of 8 to 8.5).
- The high doses of acid and caustic will increase the TDS concentration in the finished water.
- Costs associated with pH adjustment.

One potential problem associated with the use of a high alum dosage, sulfuric acid, and the resulting low pH is the residual aluminum ion in the settled water. Accordingly, the residual aluminum ion must be monitored to ensure that it does not exceed the MCL.

### Determination of Coagulant Dose for DOC Removal

Edwards (1997) developed an empirical model to estimate DOC removal during enhanced coagulation. The model was based on 21 water sources coagulated with ferric salts (250 jar tests) and 39 water sources coagulated with alum (608 jar tests). The model assumes that DOC is composed of adsorbable and nonadsorbable fractions. A portion of the adsorbable DOC adsorbs to the floc and the rest remains in solution after coagulation in accordance with an adsorption isotherm. Accordingly, the DOC remaining in solution after coagulation is the sum of the nonadsorbable DOC and the adsorbable DOC that is not adsorbed and is given by the expression

$$\text{DOC}_f = \text{DOC}_{\text{na}} + \text{DOC}_{a,f} \quad (9-17)$$

where  $\text{DOC}_f$  = final DOC concentration, mg/L  
 $\text{DOC}_{\text{na}}$  = nonadsorbable DOC concentration, mg/L  
 $\text{DOC}_{a,f}$  = adsorbable DOC remaining in solution after coagulation, mg/L

Edwards found a linear relationship between the nonadsorbable fraction of DOC and the SUVA of the influent water, which is  $\text{UV}_{254}$  absorbance of the water divided by the DOC:

$$(\text{SUVA})_i = (100) \left( \frac{\text{UV}_{254,i}}{\text{DOC}_i} \right) \quad (9-18)$$

where  $(\text{SUVA})_i$  = specific UV absorbance of influent water, L/mg·m  
 $\text{DOC}_i$  = influent DOC concentration, mg/L  
 $\text{UV}_{254,i}$  = influent  $\text{UV}_{254}$  absorbance,  $\text{cm}^{-1}$

The nonadsorbable DOC is determined from the expression

$$\text{DOC}_{\text{na}} = \text{DOC}_i \times [K_1 (\text{SUVA})_i + K_2] \quad (9-19)$$

where  $K_1, K_2$  = empirical constants from Table 9-8

The equilibrium between the amounts of adsorbable DOC that adsorb and remain in solution is described by a Langmuir isotherm:

$$q = \frac{Q_M b (\text{DOC}_{a,f})}{1 + b (\text{DOC}_{a,f})} \quad (9-20)$$

$$Q_M = x_3 (\text{pH})^3 + x_2 (\text{pH})^2 + x_1 (\text{pH}) \quad (9-21)$$

where  $q$  = DOC adsorbed at equilibrium, mg DOC/mmol of  $\text{Al}^{3+}$  or  $\text{Fe}^{3+}$  added (the adsorbent is the floc that forms after the coagulant is added)

$Q_M$  = total adsorbent capacity at monolayer coverage, mg DOC/mmol of  $\text{Al}^{3+}$  or  $\text{Fe}^{3+}$  added

$x_1, x_2, x_3$  = empirical constants from Table 9-8, unitless

pH = coagulation pH

$b$  = Langmuir equilibrium constant from Table 9-8, L/mg DOC

A mass balance is used to relate the fate of each portion of the initial DOC (i.e., at equilibrium, the initial DOC is divided between the nonadsorbable

**Table 9-8**

Summary of best-fit model coefficients for DOC removal with iron and aluminum

Parameter	DOC Model Coefficients	
	Iron	Aluminum
Standard error, mg/L	0.47	0.4
Standard error, %	9.3	9.5
90% confidence, %	±21	±21
$x_3$	4.96	4.91
$x_2$	-73.9	-74.2
$x_1$	280	284
$K_1$ , mg · m/L	-0.028	-0.075
$K_2$	0.23	0.56
$b$ , L/mg	0.068	0.147

Source: Adapted from Edwards (1997).

fraction, the adsorbable fraction that is not adsorbed, and the adsorbable fraction that is adsorbed):

$$\text{DOC}_i = \text{DOC}_{\text{na}} + \text{DOC}_{\text{af}} + q(M) \quad (9-22)$$

where  $M = \text{Al}^{3+}$  or  $\text{Fe}^{3+}$  added as coagulant, mmol/L (mM)

Substituting Eqs. 9-19 and 9-20 into Eq. 9-22 and rearranging algebraically reveals a quadratic equation that can be solved for the  $\text{DOC}_{\text{af}}$  concentration:

$$(\text{DOC}_{\text{af}})^2 + B(\text{DOC}_{\text{af}}) + C = 0 \quad (9-23)$$

where  $B$  and  $C$  are defined as

$$B = Q_M M + \frac{1}{b} - \text{DOC}_i + \text{DOC}_{\text{na}} \quad (9-24)$$

$$C = \frac{\text{DOC}_{\text{na}} - \text{DOC}_i}{b} \quad (9-25)$$

The adsorbable DOC remaining in solution is then found as the positive root (because concentration cannot be negative) of the quadratic equation

$$\text{DOC}_{\text{af}} = \frac{-B + \sqrt{B^2 - 4C}}{2} \quad (9-26)$$

The total DOC remaining after coagulation is calculated with Eq. 9-17. The DOC removal model can be used to plan jar tests for a water supply and assess how much DOC may be removed using coagulation. The trihalomethane formation potential (THMFP) reductions, which typically have to be determined from testing, can be estimated from the DOC remaining in solution. The model parameters and associated statistics shown in Table 9-8 were determined for iron and aluminum coagulation. The accuracy of the model can be improved by calibrating it to a specific site by determining actual nonadsorbable DOC or other parameters (Edwards, 1997).

This model is appropriate for preliminary evaluation to determine the proper coagulant dose and pH for enhanced coagulation. Jar testing can be used to provide more site-specific information prior to design, and more detailed investigation (i.e., pilot testing) may also be appropriate depending on the size of the facility and the NOM removal requirements. The use of this model to determine DOC remaining after enhanced coagulation is demonstrated in Example 9-3.

### Example 9-3 Removal of DOC by enhanced coagulation

Predict the DOC removal using an alum dose of 30 mg/L for the following conditions: initial DOC = 4.0 mg/L, initial UV<sub>254</sub> absorbance = 0.1 cm<sup>-1</sup>, and pH 7.

#### Solution

1. Calculate the molar concentration of Al<sup>3+</sup> added with 30 mg/L alum [Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> · 14H<sub>2</sub>O, formula weight 594 g/mol; see also Example 9-2].

$$[\text{Al}^{3+}] = 30 \text{ mg/L alum} \left( \frac{2 \text{ mmol Al}^{3+}}{594 \text{ mg alum}} \right) = 0.10 \text{ mmol/L Al}^{3+}$$

2. Calculate the specific UV absorbance using Eq. 9-18.

$$(\text{SUVA})_i = (10^2 \text{ cm/m}) \left( \frac{0.1 \text{ cm}^{-1}}{4.0 \text{ mg/L}} \right) = 2.5 \text{ L/mg} \cdot \text{m}$$

3. Calculate the nonadsorbable DOC using Eq. 9-19 and model parameters from Table 9-8.

$$\text{DOC}_{\text{na}} = 4.0 \text{ mg/L} [-0.075 (2.5 \text{ L/mg} \cdot \text{m}) + 0.56] = 1.49 \text{ mg/L}$$

4. Calculate the total adsorbent capacity using Eq. 9-21 and model parameters from Table 9-8.

$$Q_M = 4.91 (7)^3 - 74.2 (7)^2 + 284 (7) = 36.33 \text{ mg DOC/mmol Al}^{3+}$$

5. Calculate the quadratic coefficients *B* and *C* using Eqs. 9-24 and 9-25.

$$B = (36.33 \text{ mg/mmol}) (0.1 \text{ mmol/L}) + \frac{1}{0.147 \text{ L/mg}} - 4.0 \text{ mg/L}$$

$$+ 1.49 \text{ mg/L} = 7.926 \text{ mg/L}$$

$$C = \frac{1.49 \text{ mg/L} - 4.0 \text{ mg/L}}{0.147 \text{ L/mg}} = -17.07 \text{ mg}^2/\text{L}^2$$

6. Calculate the adsorbable DOC remaining in solution using Eq. 9-26.

$$\text{DOC}_{\text{a,f}} = \frac{-7.926 \text{ mg/L} + \sqrt{(7.926 \text{ mg/L})^2 - 4(-17.07 \text{ mg}^2/\text{L}^2)}}{2}$$

$$= 1.76 \text{ mg/L}$$

7. Calculate the total DOC remaining in solution using Eq. 9-17.

$$\text{DOC}_f = 1.49 + 1.76 = 3.25 \text{ mg/L}$$

8. Calculate the DOC removal and percent removal.

$$\text{DOC removal} = \text{DOC}_i - \text{DOC}_f = 4.0 - 3.25 = 0.75 \text{ mg/L}$$

$$\text{Percent DOC removal} = \frac{0.75 \text{ mg/L}}{4.0 \text{ mg/L}} \times 100 = 19\%$$

### Removal of Dissolved Inorganics

The coagulation process can sometimes effectively be used to remove dissolved constituents such as arsenic, lead, iron, manganese, and uranium (see Table 20-1). For example, coagulants such as alum, ferric chloride, and ferric sulfate have been used to remove arsenic. A detailed discussion of the coagulation process applied to the removal of selected dissolved constituents is discussed in Chap. 20.

## 9-6 Flocculation Theory

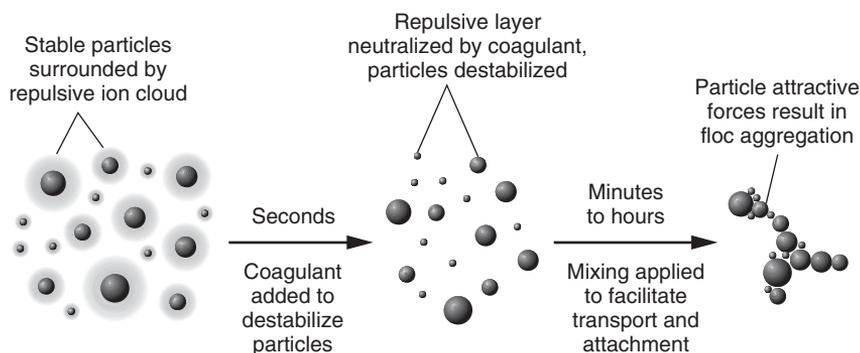

Flocculation theories have evolved from the following observations: (1) small particles undergo random Brownian motion due to collisions with fluid molecules resulting in particle–particle collisions (Smoluchowski, 1917) and (2) stirring water containing particles creates velocity gradients that bring about particle collisions (Langelier, 1921). An understanding of the theory of flocculation may be used to provide insight into process design and operation, which are discussed in the next section. For example, the theory can be used to assess the importance of mixing and what particle sizes would flocculate as a result of mixing. The three prevailing models used to describe the flocculation process are (1) spherical particles in a linear flow field, (2) spherical particles in a nonlinear flow field, and (3) fractal-based models. The main differences between the flocculation models are the rate and manner in which particles are predicted to grow in size as a result of flocculation.

### Mechanisms of Flocculation

The action of flocculation depends on the characteristics of the particles as well as the fluid-mixing conditions. The addition of a coagulant to water containing small particles causes the particulates to become destabilized and begin flocculating. The mechanisms of particle flocculation are described below. A schematic of the processes controlling the rate of particulate aggregation during coagulation and flocculation is shown on Fig. 9-17.

#### MICROSCALE (PERIKINETIC) FLOCCULATION

The rate of flocculation of small particles is relative to the rate at which particles diffuse toward one another (Smoluchowski, 1917). Thus, for small particles (less than 0.1  $\mu\text{m}$ ), the primary mechanism of aggregation

**Figure 9-17**  
Schematic illustrating the progression of the particle aggregation process.

is Brownian motion, or microscale flocculation. Microscale flocculation is also known as perikinetic flocculation. As aggregation of small particles proceeds, larger particles are formed. After a short time (seconds), microflocs ranging in size from 1 to about 100  $\mu\text{m}$  are formed (Argaman and Kaufman, 1970).

#### MACROSCALE (ORTHOKINETIC) FLOCCULATION

The major mechanism for flocculation in water treatment for particles larger than about 1  $\mu\text{m}$  is the gentle mixing of the water, typically with mechanical mixers. The mixing causes velocity gradients that causes collisions between suspended particles (Langelier, 1921), known as macroscale flocculation or orthokinetic flocculation. During the mixing processes in macroscale flocculation, however, the particle flocs are subjected to shear forces, resulting in erosion and disruption of some of the floc aggregates, or floc breakup. After some period of mixing, a steady-state floc size distribution is reached, and the formation and breakup of floc particles is roughly equal (Parker et al., 1972). The rate at which the steady-state size distribution is achieved, as well as the form of the size distribution, will depend upon the hydrodynamics of the system and the chemistry of the coagulant–particulate interactions.

#### DIFFERENTIAL SETTLING

Aggregation and growth of flocs can result from particles settling at different velocities. As large particles are formed, they begin to settle due to gravitational forces. The velocity of particles of similar densities settling in a water column is proportional to the square of their size. Differences in settling velocities cause particles with size and/or density differences to collide and flocculate. Thus, differential particle settling occurs in heterogeneous suspensions (differing particle sizes) during sedimentation, providing an additional mechanism for promoting flocculation. For suspensions containing a wide range of particle sizes, differential sedimentation can be a significant flocculation mechanism (O'Melia, 1978). Flocculation

by differential settling will not have an impact on direct filtration, dissolved air flotation (DAF), or high-rate sedimentation processes such as inclined plates because settling distances or times are too short.

### Particle Collisions

The fundamental problem in mathematical modeling of the flocculation process is predicting the change of the particle size distribution as a function of time for a given set of chemical and hydrodynamic conditions. Any general kinetic model must account for changes in the number of particles found in all size classes. Particles of size  $d_i$  collide with particles of size  $d_j$ , forming particles of size  $d_k$  when collisions are successful. At the same time, aggregates of size  $d_k$  may break up into smaller aggregates due to hydrodynamic shearing forces.

#### RATE OF PARTICLE COLLISION

The overall particle collision rate is a function of the rate of macroscale flocculation ( $r_M$ ), rate of microscale flocculation ( $r_\mu$ ), and rate of differential settling flocculation ( $r_{DS}$ ) between particles  $i$  and  $j$ .

The rate of particle attachments  $r_{ij}$  is a function of the particle concentrations and a collision frequency function  $\beta_{ij}$ :

$$r_{ij} = \alpha \beta_{ij} n_i n_j \quad (9-27)$$

where  $r_{ij}$  = rate of attachment between  $i$  and  $j$  particles  
 $\alpha$  = collision efficiency factor (attachments per collision)  
 $\beta_{ij}$  = collision frequency function for particles of  $i$  and  $j$  size classes (rate constant for collisions between particles)  
 $n_i$  = concentration of  $i$  particles  
 $n_j$  = concentration of  $j$  particles

The collision efficiency factor  $\alpha$ , defined as the ratio of collisions that result in attachment to total collisions, has a range of values between  $0 \leq \alpha \leq 1$ . The collision efficiency factor depends on the effectiveness of destabilization; for example, if particles have been destabilized completely, then  $\alpha = 1$ . Solution of mass balances on flocculation reactors that use Eq. 9-27 require the use of appropriate values of  $\beta$  to predict the change in the size distribution of the suspension as aggregation occurs (Lawler et al., 1980).

#### COLLISION FREQUENCY FUNCTION

The collision frequency function  $\beta_{ij}$  depends on the size of the particles, the flocculation transport mechanism, and the efficiency of particulate collisions. The overall collision frequency function is a function of the three individual mechanisms of flocculation as follows:

$$\beta_{ij} = \beta_M + \beta_\mu + \beta_{DS} \quad (9-28)$$

where  $\beta_{ij}$  = overall collision frequency between particles  $i$  and  $j$   
 $\beta_M$  = macroscale collision frequency, =  $r_M / \alpha n_i n_j$

- $\beta_{\mu}$  = microscale collision frequency, =  $r_{\mu}/\alpha n_i n_j$   
 $\beta_{DS}$  = differential settling collision frequency, =  $r_{DS}/\alpha n_i n_j$   
 $r_M$  = rate of attachment due to macroscale collisions  
 $r_{\mu}$  = rate of attachment due to microscale collisions  
 $r_{DS}$  = rate of attachment due to differential setting

The development of the equations used to model the collision frequency factor for the various flocculation mechanisms is presented in the following discussion for spherical particles in a linear flow field.

#### OVERALL RATE OF PARTICLE COLLISION

The formation rate of aggregates in size class  $d_k$  is the sum of all collisions between  $i$  and  $j$  particles minus the subsequent disappearance of aggregates from the  $k$  size class due to collisions with other (e.g.,  $i$  and  $j$ ) particles. The general model for aggregation, assuming no particle breakup, is given as follows (Swift and Friedlander, 1964):

$$r_k = \frac{1}{2} \alpha \sum_{j=1; i+j=k}^{j=k-i} \beta_{ij} n_i n_j - n_k \alpha \sum_{i=1}^N \beta_{ik} n_i \quad (9-29)$$

- where  $r_k$  = net formation rate of  $k$ -sized particles  
 $n_k$  = concentration of  $k$ -sized particles  
 $\beta_{ik}$  = collision frequency function for particles of size classes  $i$   
 and  $k$   
 $N$  = total number of  $n_i$  particles

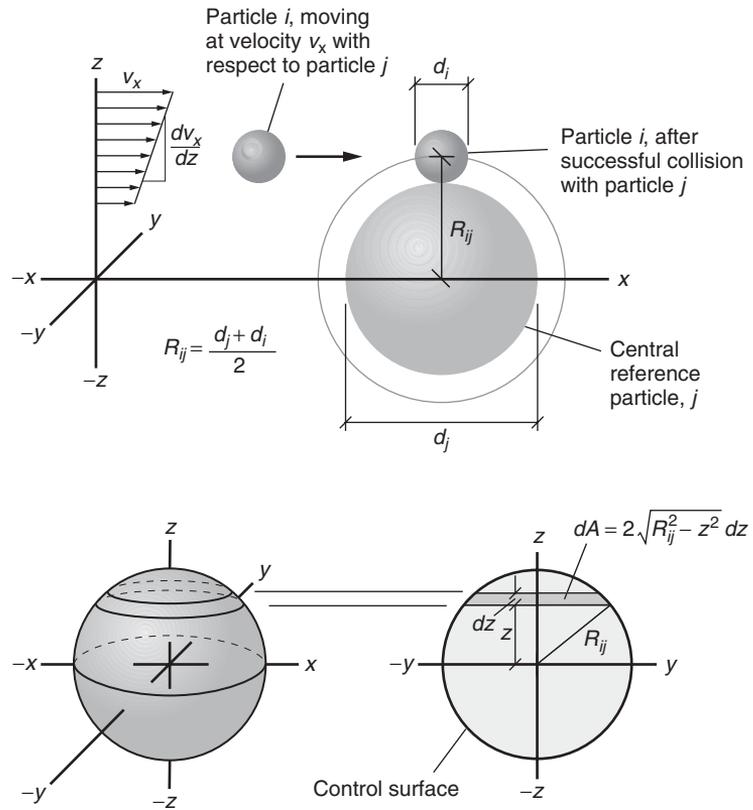

Mathematical expressions of the collision functions are derived below by considering the various flocculation mechanisms. An empirical model for particle breakup is discussed after particle formation theories.

In the linear flow field model, it is assumed that particles agglomerate as spheres and that the total floc volume fraction does not change with time. An analogy is agglomeration of small drops of oil into larger droplets in which the total volume of oil does not change. Linear flow field models for flocculation of spherical particles by macroscale, microscale, and differential sedimentation mechanisms are discussed below.

### Flocculation of Spherical Particles

#### MACROSCALE FLOCCULATION OF SPHERICAL PARTICLES IN LINEAR FLOW FIELD

Consider particles  $i$  and  $j$  with diameters  $d_i$  and  $d_j$ , respectively, suspended in and moving in fluid streamlines in the  $x$  direction with water subjected to a velocity gradient  $dv_x/dz$ , as shown on Fig. 9-18. When the distance between the centers of the particles,  $R_{ij}$ , becomes equal to  $(d_i + d_j)/2$ , a collision will occur.

**Figure 9-18**  
Definition sketch for analysis of the flocculation process.

#### *Velocity gradients*

When fluid flow is laminar and steady, the velocity gradients are well defined, as shown on Fig. 9-18. The velocity gradient on Fig. 9-18 is proportional to the shear stress on the fluid elements because it is a Newtonian fluid. Given a uniform velocity gradient, the rate of flocculation can be determined from geometric considerations, as illustrated below.

#### *Rate of flocculation of heterodisperse particles*

The rate of macroscale flocculation in a system of unequal size (heterodisperse) particles subjected to uniform mixing may be derived using the relationships shown on Fig. 9-18. The flow rate of fluid into an area element  $dA$  of the control surface is given by the following expression (Swift and Friedlander, 1964; Smoluchowski, 1917):

$$dq = (\text{velocity}) (\text{differential area}) = \left( z \frac{dv_x}{dz} \right) \left( 2\sqrt{R_{ij}^2 - z^2} dz \right) \quad (9-30)$$

where  $dq$  = differential flow of fluid through area element  $dA$ ,  $m^3/s$   
 $q$  = fluid flow rate through particle area projected onto  $y$ - $z$   
 plane,  $m^3/s$   
 $z$  = vertical direction,  $m$   
 $dv_x/dz$  = velocity gradient in  $x$  direction,  $s^{-1}$   
 $R_{ij}$  = distance between centers of particles  $i$  and  $j$ ,  $m$

In a heterogeneous solution, the flow rate of particles through the control area may be expressed as the product of the  $i$  and  $j$  particle concentrations ( $n_i$  and  $n_j$ , respectively) and the differential flow of fluid through the control surface. Assuming that the velocity gradient is constant,

$$\begin{aligned} \text{Particle flow through control surface} &= 2n_i n_j \int_{z=0}^{z=R_{ij}} dq \\ &= 4n_i n_j \left( \frac{dv_x}{dz} \right) \int_0^{R_{ij}} z \sqrt{R_{ij}^2 - z^2} dz \end{aligned} \quad (9-31)$$

Recalling from calculus that

$$\int x \sqrt{a^2 - x^2} dx = -\frac{1}{3} (a^2 - x^2)^{3/2} + c,$$

the integrated form of Eq. 9-31 is given by the expression

$$\begin{aligned} \text{Particle flow} &= 4n_i n_j \left( \frac{dv_x}{dz} \right) \left[ -\frac{1}{3} (R_{ij}^2 - z^2)^{3/2} \right]_0^{R_{ij}} \\ &= \frac{4}{3} \left( \frac{dv_x}{dz} \right) R_{ij}^3 n_i n_j \end{aligned} \quad (9-32)$$

The rate of flocculation is equal to the flow rate of particles times the collision efficiency  $\alpha$  (i.e., fraction of collisions that result in attachment):

$$r_{ij} = \frac{4}{3} \left( \frac{dv_x}{dz} \right) R_{ij}^3 n_i n_j \alpha \quad (9-33)$$

where  $r_{ij}$  = rate of collision between  $i$  and  $j$  particles (rate of flocculation)

Substituting the term  $(d_i + d_j)/2$  for  $R_{ij}$  (see Fig. 9-18) results in the following expression for the rate of flocculation, by macroscale mechanisms, between  $i$ - and  $j$ -sized particles:

$$r_M = \frac{1}{6} \left( \frac{dv_x}{dz} \right) (d_i + d_j)^3 n_i n_j \alpha \quad (9-34)$$

where  $r_M$  = rate of macroscale flocculation (sometimes referred to as  $J_m$ )

Under turbulent-flow conditions, the velocity gradient is not well defined and varies both in time and space throughout the flocculation basin. When averaged over the entire basin, the velocity gradient is known as the root-mean-square (RMS) velocity gradient and is given the symbol  $\bar{G}$  (see Sec. 6-10 and Eqs. 6-139 and 6-140).

Thus, for unequal-sized (heterodisperse) particles the collision frequency function for the macroscale flocculation rate  $\beta_M$  can be computed using Eq. 9-34 and the relationship given in the nomenclature for Eq. 9-28, resulting in

$$\beta_M = \frac{1}{6} \bar{G} (d_i + d_j)^3 \quad (9-35)$$

where  $\bar{G}$  = RMS velocity gradient,  $s^{-1}$

#### *Rate of flocculation of monodisperse particles*

When the suspension is heterodispersed, with a wide size distribution, the rate of aggregation is increased (Swift and Friedlander, 1964). Thus, the kinetic model for monodispersed suspensions is relatively conservative. The monodisperse system, initially composed of only particles with size  $d_i$  at concentration  $n_i$ , may be considered as a special case where each particle can serve as a central particle. Therefore, the net rate of aggregation is obtained by substituting  $n_i^2/2$  for  $n_i n_j$  in Eq. 9-33, as given by Eq. 9-36. The  $n_i^2$  term is divided by 2 to reflect the fact that one-half of the particles serve as central particles:

$$r_M = \frac{4}{3} \left( \frac{dv_x}{dz} \right) R_{ij}^3 n_i n_j \alpha = \frac{4}{3} \left( \frac{dv_x}{dz} \right) d_i^3 \frac{n_i^2}{2} \alpha = \frac{2}{3} \bar{G} d_i^3 n_i^2 \alpha \quad (9-36)$$

If the particles agglomerate with no void volume (e.g., Euclidean objects, coalescing oil droplets), the floc volume  $\Omega$  is time invariant because it only depends on the total number of particles initially present. Consequently, Eq. 9-36 is actually pseudo-first order (i.e., depends only on the number concentration to the first power) because the term  $n_i d_i^3$  is related to  $\Omega$ , a fixed quantity, as described below. The floc volume is given by

$$\Omega = \frac{\pi d_i^3 n_i}{6} \quad (9-37)$$

where  $\Omega$  = floc per unit of solution volume,  $cm^3/L$  ( $cm^3/10^3 cm^3$ )  
 $d$  = particle diameter,  $cm$   
 $n_i$  = number concentration of particles,  $L^{-1}$

Rearranging Eq. 9-37 for substitution into Eq. 9-36,

$$n_i d^3 = \frac{6\Omega}{\pi} \quad (9-38)$$

Substituting Eq. 9-38 into Eq. 9-36 results in the following equation for the rate of flocculation of a monodisperse system:

$$r_M = \frac{4\Omega \bar{G} \alpha n_i}{\pi} \quad (9-39)$$

Thus, the macroscale flocculation rate for a monodispersed suspension is a first-order rate expression with respect to  $n_i$ , and the rate constant is directly proportional to the velocity gradient and the floc volume fraction.

*Rate correction for turbulent conditions*

In practice, fluid flow in most flocculation units is turbulent. Under turbulent conditions, the velocity gradient is not well defined and will vary locally in the flocculation unit. As discussed in Sec. 6-10, Camp and Stein (1943) developed an expression relating  $\bar{G}$  to mixing power (see Eq. 6-140) by equating the velocity gradients to the power dissipated per unit volume ( $P/V$ ) for uniform shear flow:

$$\bar{G} = \sqrt{\frac{P}{\mu V}} \quad (9-40)$$

where  $\bar{G}$  = RMS velocity gradient,  $s^{-1}$   
 $P$  = power of mixing input to flocculation basin, W (note 1 W =  $1 \text{ kg}\cdot\text{m}^2/\text{s}^3$ )  
 $V$  = volume of flocculation basin,  $\text{m}^3$   
 $\mu$  = dynamic viscosity of water,  $\text{kg}/\text{m}\cdot\text{s}$

In turbulent flow, the rate of aggregation for particles smaller than the Kolmogorov eddy size (see Eq. 6-136) is approximately the same as it is for laminar flow because flow within eddies is laminar. Using this argument, the flocculation rate for turbulent shear should be similar to the rate for laminar flow. While this may be true in theory, it has been found that the rate is much higher due to interactions between eddies (Logan, 1999). Consequently, the rate becomes proportional to  $\bar{G}$  (Harris et al., 1966), and an empirical rate constant must be employed, shown below for the monodisperse system:

$$r_{M,T} = K_A \bar{G} \Omega n_i \quad (9-41)$$

where  $r_{M,T}$  = rate of flocculation for turbulent flow  
 $K_A$  = empirical aggregation constant

The aggregation constant depends on system chemistry, the heterogeneity of the suspension, and variations in the scale and intensity of turbulence, which are not incorporated in the velocity gradient. Because of the different flow patterns and distributions of velocity gradients promoted by various mixing devices,  $K_A$  must be determined experimentally.

### Example 9-4 Time needed for macroscale flocculation

Calculate the time required to reduce the number of particles by 50 percent under laminar conditions for macroscale flocculation, assuming first-order kinetics, for 10- $\mu\text{m}$  particles. Assume the initial particle concentration is 10,000/mL,  $\bar{G} = 60 \text{ s}^{-1}$ , and  $\alpha = 1.0$ .

#### Solution

1. Determine the volume fraction of particles using Eq. 9-37. Note  $10 \mu\text{m} = 10^{-3} \text{ cm}$ .

$$\Omega = \frac{\pi d_i^3 n_i}{6} = \frac{\pi (10^{-3} \text{ cm})^3 (10^4 / \text{mL})}{6} = 5.2 \times 10^{-6}$$

2. For first-order kinetics, Eq. 9-38 may be written as

$$\frac{dn_i}{dt} = -r_M = -kn_i \quad \text{where} \quad k = \frac{4\Omega\bar{G}\alpha}{\pi}$$

3. Integrating the above expression yields

$$n_i = n_0 e^{-kt}$$

where  $n_0$  = initial particle concentration

4. Determine the time needed to achieve 50 percent particle reduction using the equation for half-life:

$$\begin{aligned} t_{1/2} &= \frac{\ln(0.5n_0/n_0)}{k} = \frac{-\pi \ln(0.5)}{4\alpha\Omega\bar{G}} \\ &= \frac{-\pi \ln(0.5) (1 \text{ min}/60 \text{ s})}{4(1)(5.2 \times 10^{-6})(60/\text{s})} = 28.9 \text{ min} \end{aligned}$$

#### MICROSCALE FLOCCULATION OF SPHERICAL PARTICLES

The flux of  $j$ -size particles to the surface of a single  $i$ -size particle by diffusion is given by the expression

$$J_A = -D_{ij} \left( \frac{\partial n_j}{\partial r} \right)_{r=d_i/2} = \frac{-2D_{ij}n_j}{d_i} \quad (9-42)$$

where  $J_A$  = flux of particles,  $\text{m} \cdot \text{number of particle/s}$ .

$D_{ij}$  = liquid-phase diffusion coefficient for particle  $j$  to particle  $i$ ,  $\text{m}^2/\text{s}$

Thus, the flocculation rate  $r_{\mu,j}$  is given by the expression

$$r_{\mu,j} = \text{sphere surface area} \times \text{flux} = (\pi d_i^2) \left( \frac{2D_{ij}n_j}{d_i} \right) = 2\pi d_i D_{ij} n_j \quad (9-43)$$

*Rate of microscale flocculation of heterodisperse particles*

Substituting the Stokes–Einstein equation  $D_{ij} = kT/3\pi\mu d_j$  (see Sec. 7-2, Eq. 7-25) into Eq. 9-43 and incorporating the collision efficiency factor  $\alpha$  and the number of particles,  $n_i$ , an expression for the rate of flocculation,  $r_{\mu,ji}$  of all  $j$ -size particles diffusing to the surface of all  $i$ -size particles can be obtained:

$$r_{\mu,ji} = 2\pi d_i D_{ij} n_j n_i \alpha = 2\pi d_i \left( \frac{kT}{3\pi\mu d_j} \right) \alpha n_i n_j = \frac{2}{3} \alpha \left( \frac{kT}{\mu} \right) \left( \frac{d_i}{d_j} \right) n_i n_j \quad (9-44)$$

where  $k$  = Boltzmann constant,  $1.3807 \times 10^{-23}$  J/K  
 $T$  = absolute temperature, K ( $273 + ^\circ\text{C}$ )  
 $\mu$  = dynamic viscosity of water,  $\text{N} \cdot \text{s}/\text{m}^2$

Generalizing to all possible combinations of  $i$  and  $j$  to form a particle of size  $k$ , the overall rate of  $r_\mu$  is given by

$$r_\mu = \frac{2}{3} \alpha \left( \frac{kT}{\mu} \right) \left( \frac{d_i}{d_j} \right) n_i n_j + \frac{2}{3} \alpha \left( \frac{kT}{\mu} \right) \left( \frac{d_i}{d_j} \right) n_i n_j + \frac{2}{3} \alpha \left( \frac{kT}{\mu} \right) \left( \frac{d_i}{d_j} \right) n_i (2n_j)$$

$\begin{array}{ccc} j \text{ diffusing to } i & i \text{ diffusing to } j & ij \text{ diffusing toward} \\ \text{(different sizes)} & \text{(different sizes)} & \text{each other (equal size)} \end{array}$

(9-45)

Grouping terms and simplifying the rate expression in Eq. 9-45 result in the expression

$$r_\mu = \frac{2}{3} \alpha \left( \frac{kT}{\mu} \right) n_i n_j \left( \frac{1}{d_i} + \frac{1}{d_j} \right) (d_i + d_j) \quad (9-46)$$

The collision frequency function for microscale flocculation of heterodisperse particles can now be written as

$$\beta_\mu = \left( \frac{2kT}{3\mu} \right) \left( \frac{1}{d_i} + \frac{1}{d_j} \right) (d_i + d_j) \quad (9-47)$$

Brownian motion affects the movement of colloidal particles but has only a minor influence on transport of particles larger than about 1  $\mu\text{m}$  (Smoluchowski, 1917).

*Rate of microscale flocculation of monodisperse particles*

The relationship shown in Eq. 9-47 can be simplified further for a system of uniform particle size. The collision frequency function for Brownian transport for a suspension of monodisperse particles is given by the

expression

$$\beta_{\mu} = \frac{8kT}{3\mu} \quad (9-48)$$

If considering the flocculation of only one size of particles, the first term in Eq. 9-29 represents the formation (+) of doublets and the second term represents the loss (-) of singlets. Combining Eqs. 9-29 and 9-48, the instantaneous loss of singlets due to Brownian or microscale flocculation is

$$r_u = -\frac{4}{3}\alpha\frac{kT}{\mu}n_i^2 \quad (9-49)$$

where units are as defined previously.

The second-order rate constant of  $\frac{4}{3}\alpha(kT/\mu)$  is  $5.4 \times 10^{-12}$  L/s·particle at 20°C, assuming  $\alpha = 1$ . The term  $\frac{4}{3}\alpha(kT/\mu)$  is the largest second-order rate constant for a chemical reaction because it describes the rate at which two molecules collide by molecular diffusion. Multiplying the term  $\frac{4}{3}\alpha(kT/\mu)$  by Avogadro's number yields a second-order rate constant of  $3.25 \times 10^{12}$  L/s·mol. Accordingly, microscale flocculation can be a relatively fast process if the concentration of small particles ( $<0.1 \mu\text{m}$ ) is high.

### Example 9-5 Collosion Frequency Function for microscale flocculation

A suspension contains small colloids and 10- $\mu\text{m}$  coagulant floc particles. Estimate the collosion frequency function for the transport of the colloids to the floc particles by microscale flocculation if the colloids are 0.01 $\mu\text{m}$  (the size of a virus). The water temperature is 15°C. Assume there is no floc breakup and  $\alpha = 1.0$ .

#### Solution

1. Determine the collosion frequency function for 0.01- $\mu\text{m}$  particles using Eq. 9-47. Note that  $1 \text{ J} = 1 \text{ N}\cdot\text{m}$ : The viscosity of water from Table C-1 in App. C is  $1.139 \times 10^{-3} \text{ N}\cdot\text{s}/\text{m}^2$

$$\begin{aligned} \beta_{\mu} &= \left[ \frac{(2) (1.3805 \times 10^{-23} \text{ N}\cdot\text{m}/\text{K}) (288 \text{ K})}{(3) (1.139 \times 10^{-3} \text{ N}\cdot\text{s}/\text{m}^2)} \right] \\ &\quad \times \left( \frac{1}{10^{-5} \text{ m}} + \frac{1}{10^{-8} \text{ m}} \right) (10^{-5} \text{ m} + 10^{-8} \text{ m}) \\ &= 2.33 \times 10^{-15} \text{ m}^3/\text{s} \end{aligned}$$

**FLOCCULATION OF SPHERICAL PARTICLES BY DIFFERENTIAL SETTLING**

Differential particle settling is a special case of macroscale flocculation where collisions occur because each particle settles at a specific terminal settling velocity that depends on the square of the particle diameter for laminar conditions ( $Re_i < 1$ ):

$$v_{s,i} = \frac{(\rho_p - \rho_l) g d_i^2}{18\mu} \quad (9-50)$$

$$Re_i = \frac{\rho_l v_{s,i} d_i}{\mu} \quad (9-51)$$

where  $v_{s,i}$  = settling velocity for particle  $i$   
 $\rho_p - \rho_l$  = difference in density between particle and fluid  
 $g$  = acceleration due to gravity, 9.81 m/s<sup>2</sup>  
 $Re_i$  = Reynolds number for particle  $i$

Differential flow of particles through given unit area

$$= \pi (R_{ij})^2 (v_{s,i} - v_{s,j}) = \pi \left( \frac{d_i}{2} + \frac{d_j}{2} \right)^2 (v_{s,i} - v_{s,j}) \quad (9-52)$$

where  $v_{s,i} - v_{s,j}$  = velocity difference between particles  $i$  and  $j$   
 $R_{ij}$  = distance between centers of particles  $i$  and  $j$

The velocity difference allows either particle  $i$  to overtake particle  $j$  or vice versa. As with the macroscale case, the flow rate of fluid into a unit area, defined by  $R_{ij}$  (see Fig 9-18), results in the following expression for the collision rate. The resulting final form of the rate of flocculation due to differential settling  $\eta_{DS}$  is given as

$$\eta_{DS} = -\frac{\pi(\rho_p - \rho_l)g}{72\mu} (d_i + d_j)^2 (d_i^2 - d_j^2) n_i n_j \alpha \quad (9-53)$$

where  $\eta_{DS}$  = rate of flocculation due to differential setting

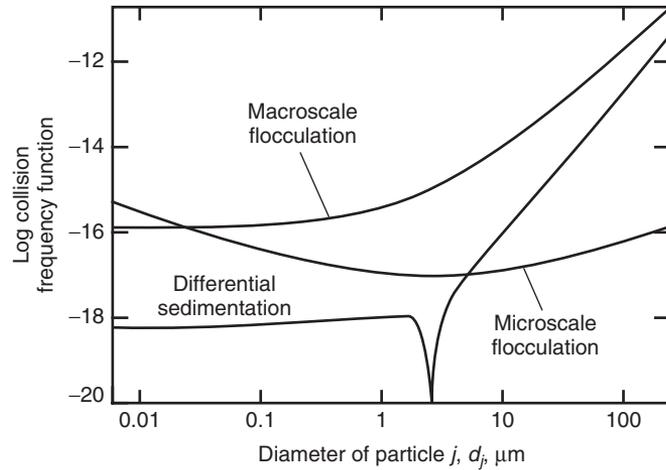

After simplification, the rate of flocculation by differential settling shown in Eq. 9-53 may be expressed as

$$\eta_{DS} = -\frac{\pi(\rho_p - \rho_l)g}{72\mu} (d_i + d_j)^3 (d_i - d_j) n_i n_j \alpha \quad (9-54)$$

By inspection, the collision frequency function (Friedlander, 2000) is

$$\beta_{DS} = \frac{\pi(\rho_p - \rho_l)g}{72\mu} [(d_i + d_j)^3 (d_i - d_j)] \quad (9-55)$$

Collision by differential sedimentation will not occur in a monodisperse system of particles of the same size and density because  $d_i - d_j = 0$ .

**Figure 9-19**

Collision frequency functions for macroscale (orthokinetic) flocculation, microscale (perikinetic) flocculation, and differential settling.

#### COMPARISON OF COLLISION FREQUENCY FUNCTIONS

The collision frequency functions for macroscale flocculation, microscale flocculation, and flocculation due to differential settling are given by Eqs. 9-35, 9-47, and 9-55, respectively. The collision frequency function may be plotted for a given system to assess the relative effect of each type of flocculation mechanism. A plot of the collision frequency functions is presented on Fig 9-19 for a system containing particles  $d_i$  of size  $2.0 \mu\text{m}$  and particles  $d_j$  with sizes ranging from  $0.01$  to  $50 \mu\text{m}$ . The curves shown on Fig. 9-19 are for a  $\bar{G}$  value of  $100 \text{ s}^{-1}$ , water temperature of  $15^\circ\text{C}$ , and particle density of  $1.1 \text{ g/cm}^3$ . As shown on Fig 9-19, the dominant flocculation mechanism is microscale flocculation for particles smaller than about  $0.035 \mu\text{m}$  and macroscale flocculation for larger particles at these conditions.

#### FLOCCULATION OF SPHERICAL PARTICLES IN NONLINEAR FLOW FIELD

The linear flow field model tends to overemphasize the importance of macroscale flocculation by not accounting for the collision efficiency associated with the hydrodynamics of particle–particle interactions and short-range attractive forces (van der Waals forces). Han and Lawler (1992) solved the appropriate equations for the nonlinear flow model, which more accurately considers the hydrodynamics and short-range forces. A further improvement in flocculation theory, in which flocculated particles are represented by fractal configurations that have a much larger size than is predicted by spherical particle models, is considered in the next section.

#### Fractal Flocculation Models

Spherical particles are considered in the linear and nonlinear flow field models described above. However, in these models the growth of floc particles is oversimplified and not considered properly because it is assumed

that the floc volume does not change with extent of flocculation. Flocs do, however, form large amorphous flakes and the size and floc volume do increase with the degree of flocculation. As a result, the flocculation rate in practice is typically faster than would be estimated by the spherical particle models.

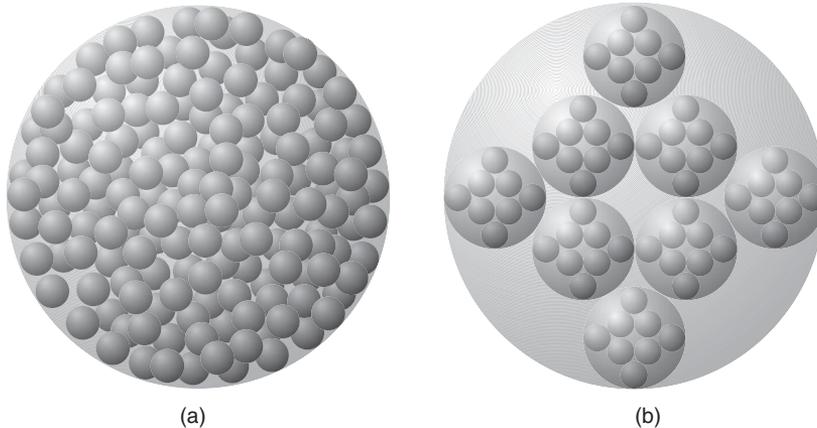

#### FRACTAL THEORY OF PARTICLE FORMATION

The growth rate of large particles from small particles depends on the shape and number of the small particles. For example, if large floc particles are spherical Euclidean objects, then the diameter of the larger particles,  $d_k$ , is proportional to the number of small particles raised to the third power,  $n_i^3$ . However, when rapid flocculation of small particles occurs, dendrites (or snowflake-like structures) form, and this forms particles that are much larger than would be predicted from the number of small particles using Euclidean geometry, as shown on Fig. 9-20. These snowflake-shaped particles are known as fractals.

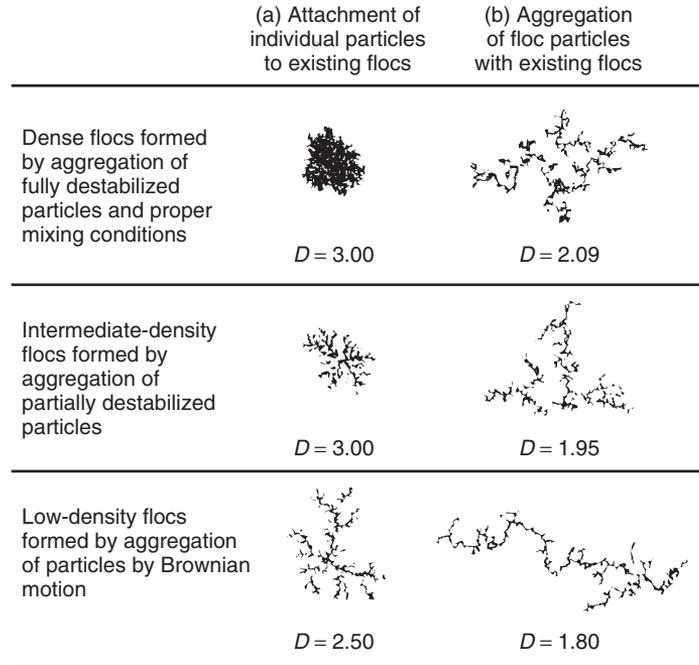

#### FRACTAL PARTICLE SHAPE AND SIZE

In the spherical particle models, it is assumed that the particles are spherical and that spherical particles are formed as a result of flocculation. However, as shown on Fig. 9-21, many shapes other than spherical are formed and aggregate size for a given number of flocculated small particles varies. Fractals may be used to describe the size of a floc particle that is constructed of small particles. The smaller particles that form the floc particle are referred to as fractal generators. For a three-dimensional object, a sphere that contains closely packed particles with a diameter  $d_p$  would scale with aggregate diameter  $d_a$  as given by the equation

$$\text{Volume} \propto \left( \frac{d_a}{d_p} \right)^3 \propto n_p^3 \quad (9-56)$$

**Figure 9-20**  
Particles made up of flocculated smaller particles: (a) Euclidean geometry and (b) fractal geometry.

**Figure 9-21**

Aggregate shapes formed by flocculation: (a) that arise from adding monomers to preformed clusters (monomer particles are added after the formation of some clusters), which is called monomer-cluster, and (b) that arise from adding all the particles at one time, which is called cluster-cluster. The fractal dimension  $D$  is in three dimensions. Aggregates that are formed from reaction-limited (slow coagulation), diffusion-limited (rapid coagulation), or ballistic (particles added on a straight-line trajectory) conditions form different aggregate shapes and have different  $D$  values. (Adapted from Schaefer, 1989).

where  $n_p$  = number of particles

The object described in Eq. 9-56 is a Euclidean object (see Fig. 9-20a) because the volume depends on the diameter of the aggregates raised to the third power.

#### FRACTAL DIMENSION

The fractal dimension  $D$  is used to describe the fractal volume by accounting for differences in particle shape:

$$\text{Volume} \propto n_p^D \quad (9-57)$$

A three-dimensional Euclidean object has a fractal dimension of 3. If a straight row of particles forms the floc particle, then  $D$  would have a numerical value of 1. If a flat circular disk of particles forms (somewhat like our galaxy),  $D$  would have a numerical value of 2. Consequently, as shown on Fig. 9-21, the size of a sphere that contains the floc particle increases dramatically with decreasing fractal number.

As shown on Fig. 9-21, different fractal aggregates and fractal dimensions are formed during flocculation depending on the suspension conditions. As presented on Fig. 9-21, (1) reaction-limited flocs are formed from particles that are fairly stable and will flocculate occasionally when there is sufficient

energy to overcome the repulsive forces, (2) ballastic flocs are formed from macroscale flocculation, and (3) diffusion-limited flocs are formed from microscale flocculation. The fractal dimension provides insight into the general shape of the aggregate that is formed.

### Example 9-6 Calculating the size of a fractal particle

Calculate the size of a spherical aggregate floc that contains 10,000 particles with a size of 0.1  $\mu\text{m}$ , assuming that the floc porosity is 0.4. Recalculate the size assuming that 100 particles of diameter 0.1  $\mu\text{m}$  form clumps and 100 of these clumps come together to form the aggregate with a porosity of 0.4. An example of the differences in packing arrangement is shown on Fig. 9-20.

#### Solution

1. Determine the volume of a spherical aggregate that contains 10,000 particles with a diameter of 0.1  $\mu\text{m}$ .
  - a. The volume of a spherical aggregate is given by the following equation and depicted on Fig. 9-20a:

$$\begin{aligned}\text{Volume of aggregate} &= \frac{4}{3}\pi(0.05 \times 10^{-6})^3 \times \frac{10,000}{0.4} \\ &= 1.309 \times 10^{-17} \text{ m}^3\end{aligned}$$

- b. The diameter of this Euclidean object is

$$d_a = 2 \left( \frac{3}{4\pi} 1.309 \times 10^{-17} \text{ m}^3 \right)^{1/3} = 2.924 \times 10^{-6} \text{ m} = 2.92 \mu\text{m}$$

2. Determine the size of aggregate that contains 100 particles.
  - a. The volume of a spherical aggregate is given by the equation

$$\begin{aligned}\text{Volume of aggregate} &= \frac{4}{3}\pi(0.05 \times 10^{-6})^3 \times \frac{100}{0.4} \\ &= 1.309 \times 10^{-19} \text{ m}^3\end{aligned}$$

- b. The diameter of this Euclidean object is

$$d_a = 2 \left( \frac{3}{4\pi} 1.309 \times 10^{-19} \text{ m}^3 \right)^{1/3} = 6.30 \times 10^{-7} \text{ m} = 0.63 \mu\text{m}$$

3. Compute the volume of a spherical aggregate containing 100 small clumps each comprised of a hundred particles.

- a. The volume is given by the following equation and depicted on Fig. 9-20b:

$$\begin{aligned}\text{Volume of aggregate} &= \frac{4}{3}\pi(0.315 \times 10^{-6})^3 \times \frac{100}{0.4} \\ &= 3.273 \times 10^{-17} \text{ m}^3\end{aligned}$$

- b. The diameter of a spherical aggregate containing 100 aggregates of 100 particle aggregates is given by the equation

$$d_a = 2 \left( \frac{3}{4\pi} 3.273 \times 10^{-17} \text{ m}^3 \right)^{\frac{1}{3}} = 3.97 \times 10^{-6} \text{ m} = 3.97 \text{ } \mu\text{m}$$

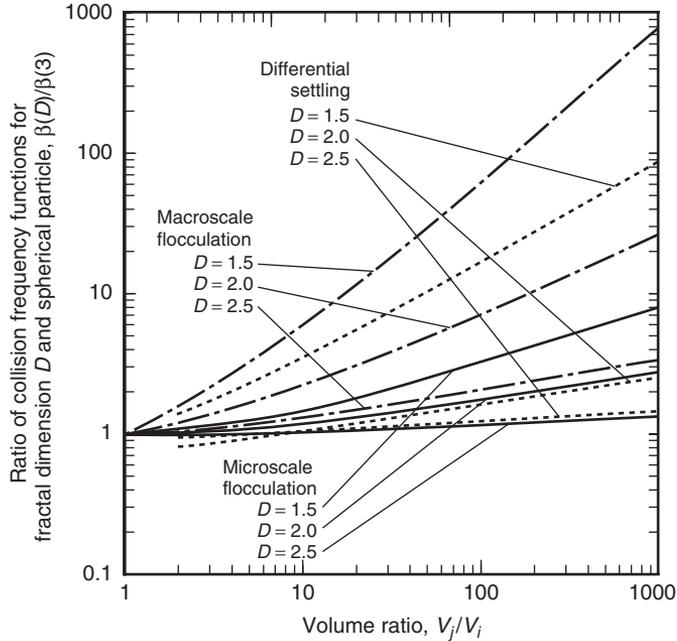

### Comment

The sphere that is made of clumps of 100 flocculated particles is much larger than a sphere made of the small floc particles.

The conditions under which the aggregates are formed provide insight into the three-dimensional appearance of the fractal. If a slowly flocculating suspension of small particles is completely destabilized, particles that come in contact with an aggregate will form branches on the surface of the aggregate. Further, as more branches are formed, the complexity and intricate nature of the branches increase. Consequently, completely destabilized suspensions have smaller fractal dimensions, as shown on Fig. 9-21. However, for particles that are not destabilized completely, attachment will not occur after every collision, and more forceful collisions are more likely to overcome the repulsive energy barrier. Thus, floc particles that form are typically dense and compact aggregates with fractal dimensions that approach the value used for Euclidean objects.

### FRACTAL COLLISION FREQUENCY

The collision frequency for the spherical particle models (Euclidean objects) is smaller than what is observed for fractal particles because fractal particles are much larger (including numerous branches) and have a greater porosity than Euclidean particles. The greater porosity of fractals must be considered when particle sizes are measured because, according to Logan (1999), certain particle measurement devices that measure particles according to solid volume, such as a Coulter counter, will report a size that is significantly smaller than the actual aggregate size. Other types of instruments (e.g., HIAC Royco) that use light blockage may be more appropriate for the determination of the true floc size. The collision efficiencies

**Figure 9-22**

Ratio of collision functions for fractal and Euclidean geometry as function of fractal dimension and volume ratio.

(assuming complete destabilization) for the fractal model are compared to those of the spherical particle model on Fig. 9-22 for the three flocculation mechanisms. The collision function increases as the size difference of the particles increases. The impact is greater for smaller fractal dimensions because the fractals grow more branches and have a much larger size as a result of flocculation. It is interesting to note that the collision functions predicted from fractal geometry are up to 1000 times higher than from Euclidean geometry. Accordingly, the flocculation rate is much faster than is predicted from spherical particle models.

When flow conditions are turbulent, floc breakup cannot be neglected. Small particles are sheared from larger aggregates when the local shear stress exceeds the internal binding forces of the aggregate. The principal mechanisms of aggregate or floc breakup are surface erosion (Argaman and Kaufman, 1970) and floc splitting (Thomas, 1964).

As discussed in Chap. 6, microscopic eddies form due to turbulent mixing, and it is likely that floc particles cannot grow much larger than  $2\eta$  ( $\eta$  is the Kolmogorov scale, discussed in Sec. 6-10) because the turbulent eddies would break up the particles. Logan (1999) compared the shear rate and eddy sizes to floc particle sizes for various mixing intensities and

## Floc Breakup

coagulants. The following conclusions were drawn: (1) polymer strengthens the floc and allows it to grow larger, (2) the mean floc size decreases with increasing  $\bar{G}$  and decreasing eddy size, and (3) clay particles appear to strengthen the floc.

Based on a surface erosion model, it has been shown (Argaman and Kaufman, 1970; Parker et al., 1972) that the formation rate of particle fragments due to breakup is dependent on the velocity gradient. If only primary particles are considered, the rate expression is

$$r_B = K_B \bar{G}^\delta \quad (9-58)$$

where  $r_B$  = rate of change of number of primary particles  
 $K_B$  = floc breakup constant  
 $\delta$  = turbulence constant

The floc breakup constant is dependent on the internal binding forces or floc strength of the aggregate. The turbulence constant varies between 2 and 4 depending on the hydraulic regime of the turbulence (Parker et al., 1972). The net rate of disappearance of primary particles under turbulent mixing conditions and the spherical particle model for macroscale flocculation may be written by combining Eqs. 9-41 and 9-58 as follows:

$$r_N = -K_A \bar{G} \Omega n_i + K_B \bar{G}^\delta \quad (9-59)$$

where  $r_N$  = net rate of floc disappearance  
 $K_A$  = aggregation constant

The aggregation constant  $K_A$  and the breakup constant  $K_B$  can be determined empirically in laboratory or pilot-scale tests (Argaman, 1971; Bratby et al., 1977; Odegaard, 1979; Parker et al., 1972). The ranges of reported values for the aggregation and breakup constants are shown in Table 9-9.

**Table 9-9**

Reported kinetic parameters for flocculation kinetics

### Use of Spherical Particle Models for Reactor Design

The simplified kinetic models of particle aggregation provide a basic understanding of the design issues of coagulation/flocculation systems, including selection of the flocculation configuration (number of tanks), type and intensity of mixing, and flocculation residence times to achieve the desired removal efficiency. From a design perspective, flocculation can be considered to be a pseudo-first-order reaction with respect to total particle number because flocculators are designed to gently mix the water and cause macroscale flocculation. Moreover, Argaman (1971) was able to use Eq. 9-59 to describe residual turbidity data.

The greatest efficiency in terms of both volume and mixing energy is obtained using a plug flow reactor. However, flocculation reactors must be mixed, and the best way to achieve an efficiency approaching that of a plug flow reactor is with a number of completely mixed flow reactors (CMFRs) in series. For equal-volume CMFRs in series, neglecting floc breakup, the flocculator performance equation for flocculation of primary particles is expressed as follows (see Eq. 6-119 in Chap. 6 for the tanks-in-series model for first-order reactions):

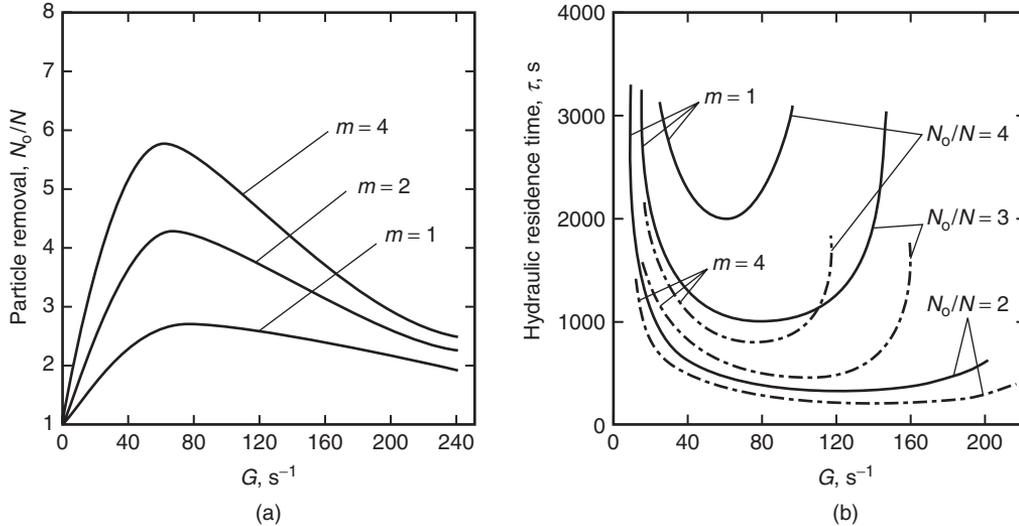

$$\frac{N}{N_0} = \frac{1}{(1 + K_A \bar{G} \Omega \tau / m)^m} \quad (9-60)$$

where  $\tau$  = hydraulic residence time of flocculator ( $V/Q$ )  
 $m$  = number of tanks in series, unitless  
 $N$  = number of particles in effluent per unit volume  
 $N_0$  = initial number of particles per unit volume

The effect on flocculation performance of increasing the number of reactors in series is illustrated on Fig. 9-23a at various  $\bar{G}$  values, as determined by changes in the turbidity (concentration of primary particles). As  $m$  increases, the optimum  $\bar{G}$  value decreases. If floc breakup is included (Eq. 9-59), the flocculation performance equation becomes (Argaman, 1971)

$$\frac{N}{N_0} = \frac{[1 + K_A \bar{G}(\tau/m)]^m}{1 + K_B \bar{G}^\delta (\tau/m) \sum_{i=1}^{m-1} [1 + K_A \bar{G}(\tau/m)]^i} \quad (9-61)$$

The use of Eq. 9-61 for process design of flocculation basins is illustrated on Fig. 9-23b. As shown on Fig. 9-23b, for a given  $\bar{G}$  and desired performance, there is a minimum required hydraulic residence time. It should be noted that, for each configuration and performance goal, an optimum value of  $\bar{G}$  can be determined. Finally, and of particular importance, several CMFRs in series decrease the required residence time and mixing power needed to achieve a given performance goal, as would be predicted by reactor design principles presented in Chap. 6.

**Figure 9-23**

(a) Performance of multicompartiment systems,  $\tau/m = 8$  min, and (b) performance of flocculator as related to  $\bar{G}$ ,  $\tau$ , and  $m$  (number of tanks). (Adapted from Argaman, 1971.)

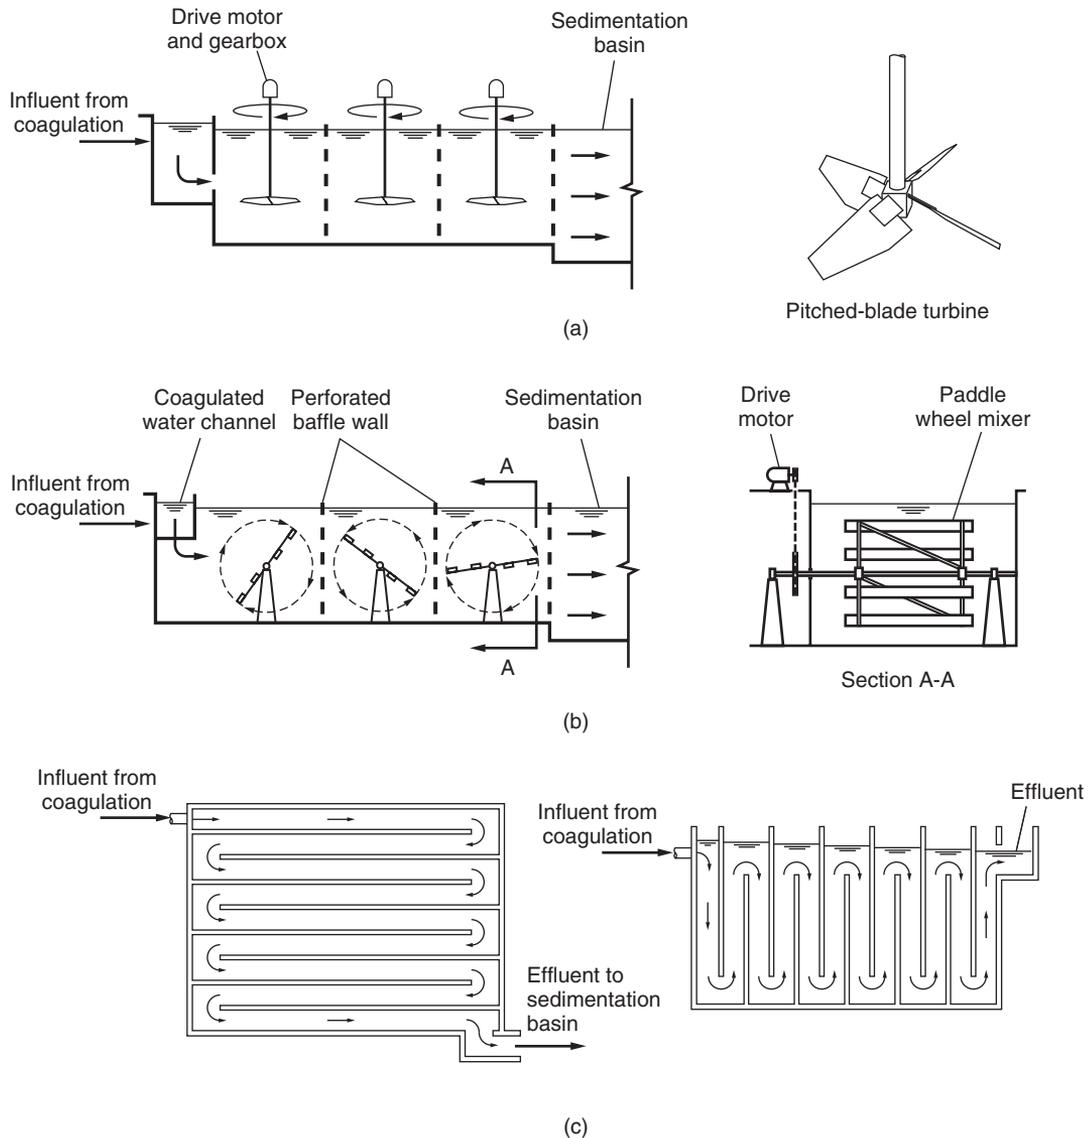

## 9-7 Flocculation Practice

The principal idea behind flocculation practice dates back to work done by Hyde and Langelier in 1921 while designing a new water treatment plant for Sacramento, California (Langelier, 1921). The mixing required for flocculation is provided by horizontal and vertical mechanical devices as well as arrangements that promote turbulence by hydraulic means alone. It has also been shown that flocculation benefits from compartmentalization so that the process operates as a series of CMFRs.

### Alternative Methods of Flocculation

In the 1920s, the first flocculators were large, flat, vertical blades rotating in cylindrical tanks made to emulate large jars. Since that time many innovative designs have come forth, some more successful than others. Today's flocculation installations can be divided into two groups: mechanical and hydraulic. In mechanical flocculation horizontal paddles and vertical turbines have become the most common configurations for the prime mover, although new innovations continue to be developed. No particular arrangement dominates in hydraulic flocculation. Occasionally designers have used agitation with air or pumped water jets to create the velocity gradients for flocculation, but these efforts have met with limited success.

Some views of these three most common approaches to flocculation are given on Fig. 9-24. Information on how these approaches compare to each

**Figure 9-24**

Common types of flocculation systems: (a) vertical-shaft turbine flocculation system, (b) horizontal paddle wheel flocculation system, and (c) hydraulic flocculation systems.

other with respect to a number of design and operational issues is presented in Table 9-10. All three of these approaches have been used successfully in numerous operations, and design details for a number of variations of each of them can be found in other sources (e.g., AWWA/ASCE, 2004; Kawamura, 2000).

**Table 9-10**

Comparison of basic approaches to flocculation

Process Issue	Horizontal Shaft with Paddles	Vertical-Shaft Turbines	Hydraulic Flocculation
Type of floc produced	Large and fluffy	Small to medium, dense	Very large and fluffy
Head loss	None	None	0.05–0.15 m
Operational flexibility	Good, limited to low $\bar{G}$	Excellent	Moderate to poor
Capital cost	Moderate to high	Moderate	Low to moderate
Construction difficulty	Moderate	Easy to moderate	Easy to difficult
Maintenance effort	Moderate	Low to moderate	Low to moderate
Compartmentalization	Moderate	Excellent	Excellent
	compartmentalization	compartmentalization	compartmentalization, some designs nearly plug flow
Advantages	<ul style="list-style-type: none"> <li><input type="checkbox"/> Generally produces large floc</li> <li><input type="checkbox"/> Reliable</li> <li><input type="checkbox"/> No head loss</li> <li><input type="checkbox"/> One shaft for several mixers</li> </ul>	<ul style="list-style-type: none"> <li><input type="checkbox"/> Flocculators can be maintained or replaced without basin shutdown</li> <li><input type="checkbox"/> No head loss</li> <li><input type="checkbox"/> Very flexible, reliable</li> <li><input type="checkbox"/> Highest energy input potential</li> </ul>	<ul style="list-style-type: none"> <li><input type="checkbox"/> Simple and effective</li> <li><input type="checkbox"/> Easy, low-cost maintenance</li> <li><input type="checkbox"/> No moving parts</li> <li><input type="checkbox"/> Can produce very large flocs</li> </ul>
Disadvantages	<ul style="list-style-type: none"> <li><input type="checkbox"/> Compartmentalization more difficult</li> <li><input type="checkbox"/> Replacement and some maintenance requires shutdown of basin</li> <li><input type="checkbox"/> Shaft breakage on startup because of high initial torque</li> </ul>	<ul style="list-style-type: none"> <li><input type="checkbox"/> Difficult to specify proper impellers and reliable gear drives in competitive bidding process</li> </ul>	<ul style="list-style-type: none"> <li><input type="checkbox"/> Little flexibility</li> </ul>

**APPLICATION OF ALTERNATIVE METHODS**

The choice among these three alternatives is usually driven by personal preference, by downstream processes, and by the level of operational expertise available. Horizontal-shaft paddles are more common in conventional treatment (includes sedimentation), although vertical turbines have been used successfully. Vertical turbines tend to dominate in direct filtration (no sedimentation) where horizontal-shaft paddles are rarely used. Hydraulic flocculation is usually employed with conventional treatment, although it has also been successfully used for direct filtration. Hydraulic flocculation is particularly popular in locations with poor access to resources and trained

personnel for maintenance and operation, but it also plays an important role in some developed countries, particularly Japan (Kawamura and Trussell, 1991). In recent years, vertical turbine flocculators have gained in popularity as impeller designs have improved and as design engineers learn how to specify them properly. One special attraction of vertical turbines is that these flocculators can be replaced or maintained while the process is operating.

#### **FLOC CHARACTERISTICS**

Provided there is sufficient flocculation time, the flocs produced by hydraulic flocculation are virtually always of settleable size. With either type of mechanical mixer, large flocs suitable for sedimentation can be attained by tapering down the power input in subsequent flocculators. However, when sedimentation is the goal, mesh-type impellers appear to have an advantage in the last stage of the flocculation process where floc breakup is particularly important (Sajjad and Cleasby, 1995). To promote growth of very large flocs in this last stage, the power input must be tuned after construction is complete and, sometimes, from one season to the next. As a result, variable-speed drives are usually provided. Less expensive two-speed drives may perform satisfactorily, particularly in the earlier stages of flocculation. Often two- or three-speed drives, judiciously chosen, are all that are necessary.

#### **DESIGN APPROACH**

The basic design criteria for mechanical flocculators are the Camp–Stein RMS velocity gradient  $\bar{G}$  and the hydraulic detention time  $t$ . Requirements of hydraulic detention time depend more on the downstream process than on the means of flocculation. Somewhat shorter flocculation times are often used for direct filtration (10 to 20 min) than for conventional treatment (20 to 30 min). Longer flocculation times are also required in colder climates. Representative design parameters for horizontal-shaft paddles and vertical turbines are shown in Table 9-11.

Corrosion of submerged metal components of the flocculator assemblies can be a serious maintenance problem. Specifying Type 316 stainless steel for submerged portions of the flocculator assembly and a cathodic protection system for structural steel are common solutions to this problem.

Vertical-shaft turbine flocculators are impellers attached to a vertical shaft that is rotated by an electric motor through a speed reducer. The impellers used for mixing can be placed in two broad classifications: (1) radial flow impellers and (2) axial flow impellers. Examples of the two types of impellers and the differences between their performance are illustrated on Fig. 9-25. The radial impeller directs flow outward from the impeller blades in a horizontal direction, through centrifugal force, with a velocity profile that peaks at the center of the blades. The axial impeller directs the flow parallel to the vertical shaft. The circulation pattern in the mixing tank is also substantially different for these two types of impellers. Two circulation

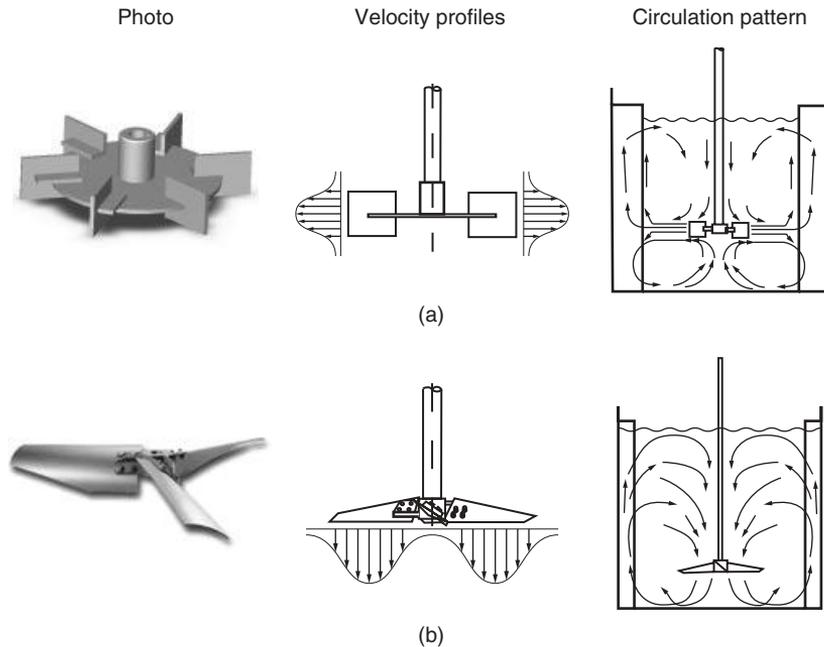

### **Vertical Turbine Flocculators**

**Table 9-11**

Typical design criteria for horizontal-shaft paddles and vertical-shaft turbines

Design Parameter	Unit	Horizontal Shaft with Paddles	Vertical-Shaft Turbines
Velocity gradient, $\bar{G}$	$s^{-1}$	5–40	10–80
Tip speed, maximum	m/s	<0.5	1–3
Rotational speed	rev/min	0.5–3	5–20
Compartment <sup>a</sup> dimensions (plan)			
Width	m	3–25	3–8
Length	m	3–8	3–8
Number of stages	No.	2–6	2–4
Variable-speed drives	—	Common	Common

<sup>a</sup>The compartment is the region influenced by an individual flocculator. Horizontal-shaft flocculators often have multiple paddle wheel assemblies on a single flocculator shaft. Vertical turbine flocculators may or may not have baffle walls between the compartments in a single stage.

**Figure 9-25**

Comparison of (a) radial and (b) axial flow mixers with respect to shape, velocity profiles, and circulation profiles. (Adapted from Oldshue and Trussell, 1991.)

loops are generated from radial flow mixers: one above the impeller and one below. Axial flow impellers, on the other hand, create one circulation pattern from the bottom of the tank to the top and back through the impeller again.

Axial flow impellers can be configured in two ways: to pump downward or to pump upward. Down pumping is usually employed in flocculation

because it helps keep the particles in the tank in suspension. The motors that drive the impellers are usually designed to rotate in a clockwise direction when viewed in plan view, as if looking down into the water. The axial impeller shown on Fig. 9-25 is arranged to pump downward.

#### IMPELLER DESIGN CRITERIA

Important design considerations for vertical turbine impellers are the displacement capacity (the rate at which the impeller pumps water), the power consumption, and the pumping head. Together, these determine much about the nature of the flow in the impeller's operating environment.

To evaluate the impeller's performance, it is important to know the nature of the flow in the mixing tank, specifically if the flow is laminar or turbulent as determined by the Reynolds number. Virtually all flocculation impellers operate in the turbulent-flow regime. The Reynolds number for a vertical turbine flocculator is given by the expression

$$\text{Re} = \frac{D^2 N \rho}{\mu} \quad (9-62)$$

where  $\text{Re}$  = Reynolds number, dimensionless

$D$  = diameter of impeller, m

$N$  = impeller's rotational speed,  $\text{s}^{-1}$

$\rho$  = density of water,  $\text{kg}/\text{m}^3$

$\mu$  = dynamic viscosity of water,  $\text{N}\cdot\text{s}/\text{m}^2$

For the vertical turbines used in flocculation, full turbulence is developed at Reynolds numbers of 10,000 and greater.

### Example 9-7 Estimating Reynolds number of vertical turbine flocculator

A vertical turbine 1.6 m in diameter is used to mix the contents of a flocculation tank 4 m in diameter. The turbine rotates at a speed of 20 rev/min. The absolute viscosity of the water is  $1.31 \times 10^{-3} \text{ kg}/\text{m} \cdot \text{s}$ . Determine if turbulent conditions are present.

#### Solution

1. Determine the Reynolds number using Eq. 9-62:

$$\text{Re} = \frac{D^2 N \rho}{\mu} = \frac{(1.6^2 \text{ m}^2)(20 \text{ min}^{-1})(998 \text{ kg}/\text{m}^3)}{(60 \text{ s}/\text{min})(1.31 \times 10^{-3} \text{ kg}/\text{m} \cdot \text{s})} = 6.5 \times 10^5$$

2. Because the computed value of  $R$  is greater than  $10^4$ , the flow regime is turbulent.

Three parameters that are important to the design of mixing devices are the power number, the pumping number, and the head number. These have the following form:

$$N_p = \frac{P}{\rho N^3 D^5} \quad (9-63)$$

$$N_Q = \frac{Q}{ND^3} \quad (9-64)$$

$$N_H = \frac{\Delta Hg}{(ND)^2} \quad (9-65)$$

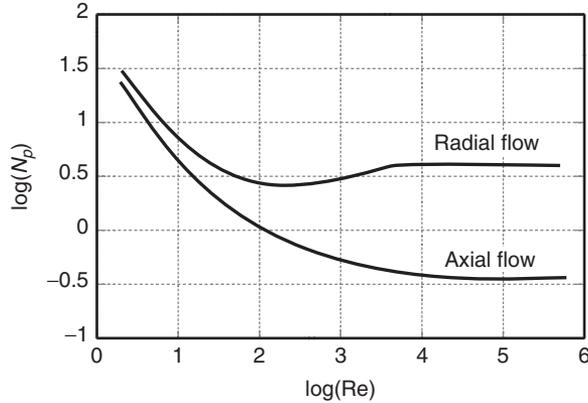

where  $P$  = power requirement, J/s (W)  
 $N_p$  = power number, dimensionless  
 $D$  = diameter of impeller, m  
 $N_Q$  = pumping number, dimensionless  
 $N_H$  = head number, dimensionless  
 $\rho$  = fluid density, kg/m<sup>3</sup>  
 $N$  = rotational speed, rev/min  
 $Q$  = flow rate imparted by impeller, m<sup>3</sup>/s  
 $\Delta H$  = head impeller imparts to impeller flow, m  
 $g$  = acceleration due to gravity, 9.81 m/s<sup>2</sup>

Power number is the most straightforward of these numbers to determine. All that is required is a torque meter on the shaft of the mixer and a tachometer to measure its rate of rotation. As a consequence, power numbers are available for most commercial impellers. The availability of power numbers is convenient because it is the power number and the rotational speed that determine the nominal Camp–Stein RMS velocity gradient  $\bar{G}$  for the basin.

In general, as the pumping number increases, the circulation pattern becomes prevalent. As the head number increases for a given pumping number, more turbulence occurs. In addition, if the pumping number and head number are available, they can be used to determine whether a particular impeller mixer is suitable for the mixing tank. For example, the circulation time is related to the pumping rate and mixing time required to achieve completely mixed conditions.

#### VARIATIONS IN POWER NUMBER

The power number changes with the flow conditions in the basin being mixed. Significant factors include the depth and shape of the basin, the submergence of the impeller, the baffling provided, the type of impeller, and the Reynolds number. Fortunately, once the basin reaches full turbulent flow, power numbers for a variety of impellers are relatively constant. The relationship of power number and Reynolds number is compared for the two classic types of impellers on Fig. 9-26. Note that, for both impellers,  $N_p$  is constant above a Reynolds number of  $10^4$ . Pumping numbers and head numbers are substantially more difficult to measure. As a result, these are not as readily available as the power number.

**Figure 9-26**

Change in power number as function of Reynolds number in baffled tank. (Adapted from Oldshue and Trussell, 1991.)

### IMPACT OF IMPELLER SHAPE

Several types of impellers used in water treatment along with their typical uses are displayed in Table 9-12. When impellers on vertical shafts were first used for flocculation, some radial flow turbines were used, particularly Rushton turbines and flat-bladed turbines. But it has been determined that, as these impellers move through the water, they create substantial trailing vortices (Van't Reit et al., 1976). Vortices represent anisotropic turbulence that contributes significantly to floc breakup. Long pitch blade turbines subsequently became more popular, but, as illustrated on Fig. 9-27, even these produce substantial trailing vortices (Shäfer et al., 1998). Today hydrofoils, or pitched-blade turbines with cambered blades (blades with an upper surface shaped like an airplane wing), are the impellers of choice. Properly designed, flocculators using these devices can form large floc similar to that formed by more traditional horizontal paddle flocculators, but Sajjad and Cleasby (1995) demonstrated that these devices are still less effective in flocculation than an ideal wire mesh impeller.

### OTHER DESIGN CONSIDERATIONS

In addition to the choice of the impeller itself, the following design parameters should be carefully scrutinized: (1) the ratio of the blade diameter to equivalent tank diameter should be greater than 0.35, preferably between 0.4 and 0.5, and (2) the velocity profile caused by the mixing blade should have a maximum of 2.5 m/s (8 ft/s) in the first stage and less than 0.6 m/s (2 ft/s) in the last stage of the flocculator. Design criteria are summarized in Table 9-13.

#### *Baffling*

Another issue related to the circulation rate and head is providing enough baffling to prevent vortexing around the impeller shaft. Vortexing occurs from the centrifugal forces created when the entire contents of the mixing chamber are brought into rotation around the impeller. These circumstances are not optimum for creating the velocity gradients that promote

**Table 9-12**

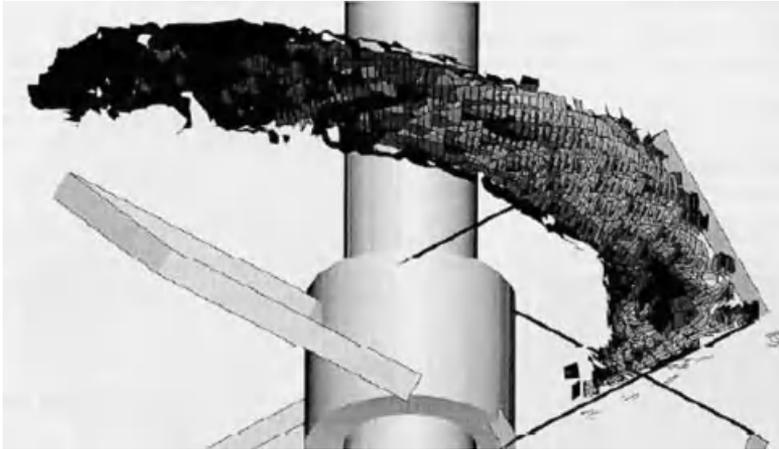

Power and pumping numbers for common impellers

Impeller Type	Photograph	Power Number	Pumping Number	Application
Flat-bladed turbine (FBT)		3.6	0.9	Blending, maintaining suspensions, flocculation
Pitched-blade turbine (45° PBT)		1.26	0.75	Blending, maintaining suspensions, flocculation
Pitched-blade turbine with camber (hydrofoil, 3 blades)		0.2–0.3	0.45–0.55	Blending, maintaining suspensions, flocculation
Cast foil with proplets		0.23	0.59	Blending viscous liquids
Rushton turbine (6 blades)		4.5–5.5	0.72	Gas–liquid dispersion, solids suspension, flocculation
Propeller (pitch of 1:1)		0.32–0.36	0.4	Blending viscous liquids

flocculation. Though circular tanks are rarely used, when they are, four baffles evenly placed around the outside of the tank are essential. The baffles should be about 10 percent of the tank diameter. The standard in the United States is  $\frac{1}{12}$ th of the tank diameter and the standard elsewhere is  $\frac{1}{10}$ th the tank diameter. Similar baffles can also be important in rectangular tanks. The appropriate placement of baffling in some alternative tank shapes is shown on Fig. 9-28.

#### *Depth and shape of flocculation chamber*

In addition to baffles, the depth and shape of the flocculation chamber can be important. Most mixing tests are conducted in square tanks with the impeller held at two-thirds of the depth of the tank. The more closely

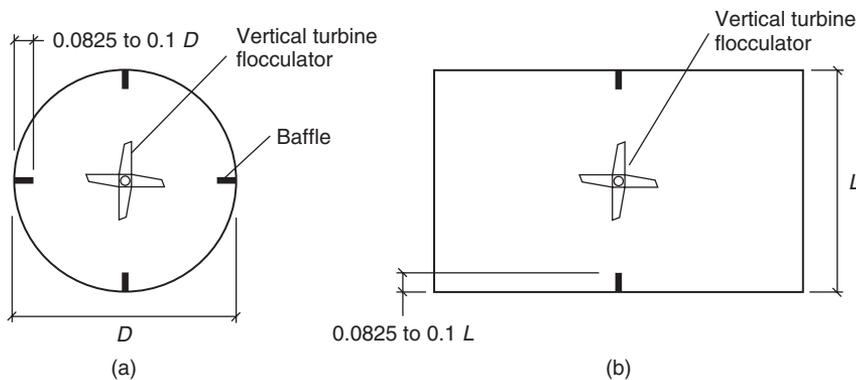

**Figure 9-27**  
Trailing vortex behind 45° pitched-blade turbine in turbulent flow. (From Schäfer et al., 1998.)

**Table 9-13**  
Key design criteria for vertical-turbine flocculator

Parameter	Range	Definition Sketch
Impeller	Hydrofoil or 45° pitched-blade turbine (PBT), hydrofoil preferred	
$D/T_e^a$	0.3–0.6, 0.4–0.5 preferred	
$H/T_e$	0.9–1.1	
$C/H$	0.5–0.33	
$N$	10–30 rev/min	
Tip speed	2–3 m/s	

$T_e = \sqrt{4A_{plan}/\pi}$ .

**Figure 9-28**  
Baffle placement in flocculation tanks using vertical-turbine impellers: (a) circular tank and (b) rectangular tank.

the full-scale design emulates those conditions, the more likely it is that the full-scale performance will replicate the manufacturer's test data. As a result, when vertical turbine impellers are used, it is wise to stick to a nearly cubical shape flocculation chamber and to locate the impeller at approximately two thirds of the chamber's water depth.

### Example 9-8 Design of vertical turbine flocculator

Vertical turbines are to be used for flocculation in a water treatment plant with a design flow rate of 75 ML/d (20 mgd) and design temperature of 10°C. Flocculation is to be designed with four parallel trains, and each train is to be made of four stages in series. The total detention time in flocculation is to be 20 min. Determine the following design features for the first stage in each flocculation train:

1. The dimensions of the stage
2. The diameter of the impeller (assume a turbine having three pitched blades with camber, a foil)
3. The water power required to achieve a  $\bar{G}$  of 80 s<sup>-1</sup> (the power that must be input to the water through the impeller shaft)
4. The maximum rotational speed
5. The pumping capacity of the impeller and circulation time in the tank

At 10°C, the absolute viscosity of water is 1.31 × 10<sup>-3</sup> kg/m · s and the density of water is 999.7 kg/m<sup>3</sup>. The circulation time is the volume of the flocculation chamber divided by the impeller pumping rate.

#### Solution

1. Determine the dimensions of the compartment:

$$\text{Volume} = \frac{(75 \text{ ML/d})(1000 \text{ m}^3/\text{ML})(20 \text{ min})}{(1440 \text{ min/d})(4 \text{ trains})(4 \text{ stages/train})} = 65.1 \text{ m}^3$$

Assume a perfect cube of length  $L$ . The size is in the range for a single flocculator compartment in each stage.

$$L = \sqrt[3]{65.1 \text{ m}^3} = 4.0 \text{ m} \quad (13.2 \text{ ft})$$

2. Determine the diameter of the impeller. Based on Table 9-13, choose an impeller diameter of 0.45 $T_e$ :

$$T_e = \sqrt{\frac{4 \times A_{\text{plan}}}{\pi}}$$

Assume  $A_{\text{plan}} = 4.0 \text{ m} \times 4.0 \text{ m} = 16 \text{ m}^2$ :

$$T_e = 4.51 \text{ m}$$

$$D = 0.45 \times 4.51 \text{ m} = 2.03 \text{ m}$$

Choose  $D = 2 \text{ m}$ .

3. Determine the power input to the water: The water power is determined by the requirement for  $\bar{G} = 80 \text{ s}^{-1}$ . Rearranging Eq. 9-40,

$$\begin{aligned} P &= \bar{G}^2 \mu V \\ &= (80 \text{ s}^{-1})^2 (1.31 \times 10^{-3} \text{ kg/m} \cdot \text{s})(65.1 \text{ m}^3) = 546 \text{ kg} \cdot \text{m}^2/\text{s}^3 \\ &= 546 \text{ W} \end{aligned}$$

4. Determine the maximum rotational speed: From Table 9-12, for a three-bladed foil,  $N_p$  values of 0.2 to 0.3, use 0.25. Rearranging Eq. 9-63,

$$\begin{aligned} N &= \sqrt[3]{\frac{P}{N_p \rho D^5}} \\ &= \sqrt[3]{\frac{546 \text{ kg} \cdot \text{m}^2/\text{s}^3}{(0.25)(999.7 \text{ kg/m}^3)(2 \text{ m})^5}} = 0.409 \text{ s}^{-1} \\ &= (0.409 \text{ s}^{-1})(60 \text{ s/min}) = 24.5 \text{ min}^{-1} \quad (\text{rev/min}) \end{aligned}$$

Note:  $N$  is within the operating range of 10 to 30 rev/min recommended in Table 9-13.

5. Determine the pumping capacity and circulation time:  
a. Pumping capacity: From Table 9-12,  $N_Q \sim 0.5$ . Rearranging Eq. 9-64,

$$\begin{aligned} Q &= N_Q N D^3 \\ &= (0.5)(0.409 \text{ s}^{-1})(2 \text{ m})^3 = 1.64 \text{ m}^3/\text{s} \end{aligned}$$

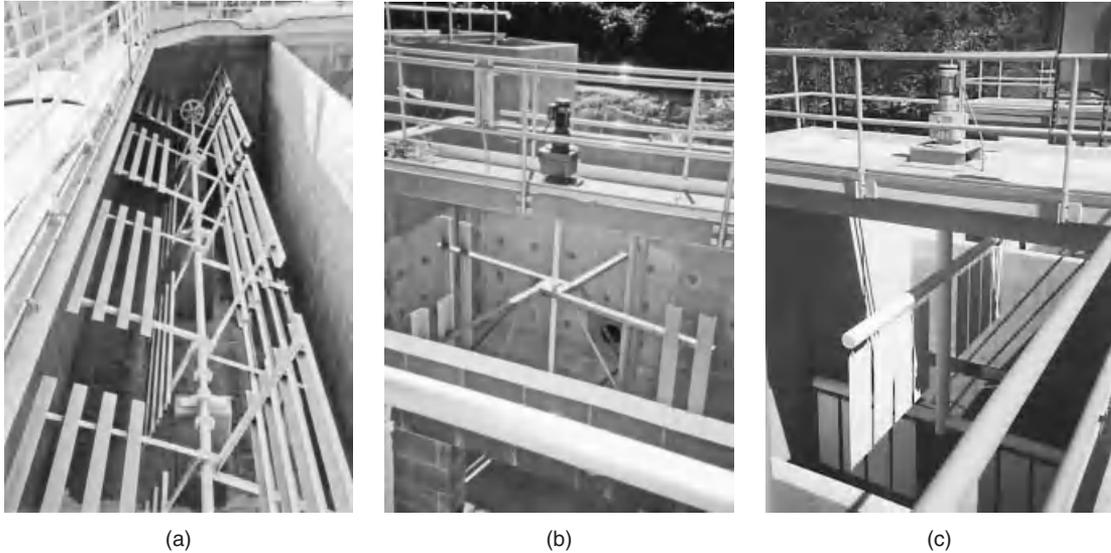

- b. Circulation time:

$$t_c = \frac{V}{Q} = \frac{65.1 \text{ m}^3}{1.64 \text{ m}^3/\text{s}} = 39.8 \text{ s}$$

The circulation time is a little less than 1 min.

Horizontal-shaft paddle wheel flocculators are often employed if conventional treatment is used and a high degree of solids removal by sedimentation is required (see Fig. 9-29). However, they require more maintenance and expense, mainly because bearings and packings are typically

### Horizontal Paddle Wheel Flocculators

**Figure 9-29**

Views of paddle flocculators: (a) horizontal paddle wheel arrangement and (b) and (c) vertical paddle arrangements. (Courtesy AMWELL A Division of McNish Corp.)

submerged. By comparison, high-energy, vertical-shaft turbine flocculators are the unit of choice for liquid–solid separation using high-rate filtration systems and dissolved air flotation. Another advantage of horizontal-shaft flocculators is that one shaft flocculates a larger basin volume, but with that advantage comes the liability that a significant amount of the mixing capacity is lost when one drive is out of commission. When these units first start rotating, a tremendous torque is suddenly applied. Consequently, most failures occur during startup, especially if the unit is started at maximum rotational speed. Consequently, these mixers should be started at the lowest speed possible to minimize the initial torque.

The power input to the water by horizontal paddles may be estimated from the expression

$$P = \frac{C_D A_p \rho v_R^3}{2} \quad (9-66)$$

where  $C_D$  = drag coefficient on paddle (for turbulent flow), unitless  
 $A_p$  = projected area of paddle,  $\text{m}^2$   
 $\rho$  = fluid density,  $\text{kg}/\text{m}^3$   
 $v_R$  = velocity of paddle relative to fluid,  $\text{m}/\text{s}$

Here,  $v_R$  is usually assumed to be 70 to 80 percent of the paddle speed without tank baffles. With tank baffles, 100 percent of the paddle speed is

**Table 9-14**  
Design criteria for paddle wheel flocculator

Parameter	Unit	Value
Diameter of wheel	m	3–4
Paddle board section	mm	100 × 150
Paddle board length	m	2–3.5
$A_p$ /tank section area	%	<20
$C_D$ (for use in Eq. 9-66)	$L/W = 1$	$C_D = 1.16$
	$L/W = 5$	$C_D = 1.20$
	$L/W = 20$	$C_D = 1.5$
	$L/W \gg 20$	$C_D = 1.90$
Paddle tip speed	m/s	Strong floc, 4
	m/s	Weak floc, 2
Spacing between paddle wheels on same shaft	m	1
Clearance from basin walls	m	0.7
Minimum basin depth	m	1 m greater than diameter of paddle wheel
Minimum clearance between stages	m	1

approached. The Reynolds number for a paddle flocculator is

$$Re = \frac{D_{pw}^2 N \rho}{\mu} \quad (9-67)$$

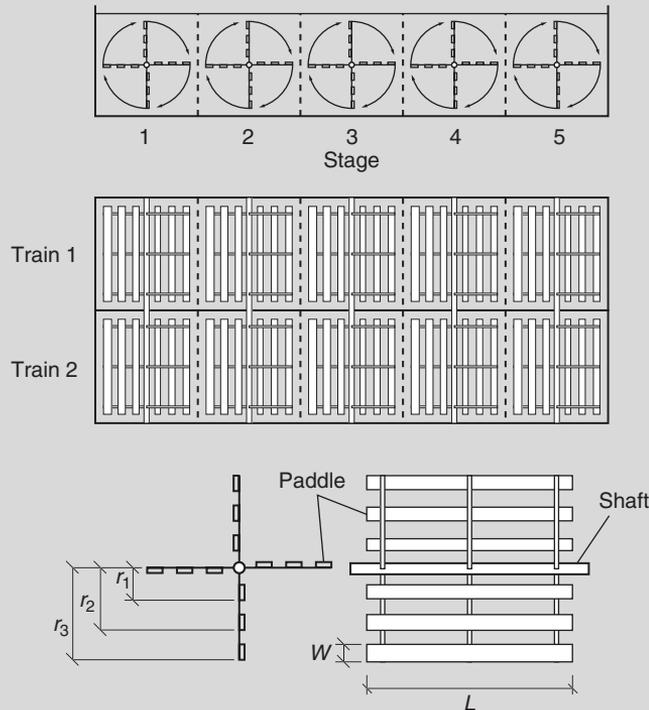

where  $D_{pw}$  = diameter of paddle wheel

For Reynolds numbers greater than 1000 (computed using Eq. 9-67), the drag coefficients for flat paddles are  $C_D = 1.16, 1.20, 1.50,$  and  $1.90$  for length-to-width ratios of 1.0, 5.0, 20.0, and infinity, respectively. Criteria that are useful for the design of paddle wheel flocculators are summarized in Table 9-14. Two things can be done to increase or decrease the  $\bar{G}$  that is produced by a paddle wheel: (1) change the number of paddle boards or (2) change the rotational speed. It is difficult to achieve 50 to 60  $s^{-1}$  with paddle wheel flocculators. Typical values of  $\bar{G}$  for paddle wheel flocculators are 20 to 50  $s^{-1}$ .

### Example 9-9 Design of horizontal paddle wheel flocculator

Horizontal-shaft paddle wheel flocculators are to be used for flocculation in a water plant with a design flow rate of 150 ML/d (40 mgd) and water temperature of 10°C. Flocculation is to be designed with two parallel trains

and each train is to be made of five stages of flocculation in series. The total detention time for flocculation is to be 20 min. The paddle wheel flocculators to be used will have the design shown below:

Two paddle wheels will be on the shaft in each stage. The paddle wheel design should include three paddle boards per arm with leading edges located at 0.67, 1.33, and 2.0 m from the shaft centerline. The width of the paddle boards is 0.15 m. Determine the following design features for the second stage in each flocculation train:

1. Dimensions of the compartment in the stage (including the number of paddle wheels and their length)
2. Water power input required to achieve a  $\bar{G}$  value of  $40 \text{ s}^{-1}$
3. Rotational speed of the paddle shaft

### Solution

1. Determine the physical features of the flocculation basins.

- a. The dimensions of the compartment are as follows:

$$\text{Basin depth} = (2 \text{ m})(2) + 1 \text{ m} = 5 \text{ m}$$

$$\begin{aligned} \text{Volume} &= \frac{(150 \text{ ML/d})(1000 \text{ m}^3/\text{ML})(20 \text{ min})}{(1440 \text{ min/d})(2 \text{ trains})(5 \text{ stages/train})} \\ &= 208.3 \text{ m}^3/\text{stage} \end{aligned}$$

$$\text{Basin area (plan)} = \frac{208.3 \text{ m}^3}{5 \text{ m}} = 41.7 \text{ m}^2$$

$$\text{Minimum length of stage} = 4 \text{ m} + 2(0.5 \text{ m}) = 5 \text{ m}$$

$$\begin{aligned} \text{Nominal width} &= \frac{41.7 \text{ m}^2}{5 \text{ m}} \\ &= 8.33 \text{ m} \quad (\text{perpendicular to flow}) \end{aligned}$$

- b. Determine paddle configuration: Two paddle wheel assemblies are needed. Clearance is needed at each end of each paddle and between the paddles.

$$\text{Required clearance} = 2(0.7 \text{ m}) + 1 \text{ m} = 2.4 \text{ m}$$

$$\text{Length of both paddles} = 8.33 \text{ m} - 2.4 \text{ m} = 5.93 \text{ m}$$

$$\text{Length of each paddle} = \frac{5.93 \text{ m}}{2} = 2.97 \text{ m}$$

- c. Summary:

Compartment:

$$\text{Depth} = 5 \text{ m}$$

$$\text{Length} = 5 \text{ m}$$

$$\text{Width} = 8.33 \text{ m}$$

Paddle wheel assemblies:

$$\text{Number} = 2$$

$$\text{Length of paddles} = 2.97 \text{ m}$$

2. Determine the water power input required to achieve a  $\bar{G}$  value of  $40 \text{ s}^{-1}$  using Eq. 9-40:

$$\begin{aligned} P &= \bar{G}^2 \mu V \\ &= (40 \text{ s}^{-1})^2 (1.31 \times 10^{-3} \text{ kg/m} \cdot \text{s})(208.3 \text{ m}^3) = 436.7 \text{ kg} \cdot \text{m}^2/\text{s}^3 \\ &= 436.7 \text{ J/s} \end{aligned}$$

3. Determine the power required by the paddles by rearranging Eq. 9-66 and noting that the areas and shapes of the first, second, and third

boards are the same; therefore

$$P = \frac{\rho C_D A_p}{2} (v_{R \text{ inside paddles}} + v_{R \text{ middle paddles}} + v_{R \text{ outside paddles}})$$

- a. Determine the areas of the boards at each position (inside, middle, and outside):

$$A_p = (2 \text{ wheels})(4 \text{ boards/wheel})(0.15 \text{ m})(2.97 \text{ m}) = 3.56 \text{ m}^2$$

- b. Check the length-to-width ratio and select the drag coefficient  $C_D$ :

$$\text{Paddle } L/W = 2.97/0.15 = 19.8$$

$$C_D \sim 1.5 \quad (\text{from Table 9-14})$$

- c. Develop parameters needed to determine the paddle power requirements:

$$\text{Velocity of paddles} = v_R = \frac{r 2\pi N(0.75)}{60 \text{ s/min}}$$

where  $r$  = distance to centerline of paddle from center of rotation

$N$  = shaft rotational speed, rev/min

0.75 = relative velocity of paddle with respect to fluid

$$r_{\text{inside}} = r_1 = 0.67 - 0.15/2 = 0.595 \text{ m}$$

$$r_{\text{middle}} = r_2 = 1.33 - 0.15/2 = 1.255 \text{ m}$$

$$r_{\text{outside}} = r_3 = 2.0 - 0.15/2 = 1.925 \text{ m}$$

- d. Substitute known values in the paddle power equation:

$$P = \frac{\rho C_D A_p}{2} (v_{R \text{ inside paddles}} + v_{R \text{ middle paddles}} + v_{R \text{ outside paddles}})$$

$$= \frac{\rho C_D A_p}{2} \left[ \frac{2\pi N(0.75)}{60 \text{ s/min}} \right]^3 (r_1^3 + r_2^3 + r_3^3)$$

$$= \left( \frac{(999.7 \text{ kg/m}^3)(1.5)(3.56 \text{ m}^3)}{2} \right) \left[ \frac{2\pi N(0.75)}{60 \text{ s/min}} \right]^3$$

$$\times [(0.595)^3 + (1.255)^3 + (1.925)^3]$$

$$= (2664.7)(4.85 \times 10^{-4} \text{ N}^3)(9.321)$$

4. Equate the required power determined in step 2 to meet the  $\bar{G}$  value to the power required by the paddles as determined in step 3 above

and solve for  $N$ :

$$436.7 = (2664.7)(4.85 \times 10^{-4} N^3)(9.321)$$

$$N = \sqrt[3]{\frac{436.7}{(2664.7)(4.85 \times 10^{-4})(9.321)}} = 3.31 \text{ rev/min}$$

There are a number of approaches to hydraulic flocculation. Monk and Trussell (1991) divided hydraulic flocculators into three groups. With some minor modifications those groups are (1) baffled channels, (2) hydraulic-jet flocculators, and (3) coarse-media flocculators. Examples of the first two types are illustrated on Fig. 9-30. Baffled channels are probably the most common application. Although most hydraulic flocculators have some disadvantages, such as inflexible mixing and a large head loss across the basin, most designs produce good floc, often without much short circuiting. Most hydraulic flocculators work best if the plant flow rate is fairly constant.

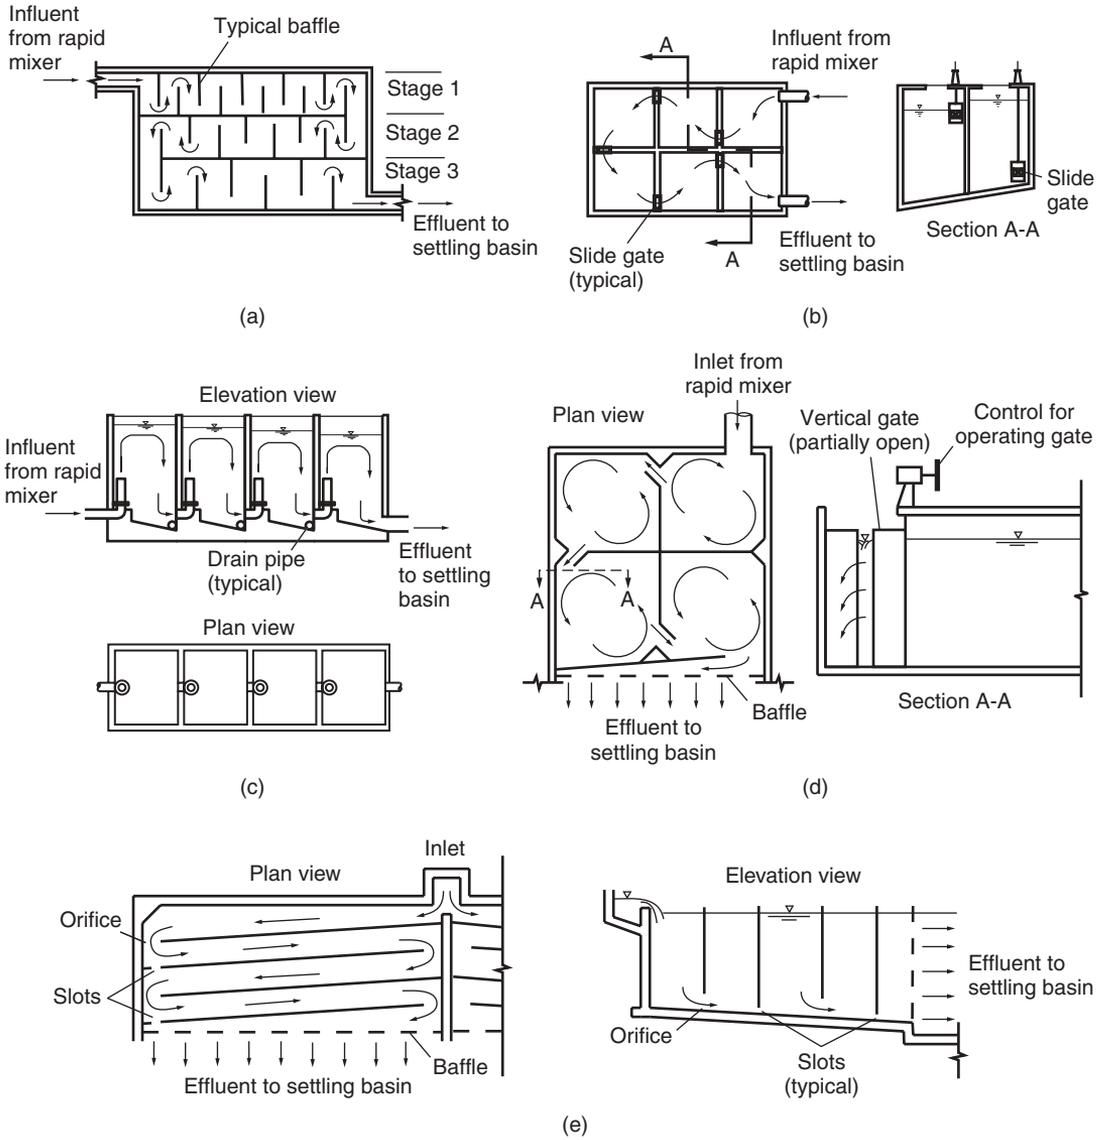

The main design issue for hydraulic flocculators is whether there is head available in the plant profile to provide the required power input. Hydraulic flocculators often operate well at low-flow conditions (even if  $\bar{G}$  is as low as  $10 \text{ s}^{-1}$ ), because the longer detention time provides for an adequate  $\bar{G}t$ . Helicoidal or tangential flow baffled channels perform as well as traditional designs and have lower head loss (Kawamura, 2000). Around-the-end baffled channels are preferred over the under-and-over baffled flocculators because they have fewer problems with scum and silt/grit buildup on the upstream side of each baffle. Several rules of thumb that prove useful in the design of hydraulic flocculators are summarized in Table 9-15.

#### BAFFLED CHANNELS

Baffled channels are the most common form of hydraulic flocculators. In these flocculators energy dissipation is achieved by changing the direction of flow of the water, either by over-under or around-the-end baffles. In principle, these are plug flow devices, but, as a result of the flow separation that occurs at each turn, their operation is actually closer to a series of CFMRs. Nevertheless, these devices have excellent compartmentalization and virtually no short circuiting, two of their greater strengths. A variety of different approaches to around-the-end flocculators are illustrated schematically on Fig. 9-30 and photographically on Fig. 9-31.

The proper input by a hydraulic system is the product of the pressure and flow rate. Because pressure can be related to head loss by ( $\Delta P = \rho g \Delta H$ ), the RMS velocity gradient in a baffled basin can be determined from the

## Hydraulic Flocculation

**Figure 9-30** Examples of some alternative designs of hydraulic flocculators: (a) tapered horizontal baffled hydraulic flocculator, (b) helicoidal flow flocculator, (c) Alabama-type hydraulic flocculator, (d) variable-gate hydraulic flocculator, and (e) orifice and channel over and under flocculator. (Adapted from Kawamura, 2000.)

**Table 9-15**

Design criteria for hydraulic flocculation

Parameter	Unit	Value
Average $\bar{G}$	$s^{-1}$	30–40
Channel velocities	m/s	0.15–0.45
Minimum residence time	min	20
Head loss coefficient at 180° turn	—	3.2–3.5
Head loss coefficient through slit or port	—	1.5
Minimum distance between baffles <sup>a</sup>	m	0.75
Minimum water depth	m	1

<sup>a</sup>To facilitate cleaning.**Figure 9-31**

Views of tapered horizontal, baffled channel hydraulic flocculators.

following expression (Monk and Trussell, 1991):

$$\bar{G} = \left( \frac{P}{\mu V} \right)^{1/2} = \left( \frac{\rho g h Q}{\mu V} \right)^{1/2} = \left( \frac{\rho g h}{\mu \tau} \right)^{1/2} \quad (9-68)$$

where  $\rho$  = density of water,  $kg/m^3$   
 $g$  = acceleration due to gravity,  $9.81 \text{ m/s}^2$   
 $h$  = head loss through basin, m  
 $\mu$  = dynamic viscosity of water,  $N \cdot s/m^2$  ( $kg/m \cdot s$ )  
 $\tau$  = detention time, s

In the most common horizontal-flow baffled hydraulic flocculator, the head loss in a baffled mixing channel from turbulence and friction on the sides of the channel can be calculated using the expression

$$h = \frac{Lv^2}{C^2 R_h} \quad (9-69)$$

where  $L$  = length of channel, m  
 $v$  = velocity of flow in channel, m/s

$C$  = Chezy coefficient, unitless  
 $R_h$  = hydraulic radius of channel, m

Head loss resulting from each  $180^\circ$  turn can be estimated as follows (Monk and Trussell, 1991):

$$h = k \left( \frac{v^2}{2g} \right) \quad (9-70)$$

where  $k$  = head loss coefficient (typically 2.5 to 4), unitless

#### HYDRAULIC-JET FLOCCULATORS

In this flocculator design energy dissipation is achieved by using the energy of a hydraulic jet created as the flow enters each flocculation compartment. There are three types in use today: (1) the helicoidal flow flocculator, (2) the Alabama flocculator, and (3) the variable-gate flocculator. Each is shown on Fig. 9-30. The helicoidal flow flocculator organizes the flow from one sector of the flocculator compartment to the next so that flow travels in a helical pattern. Turbulence is created by the discharge jet as the flow enters each compartment. The Alabama flocculator uses a simple up/down flow arrangement with the jet being created by the entrance pipe. The variable-gate flocculator is a more complex, but flexible, design that enables hydraulic flocculation to achieve constant mixing at variable flow. The head loss through each type of device that is used to create a jet is slightly different.

#### COARSE-MEDIA FLOCCULATORS

In this flocculator design energy dissipation is achieved by turbulent flow through a coarse media. Coarse-media flocculators are also called roughing filters or adsorption clarifiers because the coarse media used for flocculation also have excellent properties for storing coagulated solids. Roughing filters are described in more detailed in Chap. 10. The coarse-media flocculation process has been successful in small package plants throughout much of the United States. One particularly successful application is the Siemens Microfloc Tri-Mite, which uses a buoyant plastic media that is easily cleaned (Monk and Trussell, 1991).

Combining hydraulic and mechanical flocculation sometimes allows the water utility to capitalize on the strengths of both approaches. Using such a combination, the number of mechanical flocculators is reduced, reducing the capital and maintenance costs and increasing the reliability. In such combinations, Kawamura (2000) recommends that mechanical flocculators be located at the end of the process to keep the floc in suspension during low-flow conditions. The Houston East (Houston, Texas) plant [150 mgd ( $6.5 \text{ m}^3/\text{s}$ )] and the Mohawk (Tulsa, Oklahoma) plant [100 mgd ( $4.4 \text{ m}^3/\text{s}$ )] both utilize this design and achieve excellent settled water turbidity and operate effectively during low-flow conditions by isolating some of the treatment trains (Kawamura, 2000).

**Important Design  
Features  
in Flocculation**

The size and shape of a flocculation basin are generally determined by the type of flocculator selected and the type of sedimentation process employed downstream. If mechanical flocculators are paired with rectangular, horizontal-flow sedimentation basins, the width and depth of the flocculation basins should match the width and depth of the sedimentation basins. Similar dimensions enhance constructability and reduce overall project costs.

**SIZE OF FLOCCULATION BASIN**

The size of the flocculation basin and the flocculation time are determined by the downstream liquid–solid separation technology used. Typically, flocculation times range from 20 to 45 min for plants that use conventional settling and plate-and-tube settlers, depending on the characteristics of the raw water, water temperature, and type of coagulant used. For low-turbidity raw water in cold regions, the flocculation time should be at least 30 min. A flocculation time of 15 min is typical for direct filtration and a flocculation of time of 5 to 10 min is typical for dissolved air flotation (DAF). Jar or bench tests, conducted in conjunction with pilot studies, will aid in producing accurate design criteria. However, it is important that such tests be conducted at a representative temperature.

Although no mechanistic principle has been developed to define the relationship between basin area and water depth, Kawamura (2000) notes that basins with depths in excess of 5 m (16.5 ft) sometimes display unstable flow patterns and poor flocculation.

**INLET AND OUTLET ARRANGEMENTS**

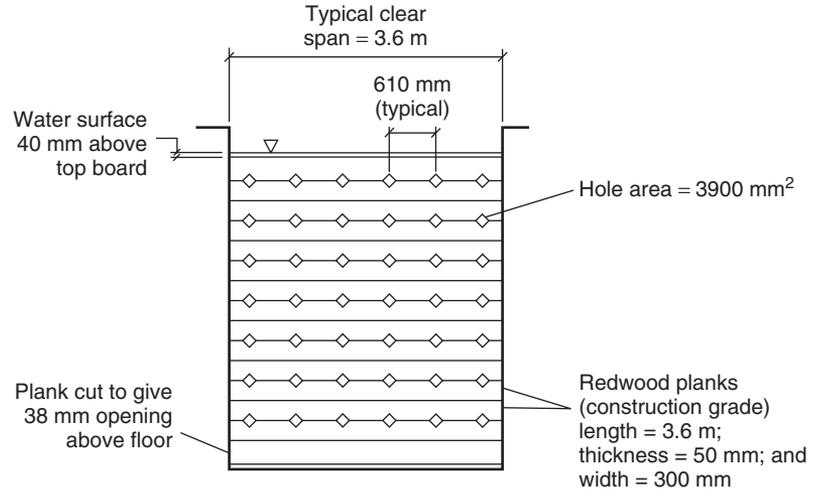

Another important consideration in flocculation basin design is uniform hydraulic loading to each basin. There are three basic types of basin inlet structures: a simple pipe connection to the basin, a weir inlet, and a submerged orifice inlet. The plant layout (especially the symmetry of the basin layout to inlet line) and maintaining an appropriate flow velocity in the distribution pipe or channel will greatly minimize uneven flow distribution to each basin regardless of the inlet type selected (Chao and Trussell, 1980).

**DIFFUSER WALLS**

Diffuser walls are often used to divide flocculation basins into separate compartments (see Fig. 9-32), to place a hydraulic division between flocculation and sedimentation basins, as well as in other situations where an even velocity profile is required and backmixing is undesirable.

*Separating flocculation and sedimentation*

As water leaves the flocculation tank after treatment, the flocs that have been formed should not be broken before they enter the liquid–solid

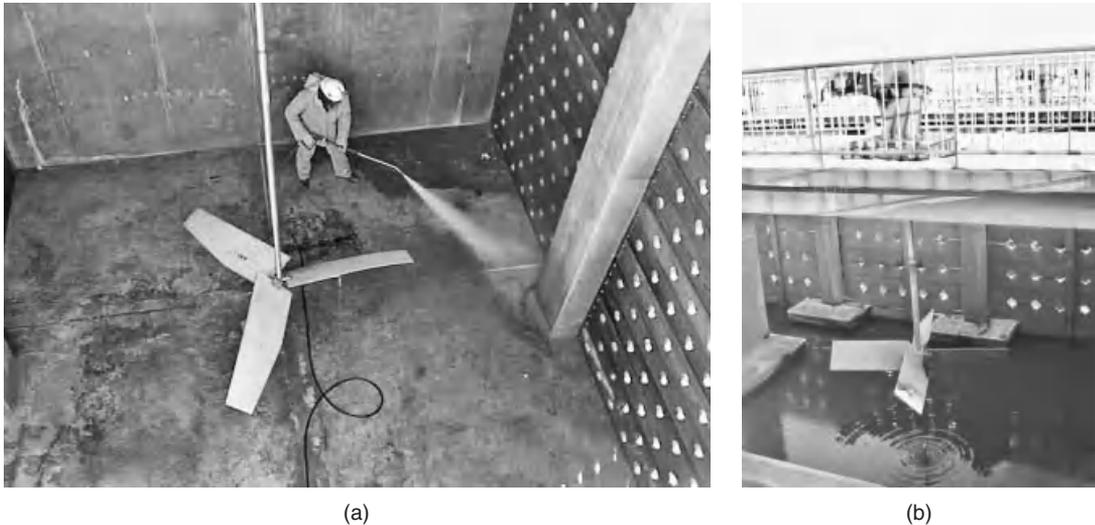

**Figure 9-32**  
Typical design of diffuser wall (see also Table 9-16 for additional design details).

separation process. The problem with this sensible requirement is that it is in direct conflict with the need to establish a uniform velocity profile across the entrance of the sedimentation tank, a requirement that is usually met through the dissipation of head loss. When conventional settling is used, a simple approach is to build the flocculation tanks as an integral part of the settling tank and provide a diffuser wall between the two tanks. The diffuser wall must have enough head loss to establish a uniform discharge profile, and yet it must not create turbulence that will shear floc. Based on operating experience, it has been found that a permeable baffle wall between the flocculation and sedimentation basins with a head loss of approximately 3 to 4 mm can be effective.

#### *Separating flocculation compartments*

As discussed earlier in the chapter, the performance of flocculation may be improved through compartmentalization to minimize short circuiting of flow. Diffuser walls are typically used for this purpose, as shown on Fig. 9-33. Baffles are placed after each flocculation stage, perpendicular to the flow path. Baffles can be specified in various shapes and arrangements, but the baffle opening must be sized correctly. The top of the baffle should be slightly submerged (30 to 40 mm) so scum does not accumulate behind the baffle, and the bottom of the baffle should also be 30 to 40 mm above the floor of the flocculator to facilitate drainage and sludge removal. If the flocculation tank is designed as an integral part of the sedimentation basin, a diffuser wall should be provided at the end of the flocculation tank to assure uniform flow distribution into the sedimentation tank.

**Figure 9-33**

Views of vertical-turbine flocculators in basin separated by diffuser walls. Typical design details for a diffuser wall are presented in Fig. 9-32 and Table 9-16.

**Table 9-16**

Diffuser wall design guidelines for flocculation basins

Parameter	Unit	Guideline
Opening area	Percent of flow cross section	2–5
Velocity through orifice		
Dividing first and second floc basins	m/s	0.55
Dividing floc and sedimentation basins	m/s	0.35
Head loss across baffle		
Dividing first and second floc basins	mm	7–9
Dividing floc and sedimentation basins	mm	3–4
Submergence of highest port	mm	15
Clearance below baffle for sludge	mm	25

Source: Adapted in part from Kawamura (2000).

#### *Design of diffuser walls*

Design criteria for diffuser walls are summarized in Table 9-16. Generally such diffusion walls are constructed of lumber, redwood when it is available, but there is no requirement other than that a durable, water-resistant material be employed. The diffuser wall shown on Fig. 9-33 is illustrative of a simple design that is easily constructed, requiring no special sophistication on the part of the contractor.

## Problems and Discussion Topics

- 9-1 If the electrophoretic velocity of a migrating particle is  $12.5 \mu\text{m/s}$  and the electrical field is  $100 \text{ V/cm}$ , estimate the zeta potential at  $25^\circ\text{C}$  if the value of the constant  $K_2$  is  $4\pi$ . The viscosity of water at  $25^\circ\text{C}$  is  $0.89 \times 10^{-3} \text{ N} \cdot \text{s/m}^2$ , and the relative permittivity for water is 78.54.
- 9-2 Particles are present in a water with the following chemical characteristics. Estimate the thickness of the particle electrical double layer.

Cation	Concentration, mg/L	Anion	Concentration, mg/L
$\text{Ca}^{2+}$	40.0	$\text{HCO}_3^-$	91.5
$\text{Mg}^{2+}$	12.2	$\text{SO}_4^{2-}$	72
$\text{Na}^+$	15.1	$\text{Cl}^-$	22.9
$\text{K}^+$	5.1	$\text{NO}_3^-$	5.0

- 9-3 Determine the thickness of the particle electrical double layer if the ionic strength is  $0.0025 \text{ mol/L}$ .
- 9-4 Prepare a plot of the thickness of the electrical double layer versus the ionic strength.
- 9-5 Calculate the amount of  $\text{Fe}(\text{OH})_3$  precipitate formed and amount of alkalinity consumed (expressed as  $\text{CaCO}_3$ ) by a  $25 \text{ mg/L}$  dose of ferric sulfate  $[\text{Fe}_2(\text{SO}_4)_3]$ .
- 9-6 A natural water with a flow of  $3800 \text{ m}^3/\text{d}$  is to be treated with an alum dose of  $60 \text{ mg/L}$ . Determine the chemical feed rate for the alum, the amount of alkalinity consumed by the reaction, and the amount of precipitate produced in  $\text{mg/L}$  and  $\text{kg/day}$ .
- 9-7 Determine the amount of  $\text{Fe}(\text{OH})_3$  produced and the amount of alkalinity consumed when  $60 \text{ mg/L}$  of ferric chloride  $[\text{FeCl}_3 \cdot 6\text{H}_2\text{O}]$  is added to a natural water. Assume enough alkalinity is present.
- 9-8 Determine the basicity of the following PACl compounds: (a)  $\text{Al}_4(\text{OH})_6(\text{Cl}_2)_2$ , (b)  $\text{Al}_2(\text{OH})_2\text{Cl}_2\text{SO}_4$ , and (c)  $\text{Al}_{15}\text{O}_6(\text{OH})_{24}\text{SO}_4$ .
- 9-9 The following data were obtained from a bench-scale coagulation flocculation test. Using these data, estimate the alum dosage for turbidity removal and for NOM removal.

Alum Dose, mg/L	DOC, mg/L	Turbidity, NTU
0.00	5.00	2.50
10.0	5.10	2.05
20.0	5.25	1.65
30.0	5.00	1.25
40.0	4.50	0.800
50.0	4.00	0.500
60.0	3.40	0.480
70.0	2.80	0.470
80.0	2.45	0.450
100	2.00	0.440
120	1.95	
140	1.90	

- 9-10 Estimate the DOC removal using alum as a function of dose for a concentration range varying from 10 to 90 mg/L for the following conditions: initial DOC = 5 mg/L, initial  $UV_{254}$  absorbance =  $0.138 \text{ cm}^{-1}$ , and pH = 7.
- 9-11 Estimate the DOC removal using ferric chloride as a function of dose varying from 5 to 50 mg/L for the following conditions: initial DOC = 5 mg/L, initial  $UV_{254}$  absorbance =  $0.138 \text{ cm}^{-1}$ , and pH = 7.
- 9-12 Using the collision frequency functions for macroscale flocculation, microscale flocculation, and flocculation due to differential settling given by Eqs. 9-35, 9-47, and 9-55, respectively, demonstrate the correctness of Fig. 9-19. Use a particle size  $d_i$  of  $2.0 \mu\text{m}$  and particles  $d_j$  ranging in size from  $100 \text{ \AA}$  to  $50 \mu\text{m}$ , a  $\bar{G}$  value of  $100 \text{ s}^{-1}$ , and a water temperature of  $15^\circ\text{C}$ .
- 9-13 Based on your reading of this chapter, provide a brief answer to the following questions: (a) Who first came up with the principal idea behind flocculation theory? When? (b) Who were the first people to put flocculation into practice? When? (c) Who proposed the concept of RMS velocity gradient? When?
- 9-14 Based on your reading of this chapter, provide a brief answer to the following questions: (a) Flocculation installations can be divided into what two groups? (b) Which type of flocculator produces very large and fluffy floc? (c) What are two advantages of vertical turbines versus horizontal-shaft paddles for flocculation? (d) What are the two principal impeller types used for flocculation? (e) What is the principal disadvantage of hydraulic flocculators?

- 9-15 Which impeller is better at keeping solids suspended in a tank?
- 9-16 A first-stage flocculator uses a six-bladed Rusthon turbine 2 m in diameter rotating at 25 rev/min. What is the Reynolds number? How much power must be applied to the shaft to rotate it? What flow does the impeller pump?
- 9-17 The impeller in Problem 9-16 is in a tank 4 m square and 4 m deep. Calculate the tank turnover time and  $\bar{G}$  values.
- 9-18 What is the largest paddle wheel that meets the design criteria in Table 9-14? How many paddle boards may be used on such a wheel?
- 9-19 Design a flocculation compartment for a horizontal-shaft flocculator with two paddles like that in Example 9-9. How fast must the paddle wheel rotate in that compartment to generate a  $\bar{G}$  value  $30 \text{ s}^{-1}$ ?
- 9-20 What is the minimum water depth for a hydraulic flocculator?
- 9-21 Describe, in your own words, the principal advantages of an Alabama flocculator versus a variable gate flocculator.

## Terminology for Gravity Separation

<b>Term</b>	<b>Definition</b>
Colloidal particles	Very small particles that do not settle out of water for a long time because of their small size and electrical charge.
Compression settling (Type IV)	Particle blanket containing a high concentration of particles that compresses by allowing water to move up through the voids within the blanket due to the weight of the particles in the blanket.
Density currents	Nonideal flow patterns that occur in sedimentation basins caused by differences in fluid density (e.g., temperature, solids concentrations) within the tank and outside forces (e.g., wind) acting on the fluid in the tank.
Discrete particles	Particles that are completely surrounded by water and have no interactions with other particles in the water.
Discrete settling (Type I)	Settling of discrete particles in water by gravity with no interactions with other particles in the water.
Dissolved air flotation	Gravity separation process in which dissolved air forms tiny bubbles in the water at the bottom of a basin. As the bubbles float upward, they attach to particles, causing the particles to float to the surface where they can be removed by skimming.
Flocculent settling (Type II)	Process in which initially discrete or flocculated particles interact with one another during the settling and form larger particles with higher settling velocities.

<b>Term</b>	<b>Definition</b>
Gravity separation	Process of removing particles suspended in water by the force of gravity.
Hindered settling (Type III)	Process in which particles interact to retard the settling of nearby particles, resulting in the formation of a layer or blanket that settles and also overtakes other particles in its path.
Particle settling velocity	Rate at which a particle settles in water.
Sedimentation basins	Tanks or chambers designed to separate and remove settleable particles from water.
Settleable particles	Suspended particles in water that can be removed by the process of gravity separation.
Stokes' law	Mathematical expression used to predict the terminal settling velocity of a discrete particle falling in a viscous fluid under the force of gravity.
Suspended particles	Small organic or inorganic material or solids found in water.

Gravity separation of suspended material from water is the oldest and most widely used process in water treatment. Gravity separation historically has meant sedimentation, where water is introduced into a large quiescent basin for a long enough period of time so that the majority of the particles in the water settle to the bottom of the basin. Most raw surface waters will contain mineral particles and organic particles. Mineral particles usually have densities ranging from 2000 to 3000 kg/m<sup>3</sup> and will settle out readily by gravity, whereas organic particles with densities of 1010 to 1100 kg/m<sup>3</sup> may require a long time to settle by gravity. In a conventional treatment train, sedimentation follows coagulation and flocculation, which are used to destabilize particles and form large aggregates that will settle out of suspension in a reasonable time period. Over time, sedimentation practice has undergone a number of changes. Sedimentation tanks have been modified to accelerate the separation process. More recently, air bubbles have been used to float particles to the water surface for removal. Adding air bubbles to the water is known as dissolved air flotation (DAF), which is discussed in this chapter along with more traditional gravity separation processes.

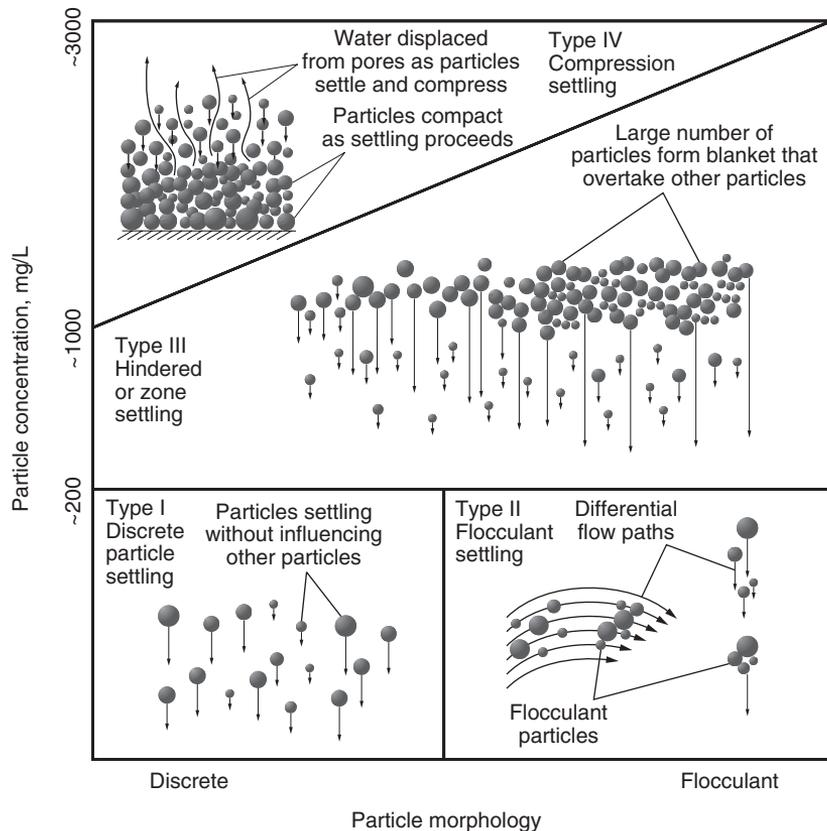

The removal of suspended matter from water at low cost and low energy consumption is conceptually simple but often involves complications that render proper sedimentation basin design a challenge for many engineers. The performance of a sedimentation basin for a given raw-water quality

can be understood with the help of particle-settling theories. When supplemented with the understanding of the practical aspects of sedimentation basin design, sedimentation basins can be designed to perform reliably and consistently.

The topics discussed in this chapter include (1) the classification of particles for settling, (2) principles of discrete particle settling, (3) discrete particle settling in sedimentation basins, (4) principles of flocculant settling, (5) principles of hindered settling, (6) conventional sedimentation basin design, (7) alternative sedimentation processes, (8) physical factors affecting sedimentation, and (9) dissolved air flotation.

## 10-1 Classification of Particles for Settling

Particles are separated into four classifications based on their concentration and morphology, as shown on Fig. 10-1. Type I particles are discrete and do

**Figure 10-1**  
Relationship between settling type, concentration, and flocculent nature of particles.

not interfere with one another during settling because the concentration is low and they do not flocculate. Type I suspensions are found in grit chambers, presedimentation basins for sand removal prior to coagulation, and settling of sand particles during backwashing of rapid sand filters. Type II suspensions consist of particles that can adhere to each other if they bump into each other (i.e., they are capable of flocculating). As particles aggregate and grow in size, they can settle faster. Type II suspensions are found when settling occurs following iron and alum coagulation and in most conventional sedimentation basins.

At concentrations higher than Type I and II suspensions, hindered, or Type III, settling occurs. In hindered settling, a blanket of particles is formed. The blanket traps particles below it as it settles; consequently, a clear interface is found above the blanket. The settling velocity of the blanket depends on the suspended solids concentration, with the blanket velocity decreasing with increasing concentration. Type III suspensions are found in thickeners (sludge disposal) and the bottom of some sedimentation basins (e.g., lime-softening sedimentation).

At much higher concentrations than are found in Type III settling, the suspension begins to consolidate slowly. This type of settling or consolidation is known as Type IV settling or compression settling. For Type IV suspensions, the particles may not really settle, and a more correct visualization of what is occurring is that water flows or drains out of a mat of particles very slowly. Type IV suspensions are found in dewatering operations, and once they are dewatered, the suspension may become a paste or cake.

## 10-2 Principles of Discrete (Type I) Particle Settling

---

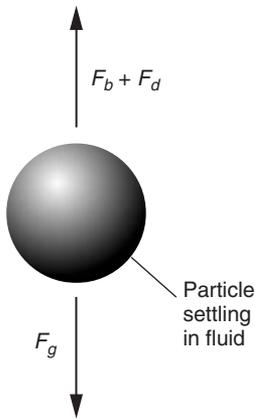

In a dilute suspension, individual particles settle based on their size and density and do not interact with each other. Settling only occurs if the vertical movement overcomes the random movement of particles. This section develops the equations that describe settling velocity and then compares the settling velocity to the velocity due to Brownian motion.

A particle moving vertically through a fluid is subjected to gravitational and drag forces. The vertical forces acting on the particle are shown in the free-body diagram on Fig. 10-2 and the force balance is given by the expression

$$\sum F = F_g - F_b - F_d \quad (10-1)$$

where  $F_g$  = gravitational force, N  
 $F_b$  = buoyant force, N  
 $F_d$  = drag force, N

**Settling Velocity  
of Discrete  
Particles**

**Figure 10-2**  
Forces acting on settling particle.

The force balance is written so that the direction of gravitational force is positive. Therefore, a positive settling velocity means that the particle settles and a negative settling velocity means the particle rises. The gravitational and buoyant forces are given by  $F = ma$ , as follows:

$$F_g = ma = \rho_p V_p g \quad (10-2)$$

$$F_b = ma = \rho_w V_p g \quad (10-3)$$

where  $m = \text{mass, kg}$   
 $a = \text{acceleration, m/s}^2$   
 $\rho_p = \text{density of particle, kg/m}^3$   
 $\rho_w = \text{density of water, kg/m}^3$   
 $V_p = \text{volume of particle, m}^3$   
 $g = \text{acceleration due to gravity, 9.81 m/s}^2$

In 1647, Issac Newton proposed that the drag force could be described by the expression

$$F_d = \frac{1}{2} C_d \rho_w A_p v_s^2 \quad (10-4)$$

where  $C_d = \text{drag coefficient, unitless}$   
 $A_p = \text{projected area of the particle in direction of flow, m}^2$   
 $v_s = \text{settling velocity of the particle, m/s}$

If the particles are spherical, the volume and projected area are given by the following expressions:

$$V_p = \frac{\pi}{6} d_p^3 \quad (10-5)$$

$$A_p = \frac{\pi}{4} d_p^2 \quad (10-6)$$

where  $d_p = \text{particle diameter, m}$

If a particle starts at rest, it will accelerate due to an imbalance in forces. As the particle velocity increases, the drag force increases until the vertical forces are balanced (i.e.,  $\Sigma F = 0$ ). At that time, the particle reaches a constant velocity known as its terminal settling velocity. For conditions typical in water treatment, the period of initial acceleration is extremely short and not relevant in sedimentation basin design. By substituting Eqs. 10-2 to 10-6 into Eq. 10-1 and setting  $\Sigma F = 0$ , the following expression for terminal settling velocity is obtained:

$$v_s = \sqrt{\frac{4g(\rho_p - \rho_w) d_p}{3C_d \rho_w}} \quad (10-7)$$

The drag coefficient as defined in Eq. 10-4 generally cannot be predicted theoretically. Drag coefficients are determined experimentally by

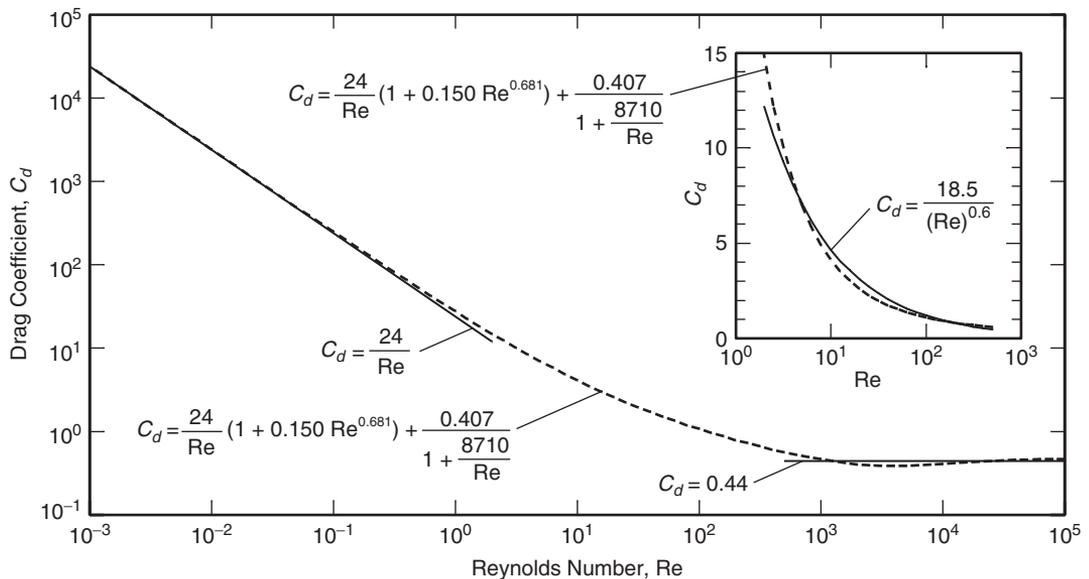

measuring settling velocity in laboratory experiments and then calculating the drag coefficient using Eq. 10-7. Analysis of experimental data reveals that the drag coefficient depends on the Reynolds number, where the Reynolds number is defined as

$$\text{Re} = \frac{\rho_w v_s d_p}{\mu} = \frac{v_s d_p}{\nu} \quad (10-8)$$

where  $\text{Re}$  = Reynolds number, dimensionless  
 $\mu$  = dynamic viscosity,  $\text{N} \cdot \text{s}/\text{m}^2$  or  $\text{kg}/\text{m} \cdot \text{s}$   
 $\nu$  = kinematic viscosity,  $\text{m}^2/\text{s}$

The drag coefficient for spheres as a function of Reynolds number is shown on Fig. 10-3. At low Reynolds numbers (laminar region), viscous forces control the drag force and the drag coefficient is larger because momentum is transferred farther into the fluid. As the Reynolds number increases, inertial forces become more significant. In the turbulent regime, inertial forces of displaced fluid control the drag force (the particle basically punches a hole in the fluid equal to the size of the projected area) and the drag coefficient becomes a constant.

Over the years, many researchers have collected experimental settling velocity data and developed various empirical correlations for the drag coefficient, some easier to use than others. Brown and Lawler (2003) conducted a rigorous reevaluation of much of the existing settling velocity

**Figure 10-3**  
 Newton's coefficient of drag for varying magnitudes of Reynolds numbers.

data and proposed an empirical correlation for the drag coefficient that fit all experimental data less than  $Re = 2 \times 10^5$ . The proposed correlation is

$$C_d = \frac{24}{Re}(1 + 0.150 Re^{0.681}) + \frac{0.407}{1 + 8710/Re} \quad (10-9)$$

While this correlation results in a single equation for drag coefficient that covers a wide range of Reynolds numbers, it cannot be substituted into Eq. 10-7 and easily manipulated to produce an equation for settling velocity. Thus, it is useful to develop simpler correlations that are reasonably accurate over smaller ranges of Reynolds numbers. For spherical particles, the drag coefficient  $C_d$  can be approximated by the following expressions, depending on the magnitude of the Reynolds number (Clark, 1996):

$$C_d = \frac{24}{Re} \quad \text{for } Re < 2 \quad (\text{laminar flow}) \quad (10-10)$$

$$= \frac{18.5}{Re^{0.6}} \quad \text{for } 2 \leq Re \leq 500 \quad (\text{transition flow}) \quad (10-11)$$

$$= 0.44 \quad \text{for } 500 < Re \leq 2 \times 10^5 \quad (\text{turbulent flow}) \quad (10-12)$$

For comparison purposes, drag coefficients calculated using Eqs. 10-9 to 10-12 are shown in Fig. 10-3. Equation 10-9 should be considered for rigorous laboratory studies, but in full-scale systems, confounding factors such as heterogeneities in particle size and geometry and currents in fluid flow reduce the usefulness of a highly accurate equation for drag coefficient. In those circumstances, the simpler Eqs. 10-10 to 10-12 are sufficient.

The equations for drag coefficients can be substituted into Eq. 10-7 to develop equations for settling velocity as a function of flow regime. In water treatment, particle settling generally occurs in the laminar and transition flow regimes. For laminar and transition flow, respectively, the equation becomes

$$v_s = \frac{g(\rho_p - \rho_w)d_p^2}{18\mu} \quad (\text{laminar flow}) \quad (10-13)$$

$$= \left[ \frac{g(\rho_p - \rho_w)d_p^{1.6}}{13.9\rho_w^{0.4}\mu^{0.6}} \right]^{1/1.4} \quad (\text{transition flow}) \quad (10-14)$$

Equation 10-13, for spherical particles and laminar flow, is commonly referred to as Stokes' law.

Equation 10-13 or 10-14 is used to calculate the settling velocity depending on whether the particle is in laminar or transition flow. However, the flow regime depends on the settling velocity, so it is not possible to predict a priori which equation applies. It is necessary to calculate the settling velocity using one of the equations, then calculate the flow regime based on the resultant settling velocity, and recalculate the settling velocity with

the other equation if necessary. For sand particles (density = 2650 kg/m<sup>3</sup>) and a temperature of 20°C, Stokes' law is valid for particles up to 0.13 mm in diameter, and Eq. 10-14 is valid for particles up to 1.7 mm in diameter. Calculating terminal settling velocity is demonstrated in Example 10-1.

### Example 10-1 Calculating terminal settling velocity

Calculate the terminal settling velocity for sand in water at 10°C having particle diameters of 75 and 180 μm and a density of 2650 kg/m<sup>3</sup>. The density and viscosity of water at 10°C is available in Table C-1 in App. C.

#### Solution

1. Calculate the settling velocity and Reynolds number for the 75-μm sand particles.
  - a. Since the settling velocity is unknown, the Reynolds number is also unknown. First, calculate settling velocity using Eq. 10-13 (Stokes' law). From Table C-1 in App. C,  $\mu = 1.307 \text{ N} \cdot \text{s/m}^2$  (or  $\text{kg/m} \cdot \text{s}$ ) and  $\rho_w = 999.7 \text{ kg/m}^3$ .

$$v_s = \frac{(9.81 \text{ m/s}^2)(2650 - 999.7 \text{ kg/m}^3)(75 \times 10^{-6} \text{ m})^2}{18(1.307 \times 10^{-3} \text{ kg/m} \cdot \text{s})}$$

$$= 0.00387 \text{ m/s}$$

- b. Check the Reynolds number using Eq. 10-8:

$$\text{Re} = \frac{\rho_w v_s d_p}{\mu}$$

$$= \frac{(999.7 \text{ kg/m}^3)(75 \times 10^{-6} \text{ m})(0.00387 \text{ m/s})}{1.307 \times 10^{-3} \text{ kg/m} \cdot \text{s}}$$

$$= 0.22$$

Because  $\text{Re} < 2$ , laminar flow exists and Stokes' law is valid. The settling velocity of a 75-μm sand particle in water is 0.00387 m/s (13.9 m/h).

2. Calculate the settling velocity and Reynolds number for the 180-μm sand particles.
  - a. Calculate the settling velocity using Eq. 10-13:

$$v_s = \frac{(9.81 \text{ m/s}^2)(2650 - 999.7 \text{ kg/m}^3)(1.80 \times 10^{-4} \text{ m})^2}{18(1.307 \times 10^{-3} \text{ kg/m} \cdot \text{s})}$$

$$= 0.0223 \text{ m/s}$$

b. Check the Reynolds number using Eq. 10-8:

$$\begin{aligned} \text{Re} &= \frac{(999.7 \text{ kg/m}^3)(1.80 \times 10^{-4} \text{ m})(0.0223 \text{ m/s})}{1.307 \times 10^{-3} \text{ kg/m} \cdot \text{s}} \\ &= 3.07 \end{aligned}$$

Since  $\text{Re} > 2.0$ , Stokes' law is not valid.

c. Calculate the settling velocity using Eq. 10-14:

$$\begin{aligned} v_s &= \left[ \frac{(9.81 \text{ m/s}^2)(2650 - 999.7 \text{ kg/m}^3)(1.80 \times 10^{-4} \text{ m})^{1.6}}{13.9(999.7 \text{ kg/m}^3)^{0.4}(1.307 \times 10^{-3} \text{ kg/m} \cdot \text{s})^{0.6}} \right]^{1/1.4} \\ &= 0.0195 \text{ m/s} \end{aligned}$$

d. Check the Reynolds number using Eq. 10-8:

$$\begin{aligned} \text{Re} &= \frac{(999.7 \text{ kg/m}^3)(1.80 \times 10^{-4} \text{ m})(0.0195 \text{ m/s})}{1.307 \times 10^{-3} \text{ kg/m} \cdot \text{s}} \\ &= 2.68 \end{aligned}$$

Because  $\text{Re} > 2$ , transition flow exists and Eq. 10-14 is valid. The settling velocity of a 180- $\mu\text{m}$  sand particle in water is 0.0195 m/s (70.1 m/h).

If the particles are hard spheres, the settling velocity as a function of particle size does follow Eq. 10-13 or 10-14. However, flocculated particles have fractal morphology and are composed of many flocculated small particles. Consequently, fractal particles do not settle as rapidly as would be estimated using a hard-sphere model. Fractal particles are discussed in Chap. 9 and a detailed discussion of fractals can be found in Logan (1999).

### Brownian Motion

Particles in natural waters can be so small that they do not settle because random movement caused by collisions with fluid molecules, known as Brownian motion, can overwhelm the vertical movement due to gravity. As presented in Chap. 7, Einstein equated the drag force (Eq. 10-4) to the force of the collisions between fluid molecules and particles resulting from the kinetic energy of the fluid molecules. For spherical particles and perfect elastic collisions, the mean square distance traveled by a particle due to Brownian motion can be described by the following relationship:

$$\overline{x^2} = \frac{2kT}{3\pi\mu d_p} t \quad (10-15)$$

where  $x$  = distance traveled due to Brownian motion, m  
 $k$  = Boltzmann's constant,  $1.38 \times 10^{-23}$  J/K

$T$  = absolute temperature, K ( $273 + ^\circ\text{C}$ )

$t$  = time, s

$\mu$  = dynamic viscosity,  $\text{N} \cdot \text{s}/\text{m}^2$

$d_p$  = particle diameter, m

When the movement due to Brownian motion is large relative to the movement due to settling, particles will not settle out of solution because the motion of the particle will be governed by collisions with water molecules. A comparison of Brownian motion and settling velocity is demonstrated in Example 10-2.

### Example 10-2 Comparison between distance traveled by Brownian motion and Stokes' settling

Estimate the size of a sand particle ( $sg_p = 2.65$ ) that would move the same distance in 1 s due to Brownian motion as it would settle in water at  $20^\circ\text{C}$  based on Stokes' law.

#### Solution

1. Rearrange Stokes' law to solve for the distance settled in 1 s, noting that  $v = x/t$ :

$$x_s = \frac{g(\rho_p - \rho_w)d_p^2}{18\mu}t$$

2. Set the equation from step 1 equal to the distance traveled by a particle by Brownian motion, and solve for particle size:

$$\left(\frac{2kT}{3\pi\mu d_p}t\right)^{0.5} = \frac{g(\rho_p - \rho_w)d_p^2}{18\mu}t$$

$$\frac{2kT}{3\pi\mu d_p}t = \left[\frac{g(\rho_p - \rho_w)t}{18\mu}\right]^2 d_p^4$$

$$d_p^5 = \frac{2kT(18\mu)^2}{3\pi\mu g^2(\rho_p - \rho_w)^2 t}$$

$$d_p = \left[\frac{216kT\mu}{\pi g^2(\rho_p - \rho_w)^2 t}\right]^{1/5}$$

3. Substitute the values from the problem statement and solve for the particle size. The density and viscosity of water at  $20^\circ\text{C}$  is available

in Table C-1 in App. C. At 20°C,  $\rho = 998.2 \text{ kg/m}^3$  and  $\mu = 1.002 \times 10^{-3} \text{ N} \cdot \text{s/m}^2$ . Note that the units for joules can be converted  $1 \text{ J} = 1 \text{ kg} \cdot \text{m}^2/\text{s}^2$ .

$$d_p = \left[ \frac{(216)(1.38 \times 10^{-23} \text{ kg} \cdot \text{m}^2/\text{s}^2 \cdot \text{K})(293 \text{ K})(1.002 \times 10^{-3} \text{ kg/m} \cdot \text{s})}{\pi (9.81 \text{ m/s}^2)^2 (2650 - 998.2 \text{ kg/m}^3)^2 (1 \text{ s})} \right]^{1/5}$$

$$= 1.01 \times 10^{-6} \text{ m} = 1.01 \text{ } \mu\text{m}$$

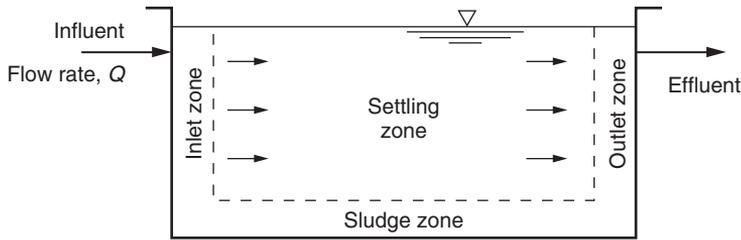

### Comment

Based on this estimate, a 1- $\mu\text{m}$  sand particle with a specific gravity of 2.65 will move about the same distance by Brownian motion and it would by settling in 1 s. Thus, particles smaller than this are unlikely to settle in a reasonable period of time because Brownian motion would keep them suspended. Clearly, the relationship between Brownian motion and settling velocity is not exact (i.e., particles will settle more slowly as the Brownian motion increases relative to the settling velocity, but there is not an exact point below which particles suddenly become nonsettleable). Nevertheless, the observation that particles smaller than about 1  $\mu\text{m}$  exhibit poor settling characteristics is correct. Coagulation and flocculation (Chap. 9) can be used to coalesce these particles into a form that settles more readily.

## 10-3 Discrete Settling in Ideal Sedimentation Basins

Particle settling is dependent on the nature of the particle and geometry of the sedimentation process. As introduced in Sec. 10-1, there are four main types of particle settling (see Fig. 10-1). The analysis of discrete particle settling in sedimentation basins, based on the principles presented in Sec. 10-2, is introduced in this section.

The theory for ideal settling was originally put forth by Hazen (1904). Camp (1936) later developed a rational theory for the removal of discrete particles in an ideal sedimentation basin. Camp divided a settling tank into four zones, as illustrated on Fig. 10-4. The inlet, sludge, and outlet zones were considered special tank areas that permit ideal settling in the settling zone but do not achieve particulate removal. In addition, the following assumptions were made by Camp to develop a theoretical basis for the removal of discrete particles: (1) plug flow conditions exist in the settling zone, (2) there is uniform horizontal velocity in the settling zone, (3) there

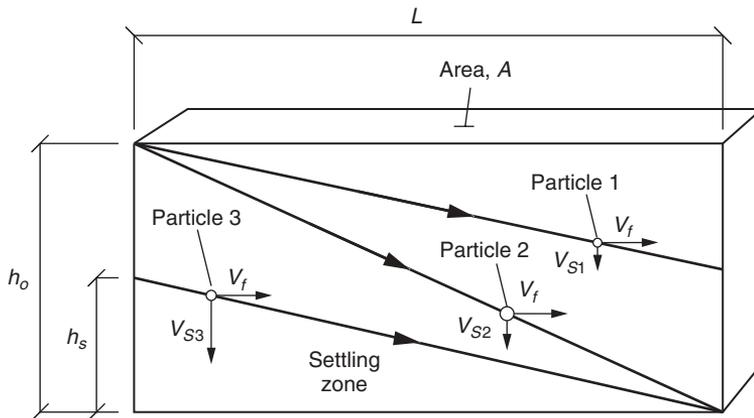

**Figure 10-4**  
Functional regions within rectangular clarifier.

is uniform concentration of all size particles across a vertical plane at the inlet end of the settling zone, (4) particles are removed once they reach the bottom of the settling zone, and (5) particles settle discretely without interference from other particles at any depth.

Particle trajectories have two components in the settling zone: the settling velocity  $v_s$  and the fluid velocity  $v_f$ , as shown on Fig. 10-5. For a rectangular sedimentation basin the fluid velocity is constant. The settling velocity for discrete particles is also constant because the particles do not flocculate or interfere with one another. Since both horizontal and vertical components of the velocity are constant, the particle trajectories are linear. As noted above, every particle that enters the sludge zone is removed. A particle from the inlet zone that enters at the top of the basin and settles in the sludge zone just before the outlet is assigned a settling velocity of  $v_c$ , or a critical settling velocity (particle 2 in Fig. 10-5). The critical particle settling velocity is given by the equation

$$v_c = \frac{h_o}{\tau} \tag{10-16}$$

### Rectangular Sedimentation Basins

**Figure 10-5**  
Discrete particle trajectories in settling zone of a rectangular clarifier.

where  $v_c$  = particle settling velocity such that particle at surface of inlet is removed in sludge zone just before outlet, m/h  
 $h_o$  = depth of sedimentation basin, m  
 $\tau$  = hydraulic detention time of sedimentation basin, h

The critical settling velocity may be defined as the overflow rate using the relationships

$$v_c = \frac{h_o}{\tau} = \frac{h_o Q}{h_o A} = \frac{Q}{A} = \text{OR} \quad (10-17)$$

where OR = overflow rate,  $\text{m}^3/\text{m}^2 \cdot \text{h}$  (equal to  $v_c$ )  
 $A$  = area of top of basin settling zone (see Fig. 10-5),  $\text{m}^2$   
 $Q$  = process flow rate,  $\text{m}^3/\text{h}$

The inlet zone is assumed to be homogenous; therefore, particles may enter the settling zone at any height  $h_s$ . Any particles in the inlet zone with a settling velocity  $v_s$  greater than or equal to the critical settling velocity  $v_c$  will be removed regardless of the starting position because their trajectories will take them into the sludge zone before they exit the basin.

Particles with a settling velocity less than  $v_c$  may also be removed, depending on their position at the inlet, as shown on Fig. 10-5. Particles at the top of the basin will pass through the settling zone and exit in the outlet zone and will not be removed. However, particles starting at position  $h_s$  and lower will enter the sludge zone before exiting the basin and will be removed. The fraction of particles that will be removed is given by the expression

$$\text{Fraction of particles removed} = \frac{h_s}{h_o} = \frac{h_s/\tau}{h_o/\tau} = \frac{v_s}{v_c} \quad (v_s < v_c) \quad (10-18)$$

where  $h_s$  = height of particle from bottom of tank at position entering settling zone, m  
 $v_s$  = particle settling velocity smaller than  $v_c$ , m/h

Other terms are as defined above. Removal of particles as a function of size is demonstrated in Example 10-3.

### Example 10-3 Particle removal in sedimentation basin

Calculate the particle removal efficiency in a rectangular sedimentation basin with a depth of 4.5 m, width of 6 m, length of 35 m, and process flow rate of  $525 \text{ m}^3/\text{h}$ . Compute the required sedimentation basin design parameters

and plot the influent and effluent particle concentrations as a function of particle size using a histogram. Assume the following influent particle-settling characteristics (adapted from Tchobanoglous et al., 2003):

Settling Velocity, m/h	Number of Particles, #/mL
0–0.4	511
0.4–0.8	657
0.8–1.2	876
1.2–1.6	1168
1.6–2.0	1460
2.0–2.4	1314
2.4–2.8	657
2.8–3.2	438
3.2–3.6	292
3.6–4.0	292
Total	7665

### Solution

1. Compute the sedimentation basin overflow rate and critical settling velocity using Eq. 10-17:

$$\text{OR} = v_c = \frac{Q}{A} = \frac{525 \text{ m}^3/\text{h}}{(6 \text{ m})(35 \text{ m})} = 2.5 \text{ m}^3/\text{m}^2 \cdot \text{h}$$

2. Compute the percent removal of particles in each size range using a data table.
  - a. Compute the average settling velocity for each particle size range; see column 2 in the table below.
  - b. Compute the fraction of particles removed using Eq. 10-18. For particles with an average settling velocity of 1.0 m/h, the fraction of particles removed is  $(1.0 \text{ m/h})/(2.5 \text{ m}^3/\text{m}^2 \cdot \text{h}) = 0.4$ ; see column 4. Note that for particle-settling ranges with a fraction removed greater than 1, a value of 1 should be used.
  - c. Estimate the number of particles that will be removed and remaining in each size range. The number of particles removed is determined by multiplying the influent particle concentration for a given settling velocity range by the corresponding percent removal,  $(876)(0.4) = 350$ ; see column 5. The number of remaining particles is determined by subtracting the removed particles from the influent particles for each size range,  $876 - 350 = 526$ , for the range 0.8 to 1.2 m/h; see column 6.

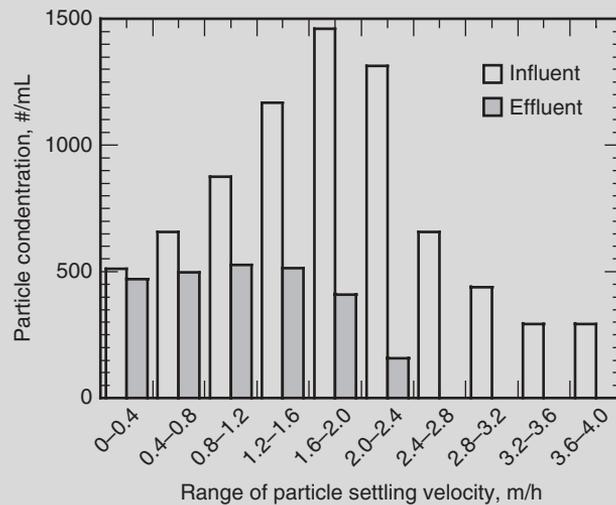

d. The remaining values are summarized in the following table:

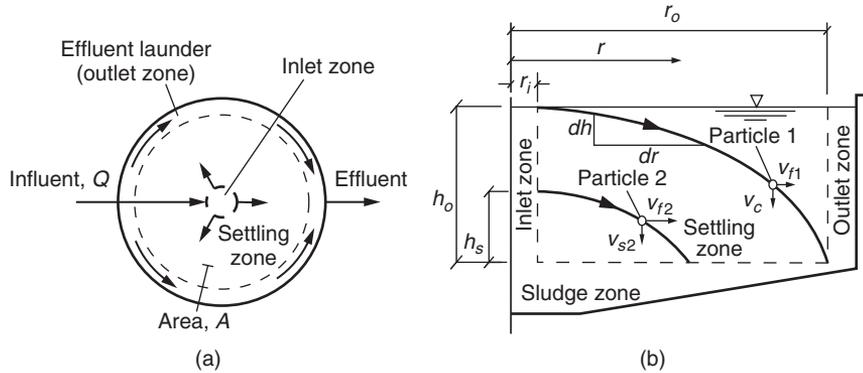

Settling Velocity, m/h (1)	Average Settling Velocity, m/h (2)	Number of Influent Particles, #/mL (3)	Fraction of Particles Removed (4)	Number of Particles Removed, #/mL (5)	Number of Particles in Effluent, #/mL (6)
0-0.4	0.2	511	0.08	41	470
0.4-0.8	0.6	657	0.24	158	499
0.8-1.2	1.0	876	0.40	350	526
1.2-1.6	1.4	1168	0.56	654	514
1.6-2.0	1.8	1460	0.72	1051	409
2.0-2.4	2.2	1314	0.88	1156	158
2.4-2.8	2.6	657	1	657	0
2.8-3.2	3.0	438	1	438	0
3.2-3.6	3.4	292	1	292	0
3.6-4.0	3.8	292	1	292	0
Total		7665		5090	2575

3. Compute the overall particle removal efficiency:

$$\text{Removal efficiency} = \frac{5090}{7665} = 0.664 = 66.4\%$$

4. Plot the influent and effluent particle concentrations for each settling velocity range using a histogram.

**Figure 10-6**

Analysis of particle settling in circular clarifier: (a) plan view of circular clarifier and (b) particle trajectory of discrete particles in settling zone of circular clarifier.

The removal of particles in a circular sedimentation tank can also be described using Eqs. 10-17 and 10-18, as shown on Fig. 10-6. As shown in Fig. 10-6, the settling zone in the circular sedimentation basin extends from radius  $r_i$  to  $r_o$ . As the fluid moves from the center of the tank (inlet zone) through the settling zone, the fluid velocity changes according to the equation

$$v_f = \frac{Q}{2\pi r h_o} \quad (10-19)$$

where  $v_f$  = fluid velocity, m/h  
 $Q$  = flow rate, m<sup>3</sup>/h  
 $r$  = distance measured from center of clarifier, m  
 $h_o$  = depth of settling zone, m

The trajectory of a particle that starts at the top of the inlet zone and enters the sludge zone just before the outlet zone is shown for particle 1 on Fig. 10-6b. For a given settling time  $t$ , the particle moves a horizontal distance given by  $v_f \Delta r$  and a vertical distance given by  $v_c \Delta h$ . Equating these and integrating, the distance that particle 1 has settled as a function of  $r$  is given by the equation

$$h = t v_c = \frac{\pi(r^2 - r_i^2) h_o}{Q} v_c \quad (10-20)$$

where  $r_i$  = radius of inlet zone, m  
 $h$  = distance from water surface for particle 1  
 (see Fig. 10-6b), m  
 $t$  = settling time, h  
 $v_c$  = critical particle settling velocity, m/h

## Circular Sedimentation Basins

Accordingly, discrete particles have a parabolic trajectory in an ideal circular sedimentation basin. Particles with a settling velocity greater than or equal to  $v_c$  are all removed. The settling velocity  $v_c$  can be related to the overflow rate according to the equation

$$v_c = \frac{h_o}{\tau} = \frac{h_o Q}{h_o \pi (r_o^2 - r_i^2)} = \frac{Q}{\pi (r_o^2 - r_i^2)} = \frac{Q}{A} = \text{OR} \quad (10-21)$$

where  $\tau$  = hydraulic detention time of basin, h  
 $r_o$  = radius of outer edge of the settling zone, m  
 $r_i$  = radius of inlet zone, m  
 OR = overflow rate,  $\text{m}^3/\text{m}^2 \cdot \text{h}$   
 $A$  = area of top of basin in settling zone,  $\text{m}^2$

The result shown in Eq. 10-21 is identical to the result given in Eq. 10-17. Consequently, the critical design parameter (overflow rate) for rectangular and circular sedimentation basins is identical.

## 10-4 Principles of Flocculant (Type II) Settling

---

Type II settling typically occurs in conventional sedimentation basins following coagulation. There are two principal mechanisms of flocculation during sedimentation: (1) differences in the settling velocities of particles whereby faster settling particles overtake those that settle more slowly and coalesce with them and (2) velocity gradients within the liquid that cause particles in a region of a higher velocity to overtake those in adjacent stream paths moving at slower velocities.

### Advantages of Flocculant Settling

Flocculation within a sedimentation basin is considered beneficial for two principal reasons. First, the combination of smaller particles to form larger particle aggregates results in faster settling particles because of the increase in size. Second, flocculation tends to have a sweeping effect in which large particles settling at a velocity faster than smaller particles tend to sweep some of the smaller particles from suspension. Consequently, many tiny particles and particles that settle slowly are removed. The net effect of flocculation during settling is a reduction in the size of the sedimentation basin necessary for effective clarification or improved water quality exiting the sedimentation basin.

### Analysis of Flocculant Settling

Design equations for Type II suspensions using the flocculation equations have proven to be impractical for sedimentation and flotation basin design. Design of sedimentation basins is usually based on overflow rates and detention times that have been reported in design manuals as guidelines or by regulatory agencies. For waters with unusual settling characteristics,

a number of investigators have developed design equations based on column experiments. In a technique developed by O'Connor and Eckenfelder (1958), measured solids concentrations taken at regular intervals throughout the depth of a quiescent settling column, slightly deeper than the proposed sedimentation basin, are related to the overall percent removal at a particular basin residence time. The water to be treated is placed in the column and allowed to settle for the detention time of the basin. The effluent concentration is equal to the average concentration in the column. The average concentration can be obtained by draining off the settled solids and then mixing the particles remaining in the column (typically with air) and then sampling the mixed liquid. The concept behind this approach is that the column represents a fluid element that travels as a plug through the basin and has a settling time equal to the basin residence time.

Several fundamentals of sedimentation basin design that are different from design principles arrived at through discrete particle settling have been established. The depth of the basin is important because flocculent particles tend to grow in size during their downward movement through the basin. A greater depth facilitates floc growth and allows for sweep flocculation at high solids concentrations at the bottom of the basin. In general, more flocculent particles are removed in deeper basins.

## 10-5 Principles of Hindered (Type III) Settling

---

Type III settling, also known as zone settling, occurs when the settling velocities of particles are affected by the presence of other particles. When particles are dispersed in solution, the movement of the fluid that is displaced by the particle motion has little impact on the drag force. However, when particle concentrations are high enough to restrict the fluid velocity fields around individual particles, a settling particle experiences increased frictional forces. In water treatment, hindered settling typically occurs in the lower regions of the sedimentation basin, where the concentration of suspended particles is highest. When Type III settling occurs, particle aggregates form a blanket of particles with a distinct interface with the clarified liquid in the basin. Zone settling is of primary importance in water treatment in sludge thickening and dewatering operations, as discussed in Chap. 21.

The solids flux in a sedimentation basin or solids thickener (see Fig. 10-7) is comprised of the downward movement of particles due to gravity settling and the downward movement of particles due to fluid flow toward the underdrain, as shown in the expression

$$J_T = J_s + J_u \quad (10-22)$$

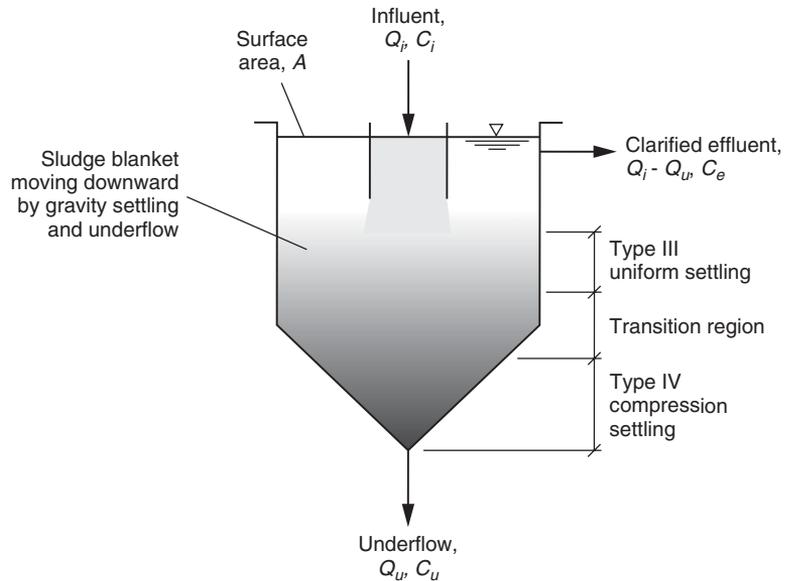

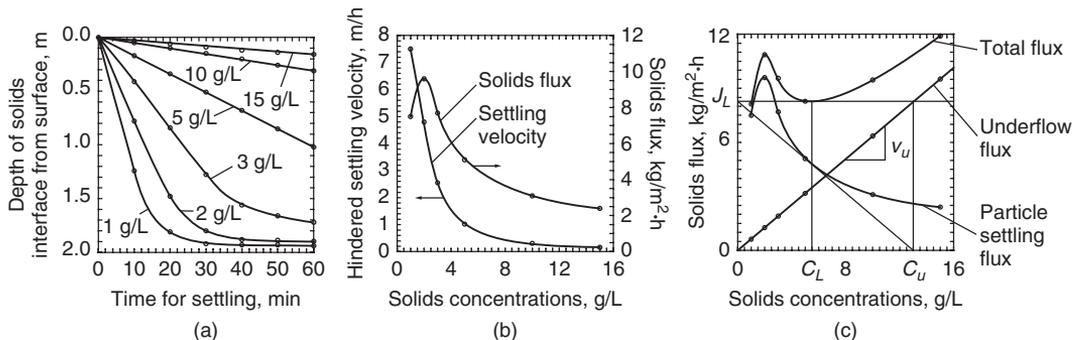

**Figure 10-7**

Diagram of sludge thickener or sedimentation basin where thickening is taking place.

where  $J_T$  = total solids flux toward the bottom of the basin,  $\text{kg}/\text{m}^2 \cdot \text{h}$   
 $J_s$  = solids flux due to particle settling,  $\text{kg}/\text{m}^2 \cdot \text{h}$   
 $J_u$  = solids flux due to fluid flow from the underflow,  $\text{kg}/\text{m}^2 \cdot \text{h}$

To determine the solids flux from gravity settling  $J_s$ , the depth of the blanket interface is measured as a function of time in a column that is initially uniformly mixed with a specified solids concentration  $C$ . Data from a settling column test is shown on Fig. 10-8. The settling velocity is

**Figure 10-8**

Analysis of zone-settling (Type III) data shown in Table 10-1: (a) interfacial settling velocity as function of concentration, (b) initial settling velocity and solids flux due to settling as function of concentration, and (c) limiting solids flux analysis for Type III settling. (Adapted from Tchobanoglous et al., 2003.)

determined from the initial slopes of the concentration curves shown on Fig. 10-8a. The solids flux values due to particle settling is determined by multiplying the concentrations of particles by their respective initial settling velocities, as shown in the equation

$$J_s = v_s C \quad (10-23)$$

where  $v_s$  = settling velocity for particle concentration  $C$ , m/h  
 $C$  = suspended solids concentration, kg/m<sup>3</sup>

The resultant settling velocity and solids flux values are reported in Table 10-1 for the data presented on Fig. 10-8a. The initial settling velocities and the values for solids flux as a function of solids concentration are presented graphically on Fig. 10-8b.

The solids flux due to the fluid flow to the underdrain,  $J_u$ , is defined as

$$J_u = \frac{Q_u C}{A} = v_u C \quad (10-24)$$

where  $Q_u$  = flow rate leaving the bottom of basin/thickener, m<sup>3</sup>/h  
 $A$  = cross-sectional area of basin, m<sup>2</sup>  
 $v_u$  = bulk downward fluid velocity, m/h

The total flux at a suspended solids concentration  $C$  can be written in terms of bulk fluid velocity and sludge blanket settling velocity by substituting Eqs. 10-23 and 10-24 into Eq. 10-22, resulting in the equation

$$J_T = (v_s + v_u) C \quad (10-25)$$

where terms are as defined previously. The use of the solids flux equations to size solids thickening basins is discussed below.

The solids loading for a basin can be determined from an analysis of the limiting flux rate. If solids loading exceeds the limiting flux rate,

### Limiting Flux Rate

**Table 10-1**

Settling velocity and solids flux values

Solids Concentration, $C$ , g/L	Initial Settling Velocities, $v_i$		Solids Flux, $J_s$ , kg/m <sup>2</sup> · h
	m/min	m/h	
1	0.125	7.50	7.5
2	0.080	4.80	9.6
3	0.043	2.55	7.7
5	0.017	1.02	5.1
10	0.005	0.31	3.1
15	0.003	0.16	2.4

solids will accumulate and eventually overflow. To determine the limiting flux rate, an underdrain solids concentration  $C_u$  must be selected. On Fig. 10-8c an underdrain concentration of 13 g/L is shown. The underdrain solids concentration is typically determined based on the requirements of downstream residuals processing operations. The limiting solids flux  $J_L$  for a given  $C_u$  can be determined by drawing a line from the desired underdrain concentration on the  $x$  axis and through the tangent to the particle settling flux curve. The intersect of the tangent line with the  $y$  axis is the value of the limiting solids flux  $J_L$  for the given particle settling flux curve and selected underdrain concentration  $C_u$ . For the case shown on Fig. 10-8c, the limiting particle concentration,  $C_L$ , is about 5.5 g/L and the limiting solids flux shown is  $8.25 \text{ kg/m}^2 \cdot \text{h}$ . The downward velocity of the bulk fluid may be determined using the relationship

$$v_u = \frac{J_L}{C_u} \quad (10-26)$$

where  $v_u$  = downward velocity of bulk fluid, m/h  
 $J_L$  = limiting solids flux,  $\text{kg/m}^2 \cdot \text{h}$   
 $C_u$  = concentration of solids in underflow,  $\text{kg/m}^3$

### Area Required for Solids Thickening

The flow rate through the underdrain can be estimated using the following mass balance analysis. For the solids thickener shown on Fig. 10-7, a solids mass balance is given by the expression

$$\begin{aligned} & \text{Suspended solids entering thickener} \\ &= \text{suspended solids leaving thickener in effluent} \quad (10-27) \\ & \quad + \text{settled solids leaving thickener in underflow} \end{aligned}$$

$$Q_i C_i = (Q_i - Q_u) C_e + Q_u C_u \quad (10-28)$$

where  $Q_i$  = influent flow rate to basin/thickener,  $\text{m}^3/\text{h}$   
 $C_i$  = influent suspended solids concentration,  $\text{mg/L}$   
 $Q_u$  = flow rate leaving the bottom of basin/thickener,  $\text{m}^3/\text{h}$   
 $C_u$  = solids concentration leaving bottom of basin/thickener,  $\text{mg/L}$   
 $C_e$  = effluent solids concentration,  $\text{mg/L}$

If it is assumed that  $C_e \ll C_u$  and  $C_e \ll C_i$ ,  $C_e$  may be considered negligible and the following expression is obtained for the flow rate through the underdrain:

$$Q_u = \frac{Q_i C_i}{C_u} \quad (10-29)$$

Once the flow rate of the underflow is determined, the area required for the basin can be determined using Eq. 10-26, substituting  $Q_u/A$  for  $v_u$ , and solving for  $A$ , as shown below:

$$A = \frac{Q_u C_u}{J_L} = \frac{Q_i C_i}{J_L} \quad (10-30)$$

where  $A$  = area required for thickening,  $m^2$

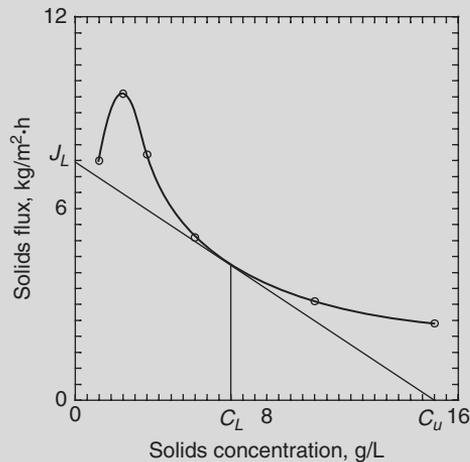

Other terms are as defined previously. Sizing of a thickener is demonstrated in Example 10-4.

### Example 10-4 Area required for thickening

Determine the area required for thickening for a basin that receives 600 mg/L of solids and a flow rate of 4000  $m^3/h$  for an underdrain concentration of 15,000 mg/L. Assume the settling velocity of the sludge blanket follows the relationship plotted on Fig. 10-8b. Also determine  $J_L$ ,  $C_L$ , and  $Q_u$ .

#### Solution

1. Determine  $J_L$  and  $C_L$ . From the data plotted on Fig. 10-8b and an underflow solids concentration of  $C_u = 15,000$  mg/L, the gravity flux is determined by drawing a line from the x axis at a solids concentration of 15,000 mg/L to the y axis such that it is tangent to the solids flux curve and intersects the y axis. The point at which the line intersects the y axis is the limiting gravity flux and is equal to  $7.45 \text{ kg/m}^2 \cdot \text{h}$ . The value for  $C_L$  can also be determined by drawing a vertical line from the tangent point to the x axis and is equal to 6500 mg/L.

2. Determine  $Q_u$  using Eq. 10-29:

$$Q_u = \frac{Q_i C_i}{C_u} = \frac{(4000 \text{ m}^3/\text{h})(600 \text{ mg/L})}{15,000 \text{ mg/L}} = 160 \text{ m}^3/\text{h}$$

3. Determine the area for thickening,  $A$ , using Eq. 10-30:

$$A = \frac{Q_i C_i}{J_L} = \frac{(4000 \text{ m}^3/\text{h})(600 \text{ g/m}^3)(1 \text{ kg}/10^3 \text{ g})}{7.45 \text{ kg/m}^2 \cdot \text{h}} = 322 \text{ m}^2$$

4. Summary:

$$J_L = 7.45 \text{ kg/m}^2 \cdot \text{h} \quad C_L = 6500 \text{ mg/L}$$

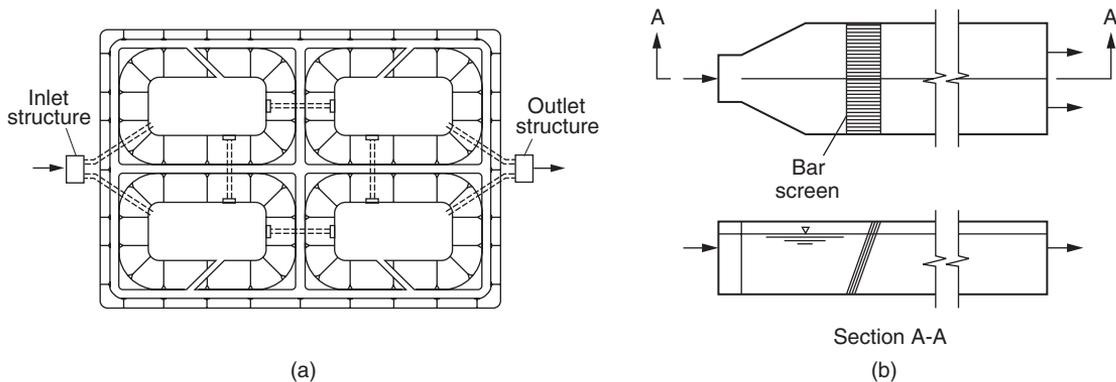

$$Q_u = 120 \text{ m}^3/\text{h} \quad A = 322 \text{ m}^2$$

## 10-6 Conventional Sedimentation Basin Design

Sedimentation basin design is based on applied theoretical principles and practical considerations, including basin location in the overall process treatment train, basin size, and basin geometry. Topics discussed in this section include design considerations for presedimentation basins and conventional sedimentation processes utilizing rectangular, circular, and square basin configurations. Alternative sedimentation processes for improved performance are described in Sec. 10-7.

### Presedimentation Facilities

Presedimentation facilities (see Fig. 10-9) are used to remove easily settleable sand and silt, often present in surface water supplies, especially

**Figure 10-9**

Typical presedimentation facilities: (a) earthen basins (both lined and unlined) and (b) rectangular tank shown without continuous mechanical sediment removal facilities.

ivers, to avoid silting in treatment plant inlet piping. In general, presedimentation basins and tanks should be located upstream of any raw-water pumping facility (low-lift pumps) and as close as possible to the intake structure to avoid silting problems in the plant intake pipeline. A minimum of two basins or tanks, either a divided single tank or two separate tanks, is required so that one can be emptied for routine maintenance and repairs without having to take the entire plant off-line. Where sand carryover is not a major problem, a single tank with a bypass pipeline may be satisfactory. Rectangular presedimentation tanks can be designed with hopper bottoms or be equipped with continuous sediment removal facilities. Typical design criteria for presedimentation tanks are listed in Table 10-2.

Assuming ideal settling in a rectangular basin as presented in Sec. 10-2, the required length of a presedimentation tank can be estimated by the equation

$$L = K \left( \frac{h_o}{v_s} \right) v_f \quad (10-31)$$

where  $L$  = length, m  
 $K$  = safety factor (typically 1.5 to 2), unitless  
 $h_o$  = effective water depth, m  
 $v_s$  = settling velocity of particle to be removed, m/s  
 $v_f$  = mean water velocity at maximum day flow rate, m/s

The settling velocities of various sizes of fine sand particles are listed in Table 10-3. An example of presedimentation tank design is presented in Example 10-5.

**Table 10-2**  
 Typical presedimentation tank design criteria

Parameter	Units	Value
Type	—	Horizontal flow, rectangular tank
Minimum number of tanks	Dimensionless	2
Depth (without automated sediment removal)	m (ft)	3.5–5 (11.5–16)
Depth (with automated sediment removal)	m (ft)	3–4 (10–13)
Minimum length-to-depth ratio	Dimensionless	6:1
Length-to-width ratio	Dimensionless	4:1–8:1
Surface loading rate <sup>a</sup>	m <sup>3</sup> /m <sup>2</sup> · d (gpm/ft <sup>2</sup> )	200–400 (3.3–6.6)
Horizontal mean flow velocity (at maximum daily flow)	m/s (ft/s)	0.05–0.07 (0.16–0.23)
Detention time <sup>b</sup>	min	6–15
Minimum size of particle to be removed	mm	0.1
Bottom slope	m/m	Minimum 1:100 longitudinal slope

Source: Adapted from Kawamura (2000).

<sup>a</sup>The surface loading rate is also known as the overflow rate.

<sup>b</sup>Detention time in earthen basins is typically on the order of 2 to 3 h or more, depending on available space.

**Table 10-3**Settling velocities of various sized discrete particles<sup>a</sup>

Particle diameter, mm	1	0.6	0.4	0.2	0.15	0.1	0.08	0.06
Settling velocity, m/s	0.138	0.077	0.048	0.022	0.015	0.0069	0.0044	0.0025

<sup>a</sup>With a specific gravity of 2.65, in still water, and a water temperature of 10°C (50°F) calculated using Eq. 10-13 or 10-14, as appropriate.

### Example 10-5 Presedimentation tank design

A grit chamber (one concrete structure divided into two tanks) is designed to remove sand of 0.1 mm and larger for an average flow of 1.0 m<sup>3</sup>/s (22.8 mgd). The maximum flow rate is to be 1.5 times the average flow and the water temperature is 10°C. Assuming a typical water depth of 3.0 m and a factor of safety of 1.75, use the information in Table 10-2 to determine the length and width of each tank and check that the surface loading (overflow) rate and the detention time are within the recommended design criteria ranges. Particle settling velocities are listed in Table 10-3.

#### Solution

1. Determine the cross-sectional area for each tank. From Table 10-2, the horizontal-flow velocity at maximum flow is 0.05 m/s. The cross-sectional area for each tank can be calculated as

$$A = \frac{(1.5)(1.0 \text{ m}^3/\text{s})}{(2 \text{ tanks})(0.05 \text{ m/s})} = 15 \text{ m}^2$$

For a water depth of 3.0 m, the width will be 5.0 m (15 m<sup>2</sup>/3.0 m).

2. Calculate the tank length. The length of each tank can be determined using Eq. 10-31 as shown below:

$$L = K \left( \frac{h_o}{v_s} \right) v_f \quad \text{where } K = 1.75$$

From Table 10-3, the settling velocity  $v_s$  for a 0.1-mm sand particle is 0.0069 m/s. The horizontal velocity at maximum daily flow rate from Table 10-2 was

$$v_f = 0.05 \text{ m/s}$$

Substituting into Eq. 10-31,

$$L = (1.75) \times \left( \frac{3.0 \text{ m}}{0.0069 \text{ m/s}} \right) \times 0.05 \text{ m/s} = 38.0 \text{ m}$$

3. Verify the length-to-depth ( $L/d$ ) and length-to-width ( $L/w$ ) ratios.

- a. From Table 10-2, the minimum length-to-depth ratio is 6:1:

$$\frac{L}{d} = \frac{38}{3.0} = \frac{12.7}{1} > \frac{6}{1} \quad \text{OK}$$

- b. From Table 10-2, the minimum length-to-width ratio is 4:1:

$$\frac{L}{w} = \frac{38}{5} = \frac{7.6}{1} > \frac{4}{1} \quad \text{OK}$$

4. Verify the detention time and surface loading rates.

- a. Determine the detention time.

$$\tau = \frac{V}{Q} = \frac{(38.0 \text{ m})(5 \text{ m})(3 \text{ m})}{\left(\frac{1.0 \text{ m}^3/\text{s}}{2 \text{ tanks}}\right) (60 \text{ s/min})} = 19 \text{ min}$$

The calculated value is higher than the typical range of detention time given in Table 10-2 (6 to 15 min) for average flow conditions, but more detention time is acceptable. The detention time will be 12.7 min at maximum flow conditions.

- b. Determine the surface loading rate using Eq. 10-17.

$$\text{OR} = \frac{Q}{A} = \frac{(1.0 \text{ m}^3/\text{s})(3600 \text{ s/h})(24 \text{ h/d})}{(38 \text{ m})(5 \text{ m})(2 \text{ basins})} = 227 \text{ m}^3/\text{m}^2 \cdot \text{d}$$

The surface loading rate range recommended in Table 10-2 is 200 to 400  $\text{m}^3/\text{m}^2 \cdot \text{d}$ . Thus, the computed value is within the acceptable range.

Although coarse screens are used with river intakes, a fine debris screen with approximately 20-mm openings is often provided at the front end of the presedimentation tank. Because the screen also acts as an effective diffuser wall, it should be installed close to the tank inlet. If a separate diffuser wall is specified, the total area of openings at the wall should be about 15 percent of the tank cross-sectional area.

Many sedimentation basins are rectangular with horizontal flow, as shown on Fig. 10-10. A minimum of two basins should be provided so that one may be taken off-line for inspection, repair, and periodic cleaning while the other basin(s) remain in operation. Basins arranged longitudinally side by side, sharing a common wall, have proven to be a cost-effective approach. In addition, a flocculation process may be incorporated into the head end of the sedimentation basin, minimizing piping, improving flow distribution to sedimentation basins, and potentially reducing floc damage during transfer between the flocculation stage and the sedimentation stage. Providing an

## Rectangular Sedimentation Basins

basin is directly attached to the sedimentation basin. The openings should be small holes (100 to 200 mm diameter circular or equivalent) of identical size, evenly distributed on the wall (see discussion of diffuser walls, Sec. 9-7, Chap. 9).

When sedimentation basins are fed from a common channel, the basin inlet structure may consist of weirs or submerged ports, with a permeable baffle about 2 m (6.5 ft) downstream in the sedimentation basin. Uniform or equal distribution of flow to each sedimentation basin is also essential.

#### SETTLING ZONE

The basic design criteria to be considered for the horizontal-flow settling zone are (1) surface loading rate, (2) effective water depth, (3) detention time, (4) horizontal-flow velocity, and (5) minimum length-to-width ratio. Typical design parameters used for rectangular sedimentation facilities are summarized in Table 10-4 and discussed below.

#### *Surface loading rate and settling velocity*

The relationship between surface loading and the settling velocity of discrete particles was developed by Hazen (1904) and discussed previously in Sec. 10-3. Hazen stated that the efficiency of an idealized, horizontal-flow settling tank is solely a function of the settling velocity of discrete particles and of the surface loading rate (the flow rate of the basin divided

**Table 10-4**  
Typical design criteria for horizontal-flow rectangular tanks

Parameter	Units	Value
Type	—	Horizontal-flow rectangular tank
Minimum number of tanks	Unitless	2
Water depth	m (ft)	3–5 (10–16)
Length-to-depth ratio, minimum	Dimensionless	15:1
Width-to-depth ratio	Dimensionless	3:1–6:1
Length-to-width ratio, minimum	Dimensionless	4:1–5:1
Surface loading rate (overflow rate)	m/h (gpm/ft <sup>2</sup> )	1.25–2.5 (0.5–1.0)
Horizontal mean-flow velocity (at maximum daily flow)	m/min (ft/min)	0.3–1.1 (1–3.5)
Detention time	h	1.5–4
Launder weir loading	m <sup>3</sup> /m · h (gpm/ft)	9–13 (12–18) <sup>a</sup>
Reynolds number	Dimensionless	<20,000
Froude number	Dimensionless	>10 <sup>-5</sup>
Bottom slope for manual sludge removal systems	m/m	1:300
Bottom slope for mechanical sludge scraper equipment	m/m	1:600
Sludge collector speed for collection path	m/min (ft/min)	0.3–0.9 (1–3)
Sludge collector speed for the return path	m/min (ft/min)	1.5–3 (5–10)

<sup>a</sup>Can be higher, depending upon characteristics of floc.

**Table 10-5**  
Settling velocity of selected floc types

Floc Type	Setting Velocity at 15°C	
	m/h	ft/min
Small fragile alum floc	2–4.5	0.12–0.24
Medium-sized alum floc	3–5	0.18–0.28
Large alum floc	4.0–5.5	0.22–0.30
Heavy lime floc (lime softening)	4.5–6.5	0.25–0.35
Fe floc	2–4	0.12–0.22
PACl floc	2–4	0.12–0.22

by the surface area) and is independent of the basin depth and detention time. However, most settling basins treat flocculated suspended matter (not discrete particles) and do not have idealized flow patterns. Furthermore, flocculent particles may increase in size while in the basin and settle faster than predicted for a discrete particle. The settling velocities of selected floc particles are presented in Table 10-5.

#### *Effective depth*

Sedimentation basins can be made shallow with a large surface area, but there is a practical minimum basin depth necessary (2.5 to 3 m minimum effective water depth) for mechanical sludge removal equipment. Also, other factors such as flow velocity, effect of wind and sun, and required basin area make shallow basins less practical. Effective water depth is even more important for a basin without mechanical sludge removal facilities since the basin must provide adequate volume for sludge deposit. With an efficient flocculation process, about 70 percent of the floc will settle within the first one-third of the basin length at average flow. Estimated sludge height for well-flocculated water under normal conditions and without a mechanical sludge removal mechanism may be 2 to 3 m (6.5 to 10 ft) at the influent end of the basin but only 0.3 m (1 ft) in the last half of the basin.

#### *Horizontal-flow velocity*

Settling characteristics and surface loading are generally the main basis of design, with Reynolds and Froude numbers being used as a check on turbulence and backmixing. The Reynolds number is determined as

$$\text{Re} = \frac{v_f R_h}{\nu} \quad (10-32)$$

where  $\text{Re}$  = Reynolds number based on hydraulic radius,  
dimensionless

- $v_f$  = average horizontal fluid velocity in tank, m/s  
 $R_h$  = hydraulic radius,  $A_x/P_w$ , m  
 $A_x$  = cross-sectional area, m<sup>2</sup>  
 $P_w$  = wetted perimeter, m  
 $\nu$  = kinematic viscosity, m<sup>2</sup>/s

The Froude number may be determined using the equation

$$\text{Fr} = \frac{v_f^2}{gR_h} \quad (10-33)$$

where     Fr = Froude number, dimensionless  
            g = acceleration due to gravity, 9.81 m/s<sup>2</sup>

Recommended values for settling zone design determined using Eqs. 10-32 and 10-33 are  $\text{Re} < 20,000$  and  $\text{Fr} > 10^{-5}$  (Kawamura, 2000). These dimensionless numbers are useful for general design guidelines because a large Reynolds number indicates a high degree of turbulence and a low Froude number implies that the water flow is not dominated by horizontal flow, and backmixing may occur. The criteria for Re and Fe are of less significance and may be exceeded for conservatively designed basins; a basin with an appropriate length:width ratio, low overflow rate, and detention time of 3 to 4 h will often achieve satisfactory performance even if the Re and Fr criteria are not met. It is more important to check these criteria for high rate rectangular basins with detention times of 2 h or less.

Placing longitudinal baffles (in the direction of flow) can help alleviate poor sedimentation basin performance. Adding longitudinal baffles produces a number of parallel narrow channels and reduces the Reynolds number and increases the Froude number. For example, if one parallel baffle is placed into the tank and the tank is divided into two parallel tanks, then the Reynolds number is decreased by 50 percent and the Froude number is increased by a factor of 2. To allow for sludge removal equipment, the baffles should be separated by at least 3 m (10 ft) and can be made of wooden planks or concrete. Baffles should never be placed in sedimentation basins where they would cause serpentine flow (180° turns) to occur because the turbulence that is caused by abrupt turns will significantly reduce particle settling.

#### *Length-to-width ratio*

The proportions of rectangular horizontal-flow sedimentation tanks can be determined from design criteria that are listed in Table 10-4. In general, long, narrow, and relatively deep (5 m) basins are preferred to minimize

short circuiting. To promote plug flow in rectangular sedimentation basins, a minimum length-to-width ratio of 4:1 to 5:1 should be maintained. Approximately 0.5 m of tank freeboard should be provided to act as a wind barrier. This will also have the additional benefit of preventing waves that are produced by wind from splashing onto walkways (Kawamura, 2000).

#### **OUTLET STRUCTURE**

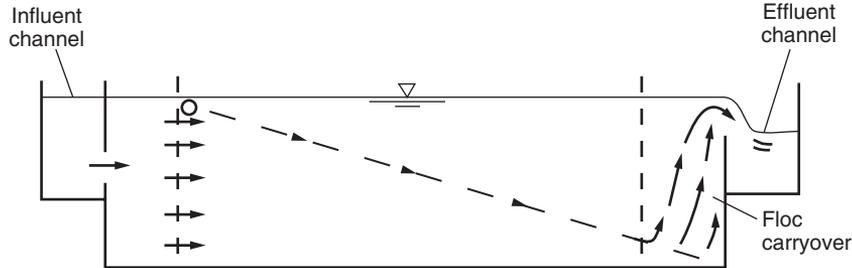

Outlet structures for rectangular tanks are generally composed of launders running parallel to the length of the tank, shown on Fig. 10-10, or a simple weir at the end of the tank. Cross baffles may be added in the vicinity of the effluent launders to prevent the return of surface currents from the end of the basin back toward the inlet. Water leaving the sedimentation basin should be collected uniformly across the width of the basin. Inadequate weir length may result in solids being carried over the effluent weir due to excessive approach velocity. Long weirs have at least three advantages for rectangular sedimentation tanks: (1) a gradual reduction of flow velocity toward the end of the tank, (2) minimization of wave action from wind, and (3) collection of clarified water located in the middle of the tank when a distinct density flow occurs in the basin. Some disadvantages of long effluent launders are that they are expensive and the support columns for them must be designed so they do not interfere with sludge collection devices. With proper sedimentation basin design, long effluent launders may provide only a marginal improvement in effluent turbidity and a simple weir at the end of the tank may provide a satisfactory result.

The water level in the sedimentation basin is controlled by the end wall or overflow weirs. V-notch weirs are commonly attached to launders and broad-crested weirs are attached to the end wall. Submerged orifices or weirs have sometimes been used on the outlet structure when discharging clarified water to a rapid sand filtration system to avoid breakup of fragile alum floc and turbidity breakthrough in rapid sand filters. For high-rate filter designs (dual and monomedia), there is little concern over floc breakage because high-rate filters require a small, strong floc, and filter aids are added prior to filtration primarily for improved particle attachment in the filter. The optimal weir-loading rate will depend on the individual design of the facility and a general rule does not exist. For example, lowering the weir loading rate by 50 percent may not result in a significant improvement of sedimentation efficiency, partly due to density currents.

In the past, installation of a permeable baffle at the tank outlet was a popular design, but the effect of the outlet baffle was often not beneficial and, in fact, may have an adverse effect on basin performance due to floc carryover, as shown on Fig. 10-11.

#### **SLUDGE ZONE**

Sludge collects in the bottom of the sedimentation basin, and in a rectangular basin, more sludge settles near the inlet than the outlet end of

**Figure 10-11**  
Floc carryover effect  
resulting from presence of  
effluent permeable baffle.

the basin. To facilitate sludge removal, the bottom of the basin is typically sloped toward a sludge hopper. For manual sludge removal systems, water is drained from the basin and pressurized water is used for solids flushing; the bottom slope should have a slope of at least 1:300 to ensure gravity movement of sludge. If mechanical sludge scraper equipment is used, the bottom slope should be at least 1:600. The basin bottom may be level when mechanical equipment uses a vacuum to remove sludge. If local labor is inexpensive or if funds for investment are limited, sedimentation tanks may be designed without mechanical sludge removal. However, provisions should be made for possible future installation of mechanical sludge removal equipment.

Manufacturers produce several types of mechanical collectors for rectangular sedimentation basins. The major types of mechanical collectors for rectangular basins are (1) chain-and-flight (plastic material) collectors (see Fig. 10-12), (2) a traveling bridge with sludge-scraping squeegees and a mechanical cross collector at the influent end of the tank, (3) a traveling bridge with sludge suction headers and pumps, and (4) sludge suction headers supported by floats and pulled by wires.

**Figure 10-12**  
Chain-and-flight-type sludge collector.

The standard maximum width of the chain-and-flight sludge collector is 6 m (20 ft), and the operation and maintenance cost usually increases for the chain-and-flight collectors if the length of the basin exceeds 60 m. When mechanical scraper units are used, the velocity of the scraper should be kept below 18.0 m/h to prevent resuspending the settled sludge. For suction sludge removal units, the velocity can be 60 m/h because the principal concern is not the resuspension of settled sludge but the disruption of the settling process.

Traveling bridges can span up to 30 m (100 ft) with widths 12 to 30 m (40 to 100 ft) usually being the most cost effective. Because the width of sedimentation basins is often less than 15 m (50 ft), using one bridge to span two or three tanks can significantly reduce the capital investment for sludge removal equipment. Both the drain and sludge draw-off pipelines should have a minimum diameter of 150 mm (6 in.) to prevent clogging problems. Additionally, traveling bridges are susceptible to high winds, and in cold-weather climates, the pumps and piping need cold-weather protection as they are exposed above the water. Sedimentation basin design is demonstrated in Example 10-6.

### Example 10-6 Sedimentation basin design

A water treatment plant with a maximum daily flow of  $3 \text{ m}^3/\text{s}$  (1.5 times the average flow of  $2 \text{ m}^3/\text{s}$ ) is treating surface water. The water is coagulated with alum and the alum floc was measured to have a settling velocity of 2.2 m/h at  $10^\circ\text{C}$  ( $50^\circ\text{F}$ ). The dynamic viscosity of water at  $10^\circ\text{C}$  is  $0.00131 \text{ kg/m} \cdot \text{s}$  and the density is  $999.7 \text{ kg/m}^3$ . Design a horizontal-flow rectangular sedimentation basin with a chain and flight sludge removal system including the number of basins and the basin dimensions. The design is based on the maximum flow rate.

#### Solution

1. Determine the number of basins. Two basins would satisfy the minimum requirement for maintenance purposes. However, if one basin were off-line, the entire plant flow would be directed through the remaining basin, possibly resulting in overloading of the basin. To minimize the risk of basin overloading, three basins will be selected.
2. Determine the size of each basin.
  - a. Select the basin width and depth. The basin width will be governed by the standard size of sludge removal equipment. The standard maximum width of the chain-and-flight sludge collector is 6 m, so basin widths in increments of 6 m will be considered, starting with 18 m. Water depths from 3 to 5 m are appropriate, according to

the design criteria listed in Table 10-4. As previously mentioned, deeper basins are recommended over shallower basins, so a depth of 4 m will be selected.

- b. Determine the basin area. The settling velocity such that the particle is removed in the sludge zone just before the outlet,  $v_c$ , is given as 2.2 m/h at 10°C. (This value is also equal to the overflow rate.) Use Eq. 10-17 to determine the basin surface area:

$$A = \frac{Q}{v_c} = \frac{3 \text{ m}^3/\text{s}}{(2.2 \text{ m/h})(1 \text{ h}/3600 \text{ s})} = 4909 \text{ m}^2$$

- c. Determine the length using the design guidelines in Table 10-4 for length-to-width ratios. For three tanks that are 18 m (60 ft) wide, the tank length and length-to-width ratio can be estimated:

$$L = \frac{4909 \text{ m}^2}{3 \text{ basins} \times 18 \text{ m}} = 90.9 \text{ m} \quad \frac{L}{W} = \frac{90.9}{18} = \frac{5.05}{1}$$

The length-to-width ratio is greater than the minimum recommendation of 4:1 to 5:1.

3. Check the various design parameters listed in Table 10-4.

- a. Check the detention times at  $Q_{\max}$  and  $Q_{\text{ave}}$ :

$$\begin{aligned} \text{Detention time for } Q_{\max} &= \frac{(18 \times 90.9 \times 4) \text{ m}^3 \times 3 \text{ basins}}{(3 \text{ m}^3/\text{s})(3600 \text{ s/h})} \\ &= 1.82 \text{ h} \end{aligned}$$

$$\text{Detention time for } Q_{\text{ave}} = 1.5 \times 1.82 \text{ h} = 2.73 \text{ h}$$

These detention times are within the acceptable range of 1.5 to 4 h.

- b. Check the length-to-depth ratio:

$$\frac{L}{D} = \frac{90.9}{4} = \frac{22.7}{1}$$

The basin length-to-depth ratio is 22.7:1, which is greater than the minimum recommendation of 15:1.

- c. Check the horizontal-flow velocity. The mean velocity is given by the expression

$$v_f = \frac{Q}{A} = \frac{(3 \text{ m}^3/\text{s})(60 \text{ s/min})}{18 \text{ m} \times 4 \text{ m} \times 3 \text{ basins}} = 0.833 \text{ m/min}$$

The mean velocity is greater than 0.3 m/min and less than 1.1 m/min.

- d. Check the Reynolds and Froude numbers using Eqs. 10-32 and 10-33:

$$Re = \frac{\rho v_f R_h}{\mu}$$

$$R_h = \frac{A_x}{P_w} = \frac{4 \text{ m} \times 18 \text{ m}}{18 \text{ m} + 2(4 \text{ m})} = 2.77 \text{ m}$$

$$v_f = \frac{0.833 \text{ m/min}}{60 \text{ s/min}} = 0.014 \text{ m/s}$$

$$Re = \frac{(999.7 \text{ kg/m}^3)(0.014 \text{ m/s})(2.77 \text{ m})}{0.00131 \text{ kg/m} \cdot \text{s}} = 29,594$$

The Reynolds number of 29,594 is higher than the recommended value of 20,000 for a horizontal sedimentation basin. The Froude number is given by Eq. 10-33:

$$Fr = \frac{v^2}{gR_h} = \frac{(0.014)^2 \text{ m}^2/\text{s}^2}{(9.81 \text{ m/s}^2)(2.77 \text{ m})} = 7.2 \times 10^{-6}$$

The Froude number is lower than the recommended value for sedimentation tanks, so the tank design must be modified.

4. Consider the addition of two longitudinal baffles per basin and recompute the Reynolds and Froude numbers.

$$R_h = \frac{A_x}{P_w} = \frac{4 \text{ m} \times 6 \text{ m}}{6 \text{ m} + 2(4 \text{ m})} = 1.71 \text{ m}$$

$$Re = \frac{(999.7 \text{ kg/m}^3)(0.014 \text{ m/s})(1.71 \text{ m})}{0.00131 \text{ kg/m} \cdot \text{s}} = 18,162 < 20,000 \quad \text{OK}$$

$$Fr = \frac{(0.014)^2 \text{ m}^2/\text{s}^2}{(9.81 \text{ m/s}^2)(1.71 \text{ m})} = 1.17 \times 10^{-5} > 10^{-5} \quad \text{OK}$$

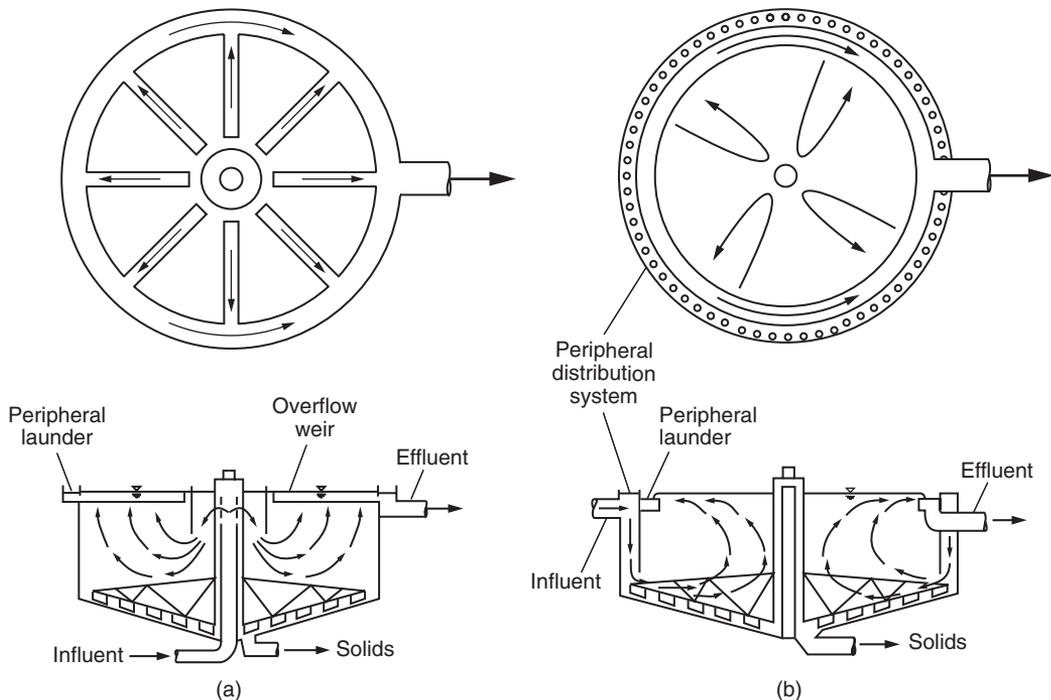

### Comment

The values of the Reynolds and Froude numbers after the addition of longitudinal baffles are within the acceptable range; however, they are evaluated at the maximum daily flow. As water demand changes with the season, the number of basins that are online needs to be selected to keep the basins operating within the Reynolds and Froude number guidelines. Note that the Re and Fr criteria are not as significant for conservatively designed basins.

### Circular Sedimentation Basins and Upflow Clarifiers

Circular sedimentation tanks, also known as upflow clarifiers, have been used in many cases because they provide an opportunity to use relatively trouble-free circular sludge removal mechanisms and, for small plants, can be constructed at a lower capital cost per unit surface area. However, circular tanks tend to need more piping for water and sludge conveyance to and from the tanks than a rectangular basin configuration.

Circular tank diameters are calculated on the basis of overflow rates using approximately the same criteria that are used for rectangular basin design (see Table 10-4). Circular tanks, as shown on Fig. 10-13, may have center feed or peripheral feed. A circular sedimentation basin with center feed and peripheral collection using radial submerged orifice weirs is shown on Fig. 10-14. The inlet structure used for center-feed configurations is a circular weir around the influent vertical rise pipe. For peripheral-feed tanks, the inlet weir is located around the perimeter of the tank. Inlet weirs provide energy dissipation and direct the flow downward into the depths of the settling tank where particles are removed. Particles settle as the water rises to the outlet structure. Baffles near the outlet and surface-skimming devices are not used unless the influent water has problems with debris and floatable material.

**Figure 10-13**

Circular sedimentation basins: (a) center feed with radial collection and (b) peripheral feed with peripheral collection.

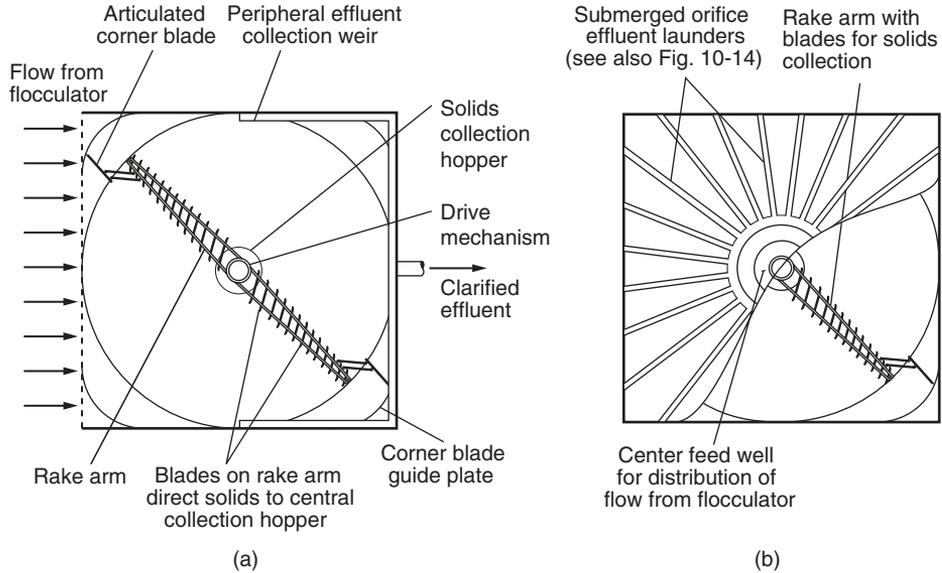

**Figure 10-14**

View of circular sedimentation basin with radial collection troughs with submerged orifices.

The design of circular clarifiers requires careful consideration of factors such as surface loading, uniform flow distribution into the settling zone, minimization of flow short circuiting from hydraulic and density currents, uniform withdrawal of clarified water, and sludge withdrawal without disturbing settling efficiency. For upflow clarifiers, the vertical-flow rise rate becomes an additional criterion; at any selected level, the flow rise must be less than the respective floc-settling rate. Refer to Table 10-5 for settling velocities of various flocs.

The most significant potential problem of center-feed circular clarifiers is short circuiting of the upward flow of water. Hydraulic short circuiting can be particularly significant when the peripheral collection channel is not equipped with radial weirs or when the influent contains a high solids concentration that flows along the tank bottom. Circular tanks may experience density currents along the bottom when the turbidity of the raw water exceeds about 50 NTU or when there is a temperature difference (as little as  $0.3^{\circ}\text{C}$  or  $0.5^{\circ}\text{F}$ ) between the inflow and the ambient water. Placing the peripheral launder trough two-thirds to three-fourths of the radial distance from the center minimizes the density currents and produces better quality water. Because of the potential problems with hydraulic short circuiting, the best use of upflow clarifiers is for clarification of waters with heavy, noncolloidal solids loading such as filter-to-waste washwater.

To address problems with short circuiting in center-feed clarifiers, a peripheral-feed clarifier was developed that introduces flow between the tank wall and an annular skirt. The peripheral-feed design allows the inflow to enter the settling zone near the tank bottom. To ensure uniform flow distribution and additional loading capacity, the orifices in the annular inlet channel should be designed so that the head loss across each orifice inlet is approximately 10 to 15 mm. Peripheral-feed designs have two to three times the loading permissible with center-feed clarifiers. Peripheral-feed,

**Figure 10-15**

Square sedimentation basins: (a) square basin close coupled with flocculation facilities and (b) square basin with center feed.

peripheral-collection clarifiers (e.g., Kraus–Fall peripheral-feed sedimentation tank) have proven more efficient for high solids influent water.

Square sedimentation tanks, shown on Fig. 10-15, were developed in an effort to combine the advantages of common-wall construction of rectangular basins with the simplicity of circular sludge collectors. However, several features of square basins have presented difficulties for sedimentation processes. For example, the effluent launders are constructed along the perimeter of the basins, resulting in the corners having more weir length per degree of radial arc. Thus, flows are not distributed equally and solids preferentially accumulate in the corners of the basin. Corner sweeps, added to the circular sludge collector mechanisms to remove sludge settling in the corners, have been a source of mechanical difficulty. While the corners can be steeply sloped so that the sludge may flow by gravity to the circular sludge collectors, there are relatively few square basins constructed for water treatment.

## Square Sedimentation Basins

### 10-7 High-Rate Sedimentation Processes

The use of large quiescent basins such as those described above to settle particles out of water has been established as an appropriate method for particle removal. However, these basins require large land areas, which

are not always available, and plant upgrades to accommodate increasing water demand may be constrained by the available site area. Increasing the overflow rate in sedimentation basins and achieving the same or better water quality would allow new water treatment plants to fit on smaller sites and existing water treatment plants to expand without having to use additional land area. For example, a high-rate tube settler module, as described below, can be installed under the long launders, significantly increasing the tank loading rate without adding basin volume. Alternative approaches to sedimentation, such as high-rate clarification using parallel-plate or tube settlers, upflow clarifiers, sludge blanket clarifiers, and ballasted sedimentation, are discussed in this section.

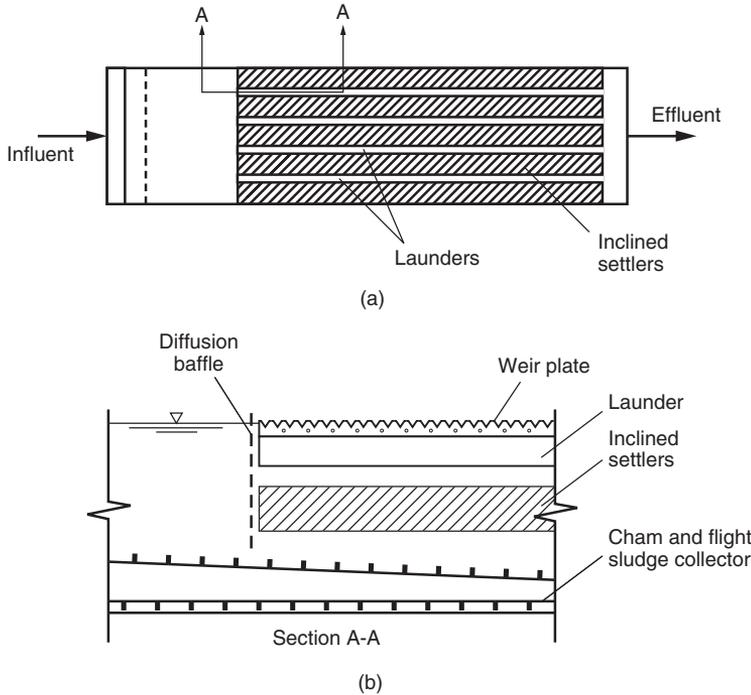

### **Tube and Lamella Plate Clarifiers**

Increasing particle size or decreasing the distance a particle must fall prior to removal can accelerate sedimentation of aqueous suspensions. Particle size increase is achieved by coagulation and flocculation prior to sedimentation. Reducing the settling distance can be achieved by making the entire basin shallower, but practical aspects of sludge storage, equipment movement, and wind effects on the surface limit this approach.

To decrease the distance a particle must fall, the clarification process must be separated from the process of sludge withdrawal and surface current effects. One approach is to provide parallel plates or tubes in the sedimentation basin, permitting solids to reach a surface after a short settling distance. If these settling surfaces (plates or tubes) were oriented in a horizontal direction, they would eventually fill with solids, which would increase the head loss and eventually increase velocities to a point that the suspended materials would be scoured back into suspension. Inclining the surfaces to a degree where the solids can slide from the plate or tube surface results in the settled particles depositing in the sludge zone. Inclined plate settlers are illustrated on Fig. 10-16. Some design aspects and process selection criteria for high-rate settlers are discussed below.

#### **SETTLING CHARACTERISTICS AND SURFACE LOADING RATE**

The settling characteristics of the suspended particles to be removed and the portion of the total tank surface area that is covered by the settler modules primarily control the surface loading for high-rate settlers. Design criteria for Lamella settlers in rectangular sedimentation basins are provided in Table 10-6. The surface loadings presented in Table 10-6 are based on the footprint area and not the top area of the plates or projected area. In cold regions where alum floc is to be removed, the maximum surface loading should be limited to  $150 \text{ m}^3/\text{m}^2 \cdot \text{d}$  ( $2.6 \text{ gpm}/\text{ft}^2$ ). Pilot testing may help establish design criteria, but criteria used for design should be more conservative than pilot test results to allow for poor inlet conditions,

**Figure 10-16** Rectangular sedimentation basin with inclined plate settlers: (a) plan view of basin and (b) section through inclined plates. (Adapted from Kawamura, 2000.)

**Table 10-6**  
Typical design criteria for horizontal-flow rectangular tanks with tube settlers

Parameter	Units	Value
Type	—	Horizontal-flow rectangular tank
Minimum number of tanks	Unitless	2
Depth	m (ft)	3–5 (10–16)
Surface loading for plate or tube settlers: alum floc <sup>a</sup>	m/h (gpm/ft <sup>2</sup> )	2.5–6.25 (1–2.5)
Surface loading for plate or tube settlers: heavy floc <sup>a</sup>	m/h (gpm/ft <sup>2</sup> )	3.8–7.5 (1.5–3.0)
Typical hydraulic diameter	mm	50–80
Maximum-flow velocity in plate or tube settlers	m/min (ft/min)	0.15 (5)
Detention time in tube settlers	min	6–10
Detention time in plate settlers	min	15–25
Fraction of basin covered by plate or tube settlers	%	<75
Launder weir loading <sup>b</sup>	m <sup>3</sup> /m · h (gpm/ft)	3.75–15 (5–20)
Flow direction	—	Normally countercurrent upflow
Plate or tube angle	deg	60°
Mean horizontal velocity	m/min (ft/min)	0.05–0.13 (0.15–0.5)
Reynolds number	Dimensionless	<20,000
Froude number	Dimensionless	>10 <sup>-5</sup>

<sup>a</sup>Before the plate or tube settlers are installed.

<sup>b</sup>Can be higher depending on the characteristics of the floc and the type of plate or tube settlers used.

density flow, inappropriate coagulant dosage, or other unforeseen negative factors. While Reynolds and Froude numbers discussed in Sec. 10-6 have only limited use in conventional sedimentation basin design, they are good design guides for high-rate settlers.

#### **DETENTION TIME IN PLATE AND TUBE SETTLERS**

The discussion on the theoretical performance of a sedimentation basin demonstrated that the removal of Type I particles depended on the overflow rate. For a basin depth  $h_o$  and a theoretical detention time  $\tau$ , particles with a settling velocity  $v_s$  would be removed if  $v_s \geq h_o/\tau$  (which is equal to the overflow rate). Consequently, if plates or tubes are inserted into a sedimentation basin, then greater particle removal is expected because the detention time remains the same, but the distance that particles must settle before they are removed is greatly reduced. Both parallel-plate settlers and tube settlers typically have detention times less than 20 min, but they still have a settling efficiency comparable to that of a rectangular settling tank with a minimum 2 h detention time.

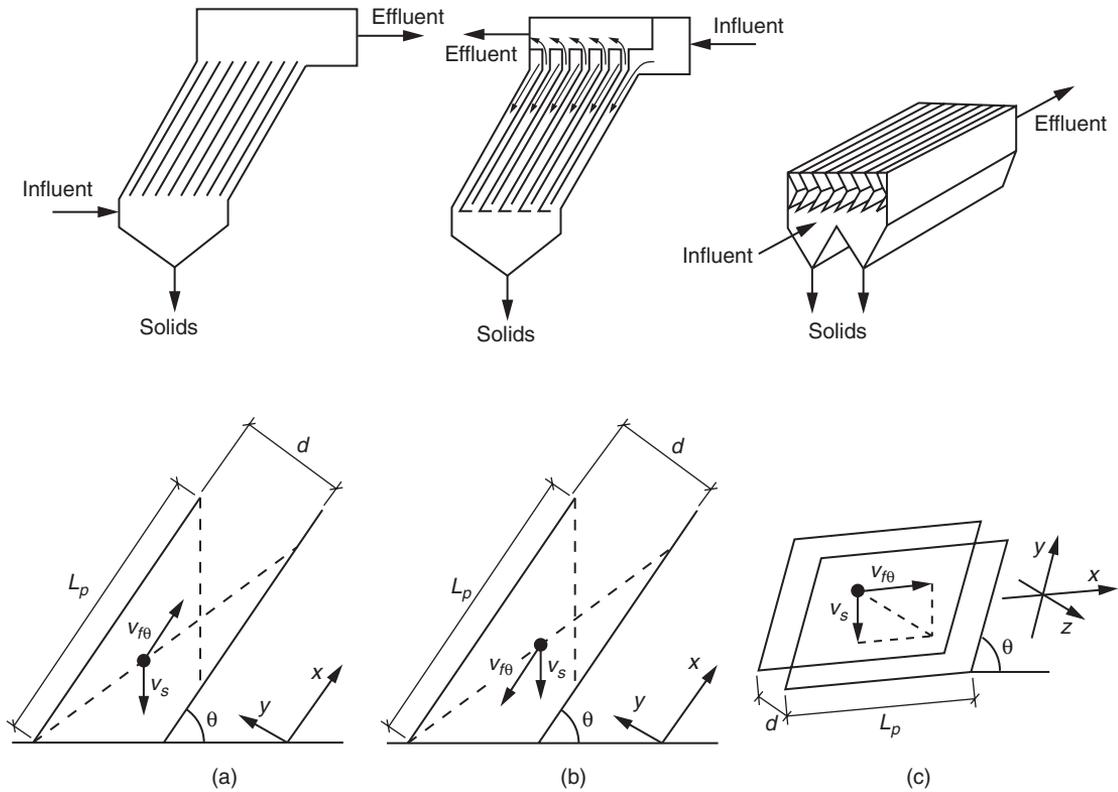

#### **SOLIDS REMOVAL**

Usually settled floc or sludge does not adhere to the plates or tubes but rather slides down to the tank bottom for subsequent mechanical sludge removal. Settlers may be designed with a scouring device, such as water jets or compressed air, to remove flocs such as biological floc that may adhere to the settler surface. For certain applications, downflow settlers can be used to enhance the self-cleaning action. A tank equipped with high-rate settler modules must provide continuous sludge removal because of the high sludge accumulation rate produced by the high-rate settler modules. A chain-and-flight sludge collector is one of the most suitable types of sludge removal mechanisms when used with high-rate settler modules, although traveling bridge collectors may also be used if channels for the sludge header passage are included.

#### **PROCESS CONFIGURATION**

To allow for better inlet flow conditions, the front one-quarter length of a rectangular horizontal-flow sedimentation basin is free from settler modules, as shown on Fig. 10-16a. Following the settling modules, a launder system is used to collect clarified water uniformly from the area covered by the settler modules. The modules can be hung from the launders, thereby eliminating an elaborate support system. Launders are usually spaced 3 to 4 m on center.

There are three alternatives for placement of tubes or plates in a sedimentation basin: (a) countercurrent, (b) cocurrent, and (c) cross flow, as shown on Fig. 10-17. The following settling analysis is presented for plate settlers; however, tube settlers may be modeled using a similar technique.

**Figure 10-17** Flow patterns for inclined settling systems: (a) countercurrent, (b) cocurrent, and (c) cross flow. (Courtesy of Inflico Degrémont, Inc.)

*Countercurrent settlers*

The settling time for a particle to move between countercurrent parallel plates is given by the expression

$$t = \frac{d}{v_s \cos \theta} \tag{10-34}$$

where  $t$  = settling time, s

$d$  = distance between two parallel plates (perpendicular to plates), m

$v_s$  = particle settling velocity, m/s

$\theta$  = inclination angle of plates from horizon, deg

If a uniform velocity is assumed, then the particle travel time spent in the plates is given by the expression

$$t_p = \frac{L_p}{v_{f\theta} - v_s \sin \theta} \tag{10-35}$$

where  $t_p$  = particle travel time spent in plates, s  
 $L_p$  = length of plate, m  
 $v_{f\theta}$  = fluid velocity in channel, m/s

If the trajectory of a particle that is shown on Fig. 10-17 is considered, then all of the particles with settling velocity  $v_s$  are removed and  $t_p$  is equal to the settling time  $t$  (equating Eq. 10-34 to Eq. 10-35). Further, those particles with a larger settling velocity are also removed, as shown by the expression

$$v_s \geq \frac{v_{f\theta} d}{L_p \cos \theta + d \sin \theta} \quad (10-36)$$

The fluid velocity  $v_{f\theta}$  may be determined from the number of channels:

$$v_{f\theta} = \frac{Q}{Ndw} \quad (10-37)$$

where  $Q$  = flow rate, m<sup>3</sup>/s  
 $N$  = number of channels, dimensionless  
 $d$  = distance between two parallel plates (perpendicular to plates), m  
 $w$  = width of channel, m

The fluid velocity  $v_{f\theta}$  is also related to the overflow rate of the basin assuming that the surface area of the basin is comprised of plates and the area occupied by the plates is ignored:

$$v_{f\theta} = \frac{Q}{Ndw} = \frac{Q}{A \sin \theta} \quad (10-38)$$

where  $A$  = top area of basin, m<sup>2</sup>

Other terms are as defined above.

Particles with settling velocities less than  $v_s$  may also be removed, depending on where they enter the plate.

#### *Co-current settlers*

For co-current settling, the settling time for a particle to move between two parallel plates is given by Eq. 10-34. The time that particles moving with the fluid spend in the plates is given by the expression

$$t_p = \frac{L_p}{v_{f\theta} + v_s \sin \theta} \quad (10-39)$$

where  $t_p$  = particle travel time spent in plates, s  
 $L_p$  = length of plate, m  
 $v_{f\theta}$  = fluid velocity in channel, m/s  
 $v_s$  = particle settling velocity, m/s

If  $t_p$  is equal to settling time  $t$  (equating Eq. 10-34 to Eq. 10-39), then the particles with settling velocity  $v_s$  are removed. Further, those particles with a larger settling velocity are also removed, as shown by the expression

$$v_s \geq \frac{v_{f\theta} d}{L_p \cos \theta - d \sin \theta} \quad (10-40)$$

#### *Cross-current settlers*

For cross-current settling, the settling time for a particle to move between two parallel plates is also given by Eq. 10-34. The time that particles moving with the fluid spend in the plates is given by the expression

$$t_p = \frac{L_p}{v_{f\theta}} \quad (10-41)$$

where  $t_p$  = particle travel time spent in plates, s  
 $L_p$  = length of plate, m  
 $v_{f\theta}$  = fluid velocity in channel, m/s

If  $t_p$  is equal to settling time  $t$  (equating Eq. 10-34 to Eq. 10-41), then the particles with settling velocity  $v_s$  are removed. Further, those particles with a larger settling velocity are also removed, as shown by the expression

$$v_s \geq \frac{v_{f\theta} d}{L_p \cos \theta} \quad (10-42)$$

The design of plate settlers is demonstrated in Example 10-7.

### **Example 10-7 Design of sedimentation process with plate settlers**

A sedimentation basin has been retrofitted with 2.0-m (6.6-ft) square inclined plates spaced 50 mm (2.0 in.) apart. The angle of inclination of the plates can be altered from  $0^\circ$  to  $80^\circ$ . Assuming that the sedimentation basin can be used for countercurrent, co-current, or cross-flow sedimentation, determine which flow pattern is the most efficient for particle removal, ignoring any hydraulic problems that may arise as a result of flow distribution and sludge resuspension (adapted from Gregory et al., 1999).

#### **Solution**

1. Develop equations that can be used to compare the ratio of settling velocity to the fluid velocity for the three flow types from Eqs. 10-36, 10-40, and 10-42. The following equations for the ratio of the settling

velocity to the fluid velocity can be used to evaluate which configuration can capture the solids with the lowest settling velocity. Laminar flow or a constant velocity across the plate is assumed:

$$\begin{aligned} \text{Countercurrent flow: } \frac{v_s}{v_{f\theta}} &= \frac{d}{L_p \cos \theta + d \sin \theta} \\ &= \frac{0.05 \text{ m}}{(2.0 \text{ m} \times \cos \theta) + (0.05 \text{ m} \times \sin \theta)} \end{aligned}$$

$$\begin{aligned} \text{Co-current flow: } \frac{v_s}{v_{f\theta}} &= \frac{d}{L_p \cos \theta - d \sin \theta} \\ &= \frac{0.05 \text{ m}}{(2.0 \text{ m} \times \cos \theta) - (0.05 \text{ m} \times \sin \theta)} \end{aligned}$$

$$\text{Cross flow: } \frac{v_s}{v_{f\theta}} = \frac{d}{L_p \cos \theta} = \frac{0.05 \text{ m}}{2.0 \text{ m} \times \cos \theta}$$

- Calculate the settling velocity–fluid velocity ratio for various plate angles for all flow types. The following table was prepared using the equations developed in step 1:

Flow Pattern	$V_s/V_{f\theta}$ for Given Angle of Inclination							
	0°	10°	20°	30°	40°	60°	75°	80°
Countercurrent flow	0.025	0.025	0.026	0.028	0.032	0.048	0.088	0.126
Co-current flow	0.025	0.026	0.027	0.029	0.033	0.052	0.106	0.168
Cross flow	0.025	0.025	0.027	0.029	0.033	0.050	0.096	0.144

- Compare the settling velocity–fluid velocity ratios calculated in step 2. For angles less than 60°, there is very little difference in the calculated ratios between the various flow arrangements. However, above 60° countercurrent flow provides the most efficient operation as particles with the smallest settling velocity are removed.

### Comment

Based on the computations shown in this example, there is little difference between the various flow arrangements for angles less than 60°. Countercurrent flow provides the most efficient operation above 60° as it allows settlement of particles with the smallest settling velocity.

### PROCESS SELECTION

While the theoretical design and operation of high-rate settlers appear to provide an excellent alternative to conventional settlers, the performance of high-rate settlers can be greatly reduced due to the following conditions (Kawamura, 2000): (1) poor flocculation, (2) poor inlet flow distribution, (3) scaling (e.g.,  $\text{CaCO}_3$ ), and (4) algal growth. In addition to these performance issues, the following aspects of high-rate clarifiers should be considered.

#### *Angle of inclination*

Early development studies were conducted using flat parallel plates, shallow trays, and circular pipes or tubes. The feed rates were set so as to maintain laminar flow at all times. Tests indicated that for alum-coagulated sludge and countercurrent flow solids would remain deposited in the tubes until the angle of inclination was increased to  $60^\circ$  or more from horizontal. However, for co-current flow, the angle of inclination could be reduced to approximately  $30^\circ$ .

#### *Flow pattern*

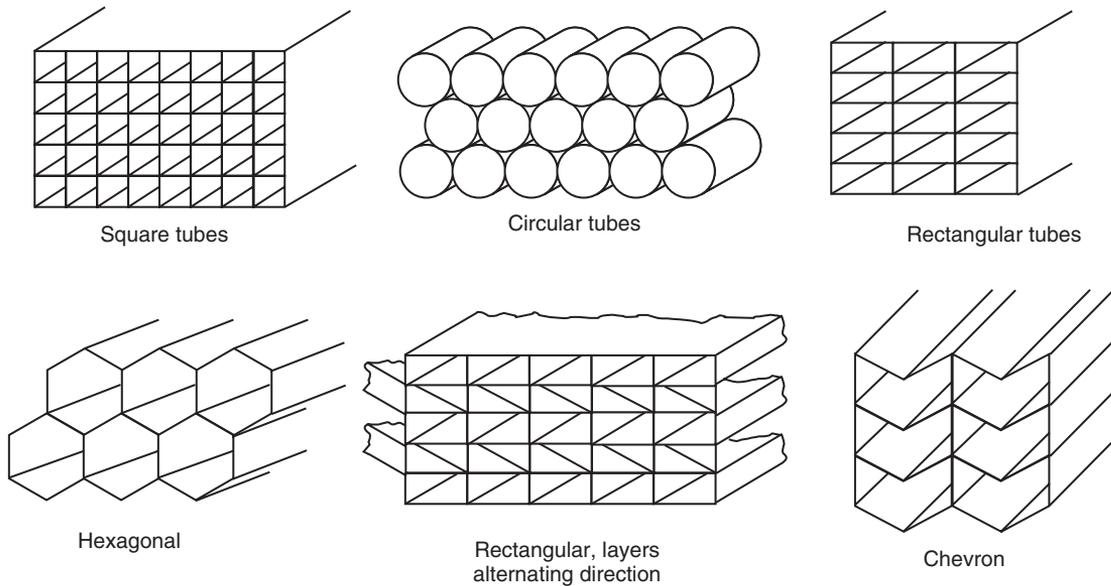

In theory, the three flow patterns described above have little difference in performance when the angle of inclination is great enough for sludge to move toward the sludge zone when under the influence of gravity. However, in practice, co-current or cross-flow designs do not perform as well as countercurrent designs. Co-current designs have the problem of keeping the effluent water from resuspending the sludge. For cross-flow designs, it is difficult to obtain good flow distribution because water flow through the sludge zone has a smaller resistance than through the plates. Consequently, countercurrent designs are the most common.

#### *Tube shape*

Based on an analysis of tube shapes, there appears to be little difference between the efficiency of the various tubes, but the hexagon tube or chevron (see Fig. 10-18) may have some advantages because sludge can collect in the notch of these channels. While parallel plates are efficient, their installation and manufacture can be difficult to maintain even spacing and ultimately uniform flow.

Solids contact clarifiers have been used to achieve suspended solids removal in less space than conventional sedimentation basins. Solids contact units are usually found in industrial and municipal applications, where lime softening or softening clarification is the major treatment process and uniform flow rates and constant water quality prevail. Solids contact clarifiers can

### Solids Contact Clarifiers

**Figure 10-18**  
Typical configurations for tube settlers. (Adapted from Gregory et al., 1999.)

be categorized as reactor clarifiers, sludge blanket reactors, and adsorption reactors. Design criteria and other data for the solids contact units are summarized and compared with conventional rectangular clarifiers in Table 10-7.

#### REACTOR CLARIFIERS

In conventional treatment process design, the unit operations of rapid mixing, flocculation, and sedimentation are all set out in individual unit processes in-series operation. In a reactor clarifier, all these processes are combined in one unit. This combined process has significant advantages, such as reduced cost and more effective use of the sludge blanket. On the other hand, because all the unit operations are in one unit, usually stacked vertically, sludge blanket or reactor clarifiers reduce, somewhat, the ability of both the designer and the operator to refine the design and operating criteria for each of these operations. Most of these devices are preengineered, packaged proprietary devices that trade reduced flexibility to achieve greater optimization of a particular process option. In some circumstances these products are an excellent choice.

There are several proprietary reactor clarifier designs. Generally, these devices are used in smaller plants; however, some of them see regular use in

Source: Adapted from Kawamura (2000).

<sup>a</sup>Reactor clarifiers and sludge blanket clarifiers are often considered as one category, solids contact clarifiers.

large water treatment facilities. Most are preengineered units that involve a trade-off between flexibility and experience with refinement of a particular design. Three of the more common design types—reactor clarifiers, sludge blanket clarifiers, and adsorption clarifiers—are illustrated on Fig. 10-19 and are described below.

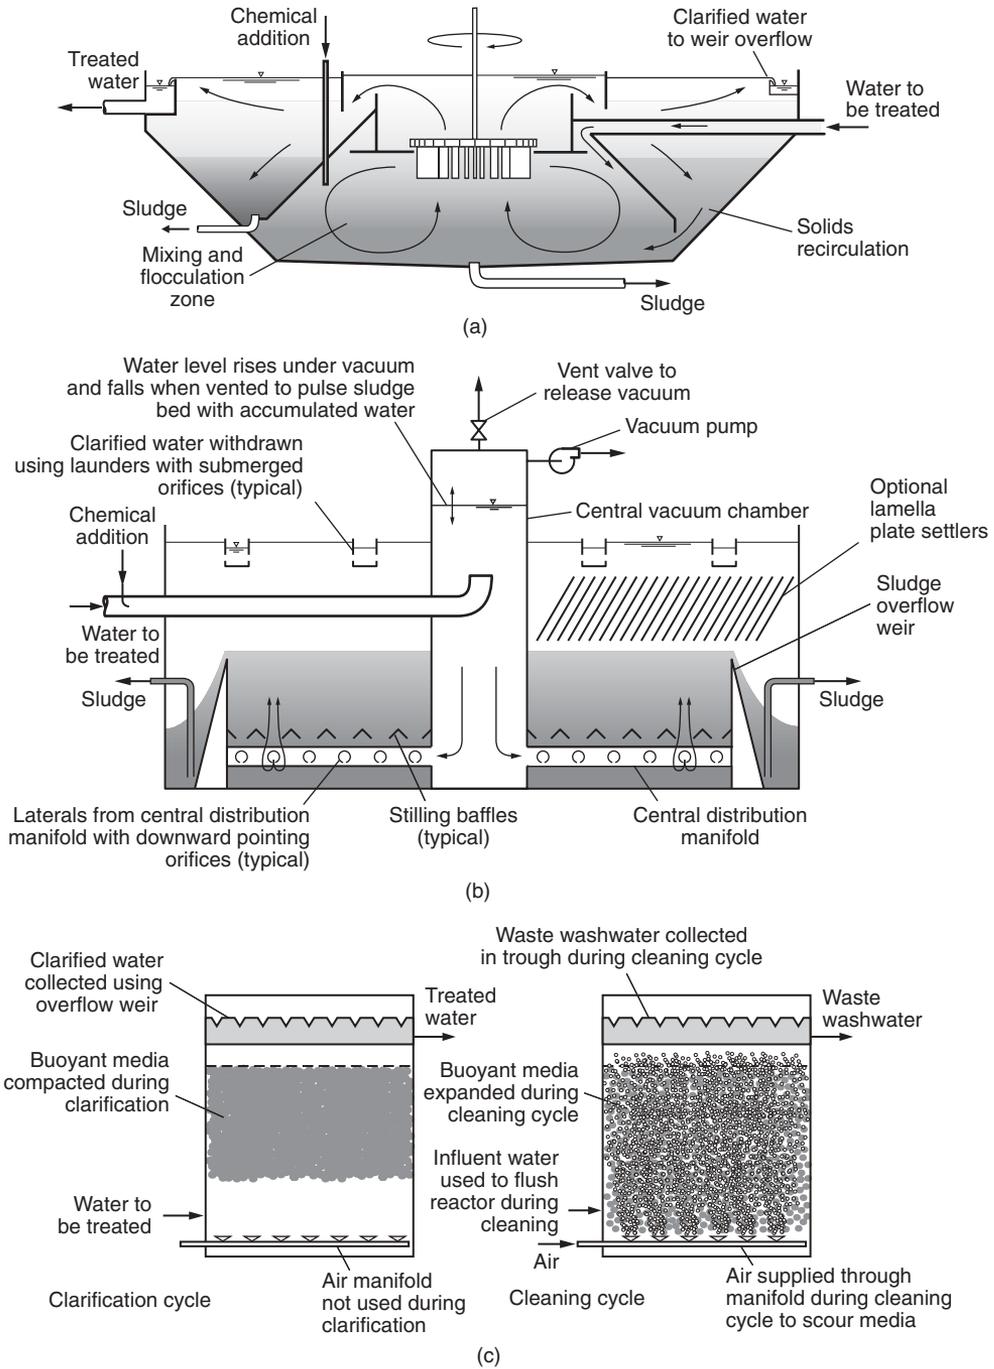

Reactor clarifiers are center-feed clarifiers with a flocculation zone built into the central compartment (see Fig. 10-19a). Generally, these units contain a single motor-driven mixer, with recirculation of the sludge slurry (sometimes optional), followed by a settling zone in a separate outer annular compartment. When slurry recirculation is featured, these are often called solids contact clarifiers and generally include an impeller that provides considerable recirculation. The concentration in the unit is controlled by an adjustable timer on a sludge blow-off line. When using alum, it is common practice to maintain the slurry concentration in the mixing zone at 5 to 20 percent of the sludge volume after 10 min of settling. The slurry concentration is somewhat higher in softening. Reactor clarifiers work well in both clarification and softening, but, in the case of clarification using aluminum or iron salts, sludge recirculation improves performance at the expense of a significantly increased chemical requirement. In the case of lime softening, sludge recirculation improves both performance and chemical consumption.

#### **SLUDGE BLANKET CLARIFIERS**

The sludge blanket clarifiers are solids contact clarifiers with a distinct solids layer that is maintained as a suspended filter through which flow passes (see Fig. 10-19b). The sludge blanket unit contains a central mixing zone for partial flocculation and a fluidized sludge blanket in the lower portion of the settling zone. Partially flocculated water flows through the sludge blanket where flocculation is completed and solids are retained by adsorption and filtration. The sludge level is normally 1.5 to 2 m (4.5 to 6 ft) below the water surface, and clarified water is collected in launder troughs along the top of the unit. Sludge blanket clarifiers are made with or without sludge recirculation mechanisms. Sludge blanket clarifiers are compared with other processes in Table 10-7.

Design criteria for sludge blanket clarifiers are essentially the same as for sludge recirculation reactor clarifiers. However, the launder troughs should be sufficiently spaced to avoid sludge spillover. The launder spacing should be less than twice the distance between the water level and the top of the fluidized sludge blanket, approximately 4.5 m (15 ft). The troughs are typically arranged radially or in parallel.

Generally, sludge blanket clarifiers should be used only where the raw-water characteristics and flow rates are relatively uniform. Given these

**Figure 10-19** Three common types of proprietary reactor clarifiers: (a) reactor clarifier (IDI Accelerator), (b) sludge blanket clarifier (Pulsator, when optional lamella plates are added, the unit is known as the Super Pulsator), and (c) IDI absorption clarifier. (Courtesy of Inflico Degrémont, Inc.)

parameters, the most effective applications are for lime softening and clarification of low-turbidity water. These units may also be used for clarification of highly turbid water (exceeding 500 NTU) if a sludge-scraping mechanism is provided.

One of the more difficult problems in operating sludge blanket clarifiers is the management of the sludge blanket itself. Some of the more popular designs accomplish this by simply allowing the sludge blanket to fall over a submerged weir that is kept a significant distance below the free surface. The Pulsator and its progeny the Super Pulsator are widely used examples of this principle. The Pulsator is shown on Fig 10-19b. Operationally, a portion of the flow is brought in the central vacuum chamber and allowed to rise above the operating water level in the clarifier by pulling a vacuum. When the water level in the vacuum chamber is about 0.5 to 1.0 m above the operating level in the clarifier, the vacuum is released by opening a valve to the atmosphere, allowing the water in the chamber to flow as a pulse through the influent distribution system located at the bottom of the tank below the sludge blanket. The pulse of water is used to contact the incoming water with the sludge blanket and to suspend and redistribute the sludge blanket. The depth of the sludge blanket is controlled by the overflow weir. The sludge blanket is typically pulsed once every 60 s (40 s to fill the vacuum chamber and 5 to 20 s to drain into the clarifier). The Super Pulsator is similar to the Pulsator but employs Lamellae settling.

#### **ROUGHING FILTERS AND ADSORPTION CLARIFIERS**

Roughing filters are used to create a zone of laminar flow during clarification. Similar in objective to the plate and tube settlers, a bed of granular material is used to establish a zone of laminar flow. The media in the bed may be heavy material such as gravel or buoyant plastic media. Suspended material deposits on the media as the water flows through the channels in the media bed. To remove the sludge, the media must be agitated to loosen the particles, which in turn fall to the bottom of the tank or are flushed from the tank with backwash water.

Most of the experimental work on gravel bed roughing filters has been done in Europe and South America. Gravel roughing filters are most frequently used ahead of slow sand filters when the raw-water source contains high turbidity or is subject to frequent runoff events. To date, gravel roughing filters have not been used on a full-scale basis in the United States, and they are not discussed further in this text. For additional information about roughing filters, refer to Collins et al. (1994).

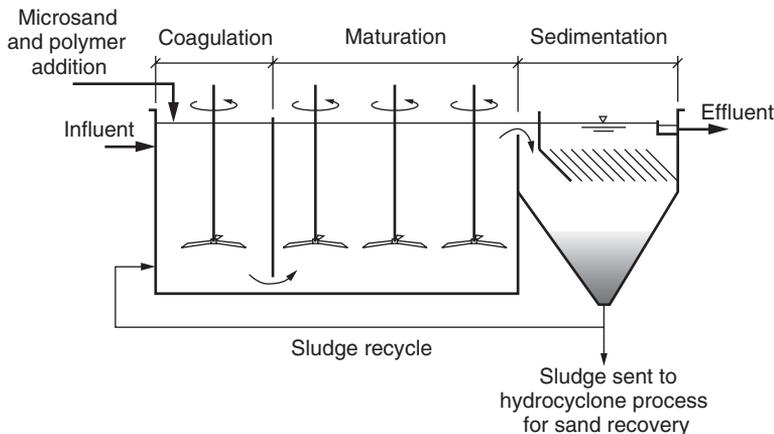

The adsorption clarifier uses buoyant plastic media as a roughing filter. As the coagulated water travels upward through the media, flocculation takes place as the tortuous path of the water causes mixing and collisions between particles. Collisions between particles and the media causes particles to stick to the media, and most of the flocculated solids can be collected in the media. The media is then occasionally washed by introducing air from

below, which reduces the bulk specific gravity of the water surrounding the media and allows it to expand and be cleaned. Both the adsorption (clarification mode) and the cleansing (flush cycle) are shown on Fig. 10-19c.

As the process name suggests, ballasted sedimentation involves the addition of ballast (usually microsand) that increases the settling velocity of the floc particles by increasing their density (providing ballast). The concept of ballasted sedimentation was first applied to water treatment in the 1970s. Currently, there are a number of proprietary sedimentation processes that employ the ballasted flocculation principle. Two well-known processes are the Actiflo process and the Densidag dense-sludge process. These processes have been used in water treatment for both the production of potable water and the treatment of filter-to-waste washwater.

A schematic of the Actiflo process is shown on Fig. 10-20. The Actiflo process involves adding an inorganic coagulant (alum or ferric) to the raw water and allowing floc to form in the first stage of flocculation. Subsequently, a high-molecular-weight cationic polymer and microsand particles (20 to 200  $\mu\text{m}$ ) are added to the second stage, and the microsand particles flocculate with the preformed floc particles in the second and third stages. After flocculation, the ballasted floc is settled and the sludge containing the microsand is sent through a hydrocyclone (not shown) where the microsand is recovered and reused and the sludge is sent on for further treatment. The microsand is fed at a rate that is approximately 0.15 to 0.4 percent of the influent flow rate and the sludge ultimately contains 10 to 12 percent sand by weight.

The surface loading rate for an Actiflo unit ranges from 35 to 62 m/h, which can be up to 50 times greater than the surface loading rate for a conventional rectangular sedimentation basin. The small size of the Actiflo unit can be attributed to the use of high mixing energy ( $\bar{G}$  values

**Figure 10-20**  
Schematic of Actiflo process.

## Ballasted Sedimentation

ranging from 150 to 400  $s^{-1}$ ), shorter detention times for flocculation (between 9 and 10 min), floc settling velocities 20 to 60 times greater than conventional flocculation and sedimentation, and the use of lamella plate settler modules to accelerate particle removal.

The advantages of the high-rate settling processes include (1) a small footprint requirement at water treatment plants with site constraints; (2) turbidity removal down to the 0.5-NTU level, but treating to 2.0 NTU is more common to reduce polymer usage and potential polymer carryover into the filters; (3) a quick process startup, about 15 min; (4) robust process that is not easily upset by changes in raw-water quality; and (5) potential savings in capital costs based on the small footprint. The disadvantages are (1) a heavy dependence on mechanical equipment and a short processing time; (2) the entire process must be shut down when there is a power outage lasting more than 10 min; (3) a higher coagulant dosage is required than for conventional processes with a high proportion of polymers, which may cause problems in downstream processes such as filter blinding and reduced filter run time; (4) potential for sand carryover (e.g., Actiflo process) into downstream processes; and (5) proprietary processes, which may limit competitive bidding.

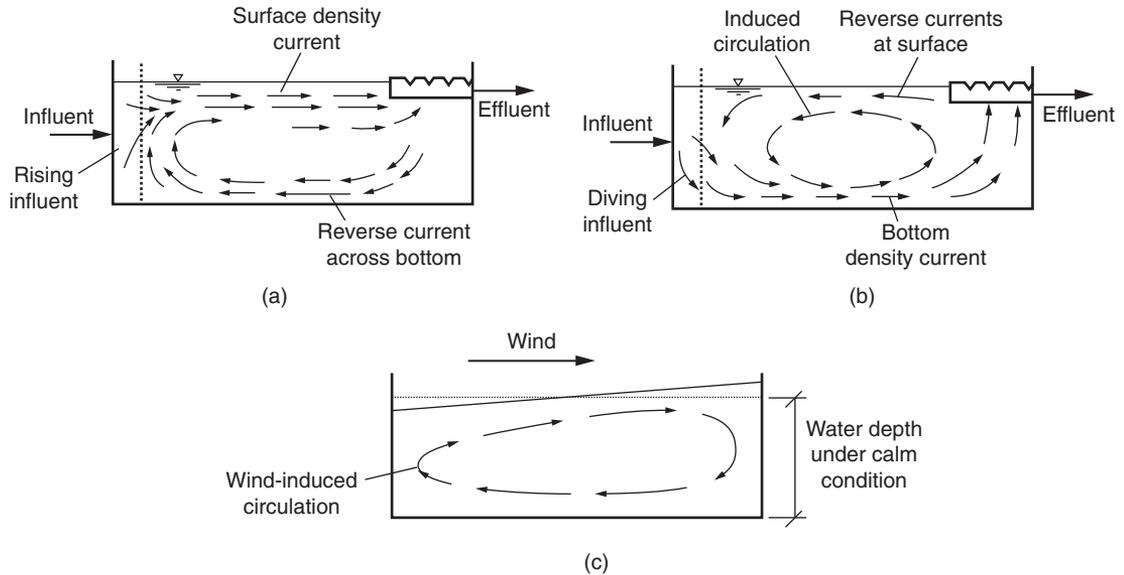

## 10-8 Physical Factors Affecting Sedimentation

---

Accurate prediction of settling tank performance by mathematical and experimental methods is a challenge to even the best design engineers. Model testing using tracers and settling columns are limited by scale-up, which cannot be expressed adequately by principles of similitude, primarily because solid particles are not easily scaled down. In addition, many of the simplifying assumptions of modeling do not hold true in prototype units. Factors such as temperature gradients, wind effects, inlet energy dissipation, outlet currents, and equipment movement affect tank performance but are not easily modeled. Density currents, inlet energy dissipation, outlet currents, and equipment movement are presented and discussed in this section. Most of the information presented below on the physical factors related to sedimentation is directed toward conventional sedimentation basins and less toward innovative designs.

### Density Currents

When feed water is entering the sedimentation basin, it can form a surface or a bottom density current, as illustrated on Figs. 10-21a and 10-21b, respectively, depending on the relative densities of the feed water and water in the basin. Under these flow conditions, actual flow-through velocity will depart from the theoretical, idealized average basin velocity. The theoretical velocity is equal to the total incoming flow divided by the total cross-sectional

**Figure 10-21**

Nonideal flow in conventional sedimentation basin: (a) surface density currents, (b) bottom density currents, and (c) wind-induced currents.

area in the basin. Short circuiting caused by density currents has been observed in many water treatment plants (Camp, 1946; Harleman, 1961; Kao, 1977). Methods used to minimize the effects of density currents have been reported by a number of investigators (Camp, 1946; Fitch and Lutz, 1960; Harleman, 1961; Hudson, 1972; Kao, 1977; Sank, 1978). Kawamura (2000) reported density flow velocities of 0.8 to 1.8 m/min (2.6 to 6 ft/min) in the bottom of sedimentation tanks as compared to design velocity of 0.4 m/min (1.3 ft/min). These density flow velocities were observed during the day when the surface temperature was 0.2 to 0.5°C warmer than the influent raw water.

The velocity of the density current can be evaluated by the following expression (Harleman, 1961):

$$v_{fd} = \left\{ 8g \frac{\Delta\rho}{\rho} \left[ \frac{hs}{f(1+\alpha)} \right] \right\}^{0.5} \quad (10-43)$$

where  $v_{fd}$  = velocity of density flow, m/s  
 $g$  = acceleration due to gravity, 9.81 m/s<sup>2</sup>  
 $\Delta\rho$  = density difference between two liquids, kg/m<sup>3</sup>  
 $\rho$  = density of influent, kg/m<sup>3</sup>

$h$  = depth of density current flow, m

$s$  = slope of channel bottom, m/m

$f$  = Darcy–Weisbach friction factor, unitless

$\alpha$  = correction factor for kinetic energy ranging from 0 to 1  
(0.43 for turbulent flow), unitless

Basin inlet and outlet arrangements should be designed to provide some degree of control in minimizing the effects of density currents. At the inlet, the following techniques have been used: (1) feed flow is distributed uniformly through the basin cross section in the plane perpendicular to the flow by employing diffuser walls and (2) devices that will break up the feed stream and dissipate the energy by turbulence.

Improvements can be made in the basin to control the density currents. These improvements include tube settlers, redistribution baffles, or intermediate diffuser walls. Launderers extending into sedimentation basins have been used to control the effluent flow distribution, which is more effective for controlling bottom density currents than surface density currents.

#### TEMPERATURE DIFFERENTIALS

The addition of warm influent water to a sedimentation basin containing cooler water can lead to a short-circuiting phenomenon in which the warm water rises to the surface and reaches the effluent launders in a fraction of the nominal detention time. Conversely, cold water added to a basin containing warm water tends to force the incoming water to dive to the bottom of the basin, flow along the bottom, and rise at the basin outlet.

Studies were conducted by Kawamura (1981) using a 1:25 scale model with dynamic similitude following the Froude law. Temperatures in the tank and the feed flow were kept constant with the feed flow about 0.3°C lower than the water in the tank. Without diffuser walls in the tank, the density current flowed along the bottom of the tank at a relatively shallow depth and took less time to reach the outlet. Under these conditions, the top two-thirds of the tank depth was not used effectively. To improve the hydraulic efficiency, diffuser walls with approximately 7 percent net opening were added. With the modified diffuser walls, head losses created at the diffuser walls forced the retardation and mixing of the density current with the ambient water, improving the flow distribution in the tank and the efficiency of hydraulic performance.

When conducting tracer tests in pilot plant investigations, Tekippe and Cleasby (1968) found that minor temperature differences greatly reduced the reproducibility of experiments and overshadowed minor differences in inlet and outlet design variables. The performance of sedimentation tanks that are constructed with metallic walls and exposed to sunlight may also be unpredictable. The heat transmitted through the wall on the sunny side of the basin tends to warm the water, making it less dense than water on

the shaded side. The warm water in turn rises, forming a density current that, if sufficiently severe, can invert the contents of the basin.

#### SOLIDS CONCENTRATION EFFECTS

Density current problems similar to those discussed above may also be caused by changes in influent solids concentrations resulting from flash floods or strong winds on lake water surfaces. A rapid increase in turbidity increases the density of the influent and causes it to plunge as it enters the sedimentation basin. In a center-feed circular tank, when the influent is denser than the water in the tank, it falls to the bottom and flows outward from the center in a radial direction; rising toward the effluent launders near the perimeter. Water not leaving the basin through the effluent launders returns along the surface of the basin. These currents tend to leave the center of the basin in a relatively stagnant position, thereby reducing the effective volume and detention time for settling. The effect of solids concentration on the mass of water in a basin is presented in Example 10-8.

### Example 10-8 Effect of solids concentration on mass of water

Calculate the difference in mass of water in a sedimentation basin 20 m wide by 100 m long by 5 m deep (10,000 m<sup>3</sup> of water) containing 20 mg/L of solids and 2000 mg/L of solids. Assume the solids have a density of 2.5 g/mL and the water has a density of 0.99823 g/mL. The volume of solids and water in a 1-L solution can be determined from the following expressions:

$$V_{\text{solids}} = \frac{\text{mass of solids (g)}}{\text{density (g/mL)}}$$

$$V_{\text{water}} = 1000 \text{ mL} - V_{\text{solids}} \text{ (mL)}$$

#### Solution

1. Calculate the densities of the two solutions.
  - a. Determine the volume of solids and water in a 1-L solution with solids concentrations of 20 and 2000 mg/L. For solids concentration of 20 mg/L,

$$V_{\text{solids}} = \frac{\text{mass of solids (g)}}{\text{density (g/mL)}} = \frac{0.02 \text{ g}}{2.5 \text{ g/mL}} = 0.008 \text{ mL}$$

$$\begin{aligned} V_{\text{water}} &= 1000 \text{ mL} - V_{\text{solids}} \text{ (mL)} = 1000 \text{ mL} - 0.008 \text{ mL} \\ &= 999.992 \text{ mL} \end{aligned}$$

For solids concentration of 2000 mg/L,

$$V_{\text{solids}} = \frac{\text{mass of solids (g)}}{\text{density (g/mL)}} = \frac{2 \text{ g}}{2.5 \text{ g/mL}} = 0.8 \text{ mL}$$

$$V_{\text{water}} = 1000 \text{ mL} - V_{\text{solids}} (\text{mL}) = 1000 \text{ mL} - 0.8 \text{ mL} \\ = 999.2 \text{ mL}$$

- b. Determine the density of a 1-L solution with solids concentrations of 20 and 2000 mg/L. For solids concentration of 20 mg/L,

$$\rho_{\text{solution}} = \frac{V_{\text{solids}} \rho_{\text{solids}} + V_{\text{water}} \rho_{\text{water}}}{V_{\text{solids}} + V_{\text{water}}} \\ = \frac{(0.008 \text{ mL})(2.5 \text{ g/mL}) + (999.992 \text{ mL})(0.99823 \text{ g/mL})}{0.008 + 999.992 \text{ mL}} \\ = 0.998242 \text{ g/mL}$$

For solids concentration of 2000 mg/L,

$$\rho_{\text{solution}} = \frac{(0.8 \text{ mL})(2.5 \text{ g/mL}) + (999.2 \text{ mL})(0.99823 \text{ g/mL})}{0.8 + 999.2 \text{ mL}} \\ = 0.998431 \text{ g/mL}$$

2. Calculate the mass of the two solutions.

- a. The mass of 10,000 m<sup>3</sup> (10<sup>7</sup> L or 10<sup>10</sup> mL) of water with a solids concentration of 20 mg/L is given as

$$\text{Mass of solution} = (0.998242 \text{ g/mL})(10^{10} \text{ mL}) \\ = 9.98242 \times 10^9 \text{ g}$$

- b. The weight of 10,000 m<sup>3</sup> of a 2000-mg/L solution is given as

$$\text{Mass of solution} = (0.998431 \text{ g/mL})(10^{10} \text{ mL}) \\ = 9.98431 \times 10^9 \text{ g}$$

- c. The weight difference between a solution containing 20 and 2000 mg/L of solids in a sedimentation basin is 1890 kg.

### Comment

The increased mass of the water with solids concentration of 2000 mg/L would result in density flow and poor clarifier performance if appropriate measures were not taken.

The remediation of problems of varying influent turbidity are similar to those for incoming temperature differences and include diffuser walls in the basin. Additionally, the source of water should be carefully selected and the method of removing water from the source should minimize quality variations. It should be noted that changes in water density resulting from variable dissolved solids (salinity) concentration may also lead to density flow and short circuiting.

Wind can have a pronounced effect on the performance of large, open gravity settling basins. High wind velocity tends to push the water to the downwind side of a basin and produces a surface current moving in the direction of the wind. An underflow current in the opposite direction is also created, which moves along the bottom of the tank. The resulting circulating current, shown on Fig. 10-21c, can lead to short circuiting of the influent to the effluent weir and scouring of settled particles from the sludge zone. For open sedimentation basins with length or diameter greater than 30 m, wind effects can be significant and result in reduced effluent quality. Wind-induced currents were studied by Baines and Knapp (1965) and Hidy and Plate (1966) in laboratory wind–water tunnels. Liu and Perez (1971) have also modeled wind-induced currents by numerically solving the governing equations of motion with assumptions of the kinematic eddy viscosity of water.

When long and shallow rectangular settling basins are used, orienting the basin with the local prevailing wind direction should be considered. In areas with strong predictable winds, sedimentation basins should be positioned so that the water flow parallels the wind, and wave breakers (launders or baffles) should be placed at approximately 20- to 30-m (65- to 100-ft) intervals. Changes in water surface elevation are minimized when the wind blows across the length of the rectangular settling basin, as opposed to across the width, and the effects of wind currents on sedimentation basin performance are minimized. Wind-induced wave patterns on the surface of the water may cause the formation of circulation patterns in the basins, which in turn affect settling rates. Where sandstorms or other wind-induced particle deposition is expected, a windbreak or cover over the basins may also be necessary. Trees may not be the best windbreaks because leaves and small branches can drop into the basin and clog the sludge withdrawal system.

Sedimentation basin performance is strongly influenced by inlet energy dissipation. When the flocculation basin is not directly attached to the sedimentation basin, water may be conveyed to the basin through a pipe at high enough velocities to keep solids in suspension. The influent flow must be slowed down and distributed over a broad area to begin the sedimentation process. In rectangular basins, flow is often distributed with

## Wind Effects

## Inlet Energy Dissipation

a channel across the inlet end of the basin. Baffles are then used to distribute the flow across the tank cross section in a horizontal and vertical direction, simultaneously. If the energy dissipation is not engineered carefully, density and eddy currents and excessive velocity vectors will be created.

### **Outlet Currents**

Outlet currents in a sedimentation basin are often related to design details of effluent weirs and launders. Initially, these weirs were simply flat plates across the end of a rectangular basin. The width of the basin established the length of the weir. When tanks were designed in a long, narrow configuration, the weir length was relatively short and was believed to contribute to formation of outlet currents that, if severe, could sweep settleable particles into the tank effluent. The problem of currents was compounded in early designs because the flat weir plates were sometimes not level. Concern for this led to the development of V-notch weirs, which provide better lateral distribution of outlet flow when leveling is imperfect.

For upflow clarifiers, such as solids contact basins, launders carefully spaced across the surface are considered of vital importance to good performance. The launders, which are often arranged in a radial pattern, serve an important role in directing the vertical flow through the solids contact zone. As solids contact tanks become larger, strategic location of radial weirs becomes more critical.

In general, for most water treatment sedimentation basins, performance is primarily a function of density currents and inlet energy dissipation rather than outlet currents. Careful design of effluent weirs will not solve problems associated with density currents created by other design deficiencies.

### **Equipment Movement**

Another potential effect on sedimentation basin performance is the movement of equipment within the basin. Sludge collection mechanisms, normally consisting of chain-and-flight scrapers, bridge-mounted scrapers, or hydraulic vacuum units, must move through the liquid contents of the tank to remove settled sludge. If equipment movement is excessive, currents may be introduced that upset the sedimentation process. Most equipment moves at a rate of 15 to 30 m/h and has a minimal effect. However, equipment movement in the vicinity of the effluent launders is important because of the potential for disturbed settled solids to be caught in the effluent currents and carried over the effluent weir.

## **10-9 Dissolved Air Flotation**

---

Dissolved air flotation (DAF) is a unit operation that involves the use of fine air bubbles for the separation of solid and semisolid (floc) particles from a liquid. Fine air bubbles are introduced near the bottom of the basin containing the water to be treated. As the bubbles move upward through the water, they become attached to particulate matter and floc particles,

and the buoyant force of the combined particle and air bubbles causes the aggregated particles to rise to the surface. Thus, particles that are heavier than the liquid can be made to float. Particles that rise to the surface are removed for further processing as residuals, and the clarified liquid is filtered to remove any residual particulate matter. A summary overview of the DAF process, including a process description, DAF applications, theoretical factors affecting DAF, and design considerations for DAF systems, is presented in this section. Additional details may be found in Zabel and Hyde (1977), Zabel (1985), Gregory et al. (1999), Haarhoff and Edzwald (2004), Haarhoff (2008), Edzwald (2010), and Gregory and Edzwald (2010).

The DAF process dates back to the 1920s when a vacuum system was used. Two such plants were still in operation in Sweden in the 1970s. The pressurized process in use today was developed in Finland and Sweden in the 1960s. Since then, the use of pressurized DAF technology has spread throughout the world. The DAF was first used in the United States in the early 1980s (Haarhoff, 2008). It is now estimated that there are more than 150 DAF plants in the United States and Canada, and the popularity of the process is continuing to increase.

Like other gravity separation processes, raw water is coagulated and flocculated prior to entering the DAF basin. The water is introduced into the contact zone of the flotation basin near the floor, as shown on Fig. 10-22a. A baffle wall separates the contact zone from the separation (clarification) zone and limits short circuiting. In the contact zone (see Fig. 10-22b), a cloud of air bubbles called white water, typically 10 to 100  $\mu\text{m}$  in diameter, adheres to floc particles in the influent creating floc–bubble aggregates with a net specific gravity below that of surrounding liquid.

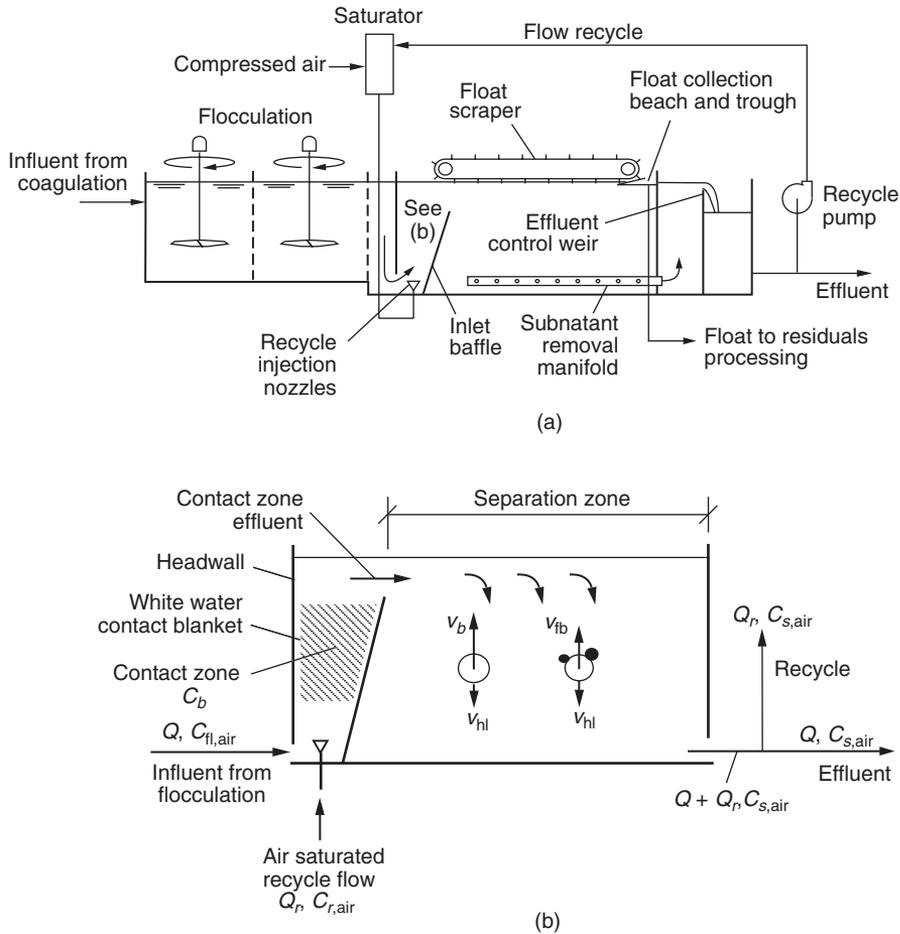

In the separation zone (see Fig. 10-22b), floc particles rise to the surface and form a discrete layer of solids known as float (as the float thickens before removal it is termed sludge). The float layer collects at the effluent end of the basin and is removed into a float collection trough. Float removal is accomplished either with a mechanical skimming device or hydraulically by solids overflow into the collection trough. The hydraulic removal of float is achieved by temporarily prohibiting water from leaving the basin, which causes the water level in the basin to rise and float to overflow into the float collection trough. Clarified water is removed through a perforated pipe lateral system, a false-floor system with a plenum, or an underflow baffle wall. An effluent weir is the ultimate point of discharge of the clarified water, as shown on Fig. 10-22a.

In water treatment plants, the DAF process is used for the removal of various forms of particulate matter from water including:

1. Low-density particulate matter such as algae
2. Dissolved organic matter (natural color)

## Process Description

## Dissolved Air Flotation Applications

**Figure 10-22**  
Dissolved air flotation process schematic.

3. Particulate matter from low- to moderate-turbidity waters
4. Algae, dissolved organic matter, and turbidity from low-temperature waters
5. Suspended material from filter waste washwater

Because gravity separation processes rely on density differences between particulate matter and water, separation of light particles or separation at low temperatures can be challenging. Dissolved air flotation takes advantage of these characteristics by widening the density difference by making the floc–bubble aggregate buoyant. The advantages and disadvantages of the DAF process compared to other clarification processes are presented in Table 10-8.

**Table 10-8**

Advantages and disadvantages of DAF in comparison with other clarification technologies

Advantages	Disadvantages
<ul style="list-style-type: none"> <li>• High loading rate: Typically 10–20 m/h. New process variants have operated successfully up to 40–45 m/h.</li> <li>• Very thick float (sludge) product: Typically 2–3% total solids float can be achieved using hydraulic or mechanical skimming devices. Float can be dewatered without intermediate thickening.</li> <li>• Often, no polymer is required, as DAF does not require a large, dense floc. Coagulant dosages may also be reduced in some circumstances.</li> <li>• Shorter flocculation times, as compared to gravity separation, are possible, because a smaller floc particle size is required.</li> <li>• Rapid startup, typically &lt;30–60 min to reach steady state, depending on size.</li> <li>• Excellent algae removal efficiencies.</li> <li>• Excellent <i>Giardia</i> and <i>Cryptosporidium</i> removal efficiencies (~2–2.5 log), depending on temperature.</li> <li>• Smaller footprint required as compared to conventional flocculation and gravity sedimentation</li> </ul>	<ul style="list-style-type: none"> <li>• Requires a cover or housing to protect the float layer from wind and precipitation.</li> <li>• Mechanically more complex than conventional gravity clarifiers.</li> <li>• More power intensive as compared to conventional flocculation and sedimentation (2.5–3 to 0.75–1 kWh/10<sup>3</sup> m<sup>3</sup> · d).</li> <li>• Generally not well suited for clarification of high-turbidity silt-laden waters.</li> <li>• Because DAF is more mechanically intensive, may not be suitable for locations where equipment maintenance is likely to be neglected.</li> </ul>

Proper coagulation is, perhaps, the most important factor affecting DAF performance. If destabilized floc particles (low particle charge and fairly hydrophobic) are not produced, then floc particle attachment to air bubbles will be poor (Edzwald, 2010). Other factors that are important in the DAF process include (1) floc characteristics, (2) bubble size and rise velocity, (3) air loading, (4) floc–bubble attachment, and (5) the solubility of gases at elevated pressure.

### Factors Affecting DAF Performance

#### FLOC CHARACTERISTICS

A large, readily settleable floc is appropriate for sedimentation, while a small, low-density floc is appropriate for DAF. A low-density floc contributes to the density of the floc–bubble aggregate being significantly less than the density of water, allowing the floc–bubble aggregate to float. In addition, the higher inherent turbulence of the DAF process, particularly in the contact zone of the basin, is more suitable for a small floc that is able to withstand high shear forces without disintegration.

The requirements for a small, low-density floc result in some significant differences in pre-DAF flocculation system design as compared to presedimentation flocculation as follows:

- Flocculation times can typically be reduced. Flocculation times as short as 5 min have been used successfully in DAF flocculation design.

In full-scale systems, 10 to 15 min is typical. In small-package plants, detention times are on the order of 20 min.

- Higher flocculation energy is usually beneficial to develop a small, tough floc. Typical design flocculation  $\bar{G}$  values range from 50 to  $100 \text{ s}^{-1}$ .
- Polymers used as flocculation aids are rarely needed or used.
- Reductions in coagulant dosages may be possible as a result of improved performance with smaller floc (Edzwald, 1995).
- Design of the baffling between the last stage of the flocculator and the DAF inlet should be an over-under baffle arrangement, so that flocculated water flows downward and into the DAF basin at floor level, encouraging interaction between the flocculated water and the recycle stream (see Fig. 10-22).

#### **BUBBLE SIZE AND RISE VELOCITY**

Generation of microbubbles is achieved by supersaturating a recycled side stream with air at an elevated pressure. Microbubbles are formed when the pressure of the saturated side stream is released. The side stream may be taken from the clarified water when the solids content is low enough not to cause saturator or injection nozzle fouling problems. Filtered water is used when the solids content is too high or the DAF and filtration processes are in the same concrete tank with flotation over the filters, typical in most small plants and in large plants where land (or space) is limited.

Generation of bubbles between 10 and  $100 \mu\text{m}$  in size is important for adequate floc-bubble attachment and flotation. Because floc-bubble attachment is a surface phenomenon, it is important that the bubbles be small enough that the total surface area for adherence is large. However, the bubbles must not be larger than  $130 \mu\text{m}$  to maintain laminar flow conditions (Gregory et al., 1999).

The bubble rise velocity depends upon the size of the bubble and the water temperature. Optimum conditions for maximum collision and attachment between floc particles and bubbles occur when the bubbles rise in the laminar flow regime, minimizing the impact of particles detaching from the bubbles due to the fluid shear forces. In the laminar flow region, Stokes' law (Eq. 10-13) can be used to estimate bubble rise velocity.

#### **FLOC-BUBBLE AGGREGATE RISE VELOCITY**

An important consideration is the rise velocity of the aggregates that form when bubbles attach to the floc. Floc-bubble aggregates are not spherical particles so the drag coefficients tend to vary somewhat from the drag coefficients for spherical particles presented in Sec. 10-2. Furthermore, the density and size of the floc-bubble aggregates must be determined

from the density and size of the bubbles and particles. The density of the floc–bubble aggregate is calculated from the expression (Edzwald, 2010)

$$\rho_{pb} = \frac{\rho_p d_p^3 + N_b \rho_b d_b^3}{d_p^3 + N_b d_b^3} \quad (10-44)$$

where  $\rho_{pb}$  = particle–bubble aggregate density, kg/m<sup>3</sup>  
 $\rho_p$  = particle density, kg/m<sup>3</sup>  
 $\rho_b$  = air bubble density, kg/m<sup>3</sup>  
 $d_p$  = particle diameter, m  
 $d_b$  = mean bubble diameter, m  
 $N_b$  = number of bubbles attached to floc particle

The equivalent spherical diameter of the floc–bubble aggregate can be determined from the expression

$$d_{pb} = \left( d_p^3 + N_b d_b^3 \right)^{1/3} \quad (10-45)$$

where  $d_{pb}$  = equivalent spherical diameter of floc–bubble aggregate, m

For laminar flow, the drag coefficient varies gradually from  $C_d = 24/\text{Re}$  for flocs of 40  $\mu\text{m}$  and smaller to  $C_d = 45/\text{Re}$  for flocs of 170  $\mu\text{m}$  (Edzwald, 2010). Thus, Stokes' law is appropriate for floc of 40  $\mu\text{m}$  (using the floc diameter and density from Eqs. 10-44 and 10-45) but the coefficient in the denominator should be adjusted for larger floc rising in laminar flow conditions. When flow is transitional ( $1 < \text{Re} < 50$ ), the drag coefficient has been reported as (Haarhoff and Edzwald, 2004)

$$C_d = \frac{45}{\text{Re}^{0.75}} \quad (10-46)$$

Substituting Eq. 10-45 into Eq. 10-7 and solving for the rise velocity as was done in Sec. 10-2 yields

$$v_{pb} = \left[ \frac{g (\rho_w - \rho_{pb}) d_p^{1.75}}{33.75 \rho_w^{0.25} \mu^{0.75}} \right]^{1/1.25} \quad (10-47)$$

where  $v_{pb}$  = rise velocity of floc particle–bubble aggregate, m/h  
 $g$  = acceleration due to gravity, 9.81 m/s<sup>2</sup>  
 $\rho_w$  = water density, kg/m<sup>3</sup>  
 $d_{pb}$  = equivalent spherical diameter of floc–bubble aggregate, m  
 $\mu$  = dynamic viscosity of water, N · s/m<sup>2</sup>

**AIR LOADING**

Recycle systems are designed to provide a target air loading per unit volume of raw water treated to ensure a dense bubble cloud forms within the contact zone. As noted previously, this dense bubble cloud, which to the naked eye appears as “milky” water, has been termed the “white water blanket (WWB).” The WWB contact zone provides an opportunity to capture the relatively low density of solids.

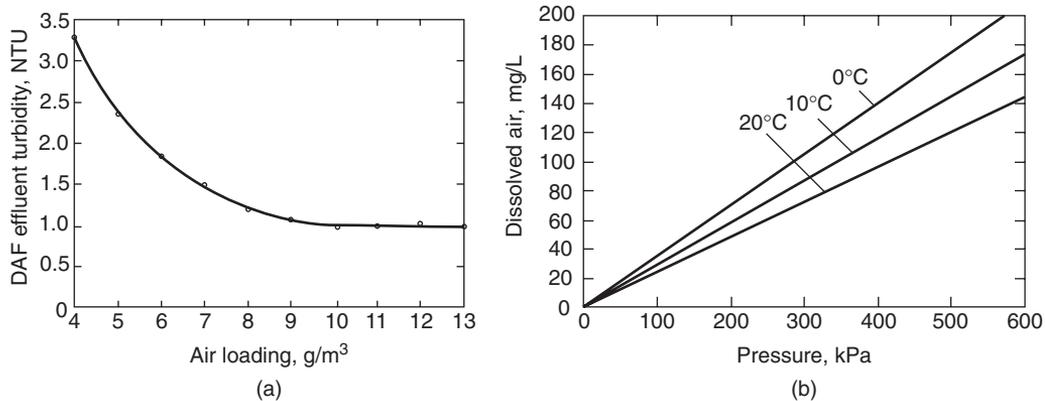

The effects of air loading on the DAF process are illustrated on Fig. 10-23a. Effluent turbidity declines with increasing air loading until a break point is reached where the application of additional air provides no corresponding increase in process performance.

The mass concentration of air released can be calculated from the following expression (Gregory et al., 1999):

$$C_b = \frac{e(C_r - C_{fl})r - k}{1 + r} \quad (10-48)$$

- where
- $C_b$  = mass concentration of air released, mg/L
  - $e$  = efficiency factor, dimensionless
  - $C_r$  = mass concentration of air in recycle flow, mg/L
  - $C_{fl}$  = mass concentration of air in flocc tank effluent, mg/L
  - $r$  = recycle ratio, dimensionless
  - $k$  = factor to account for air deficit in incoming flocculated water

The efficiency factor is used to account for minor pressure losses between the saturator and the point of air release. Henry’s law is used to calculate the mass concentration of air in the recycle flow, as will be illustrated in

**Figure 10-23**

Effects of (a) air loading on DAF effluent turbidity (adapted from Zabel, 1985) and (b) pressure and temperature on air solubility.

Example 10-9. The air concentration in the saturator can be expressed either as the bubble number concentration ( $N_b$ ) or the bubble volume concentration ( $\phi_b$ ). These values can be determined from the expressions

$$\phi_b = \frac{C_b}{\rho_{\text{air}}} \quad (10-49)$$

$$N_b = \frac{10^{12} \times 6\phi_b}{\pi d_b^3} \quad (10-50)$$

where  $\phi_b$  = bubble volume concentration, L/L  
 $C_b$  = mass concentration of air released, mg/L  
 $\rho_{\text{air}}$  = density of air saturated with water vapor, mg/L  
 $N_b$  = bubble number concentration, no./mL  
 $10^{12}$  = conversion factor,  $\mu\text{m}^3/\text{mL}$   
 $d_b$  = mean bubble diameter,  $\mu\text{m}$

It has been found that flotation performance increases as  $N_b$  increases because there are more collision and attachment opportunities between the bubbles and particles. Attached air bubbles provide lower floc particle density and larger volume, producing floc particle–bubble aggregates that have high upward velocities (Gregory et al., 1999).

#### MINIMUM VOLUME OF GAS NEEDED

The minimum volume of gas needed to achieve flotation can also be approximated with the following expression:

$$\frac{\phi_g}{\phi_p} = \frac{\rho_p - \rho_w}{\rho_w - \rho_g} \quad (10-51)$$

where  $\phi_g$  = minimum volume of gas required for flotation, mL/L,  
 ppm  
 $\phi_p$  = volume of particle, mL/L, ppm  
 $\rho_p$  = density of particle,  $\text{kg}/\text{m}^3$   
 $\rho_w$  = density of water,  $\text{kg}/\text{m}^3$   
 $\rho_b$  = density of air,  $\text{kg}/\text{m}^3$

Because the density of air relative to water is small Eq. 10-51 can be written as follows:

$$\frac{\phi_g}{\phi_p} \simeq \rho_p - 1 \quad (10-52)$$

In general, the amount of air relative the amount of floc must be significantly greater.

**SOLUBILITY OF AIR AT ELEVATED PRESSURE**

The increased solubility of gases in water at elevated pressure is the fundamental principle that allows the formation of microbubbles. The solubility of air in water increases in an essentially linear fashion, in the temperature range of concern in water treatment, with increasing pressure according to Henry's law, as presented and discussed in Chap. 14 and repeated here for convenience. The application of Henry's law is illustrated in Example 10-9.

$$Y = H_{YC} C \quad (14-25)$$

where  $Y$  = gas-phase concentration, mg/L  
 $H_{YC}$  = dimensionless Henry's constant  
 $C$  = liquid-phase concentration in equilibrium with gas-phase concentration  $y$ , mg/L

### Example 10-9 Estimating the saturation concentration of air in water as function of temperature and pressure

Determine the mass concentration of air in solution at 0 and 20°C if a DAF saturator is to operate at a pressure of 600 kPa (500 gauge).

**Solution**

1. Determine the mass concentration of air in solution at 0°C and 600 kPa.
  - a. From App. B, the mass concentration of air at 0°C and 1 atm, which corresponds to the density of air, is 1.2928 g/L.
  - b. Using the temperature coefficients given in Table 14-4 and Eq. 14-11, determine the value of the dimensionless Henry's constant,  $H_{YC}$ , at 0°C and 1 atm:

$$H_{YC} = K_C \exp\left(-\frac{\Delta H_{\text{dis}}^{\circ}}{RT}\right)$$

$$K_C = 3,368$$

$$\Delta H_{\text{dis}}^{\circ} = 10.28 \times 10^3 \text{ J/mol}$$

$$\begin{aligned} H_{YC} &= K_C \exp\left(-\frac{\Delta H_{\text{dis}}^{\circ}}{RT}\right) \\ &= 3368 \exp\left\{-\frac{10.28 \times 10^3 \text{ J/mol}}{(8.314 \text{ J/mol} \cdot \text{K})(273 + 0) \text{ K}}\right\} \\ &= 36.3 \end{aligned}$$

c. Rearrange Eq. 14-25 and solve for the mass of air in solution:

$$C = \frac{Y}{H_{YC}} = \frac{1292.8 \text{ mg/L}}{36.3} = 35.6 \text{ mg/L}$$

d. Determine the mass of air in solution at 600 kPa.

Note: 1 atm = 101.325 kPa

$$C = 35.6 \text{ mg/L} \left( \frac{600}{101.325} \right) = 210.8 \text{ mg/L}$$

2. Determine the mass concentration of air in solution at 20°C and 600 kPa.

a. From equation in App. B, the density of air at 20°C and 1 atm is 1.204 g/L.

b. From Table 14-4 the value of the dimensionless Henry's constant,  $H_{YC}$ , at 20°C and 1 atm is 49.58.

c. Solve for the mass of air in solution:

$$C = \frac{Y}{H_{YC}} = \frac{1204 \text{ mg/L}}{49.58} = 24.28 \text{ mg/L}$$

d. Determine the mass of air in solution at 600 kPa:

$$C = 24.28 \text{ mg/L} \left( \frac{600}{101.325} \right) = 143.8 \text{ mg/L}$$

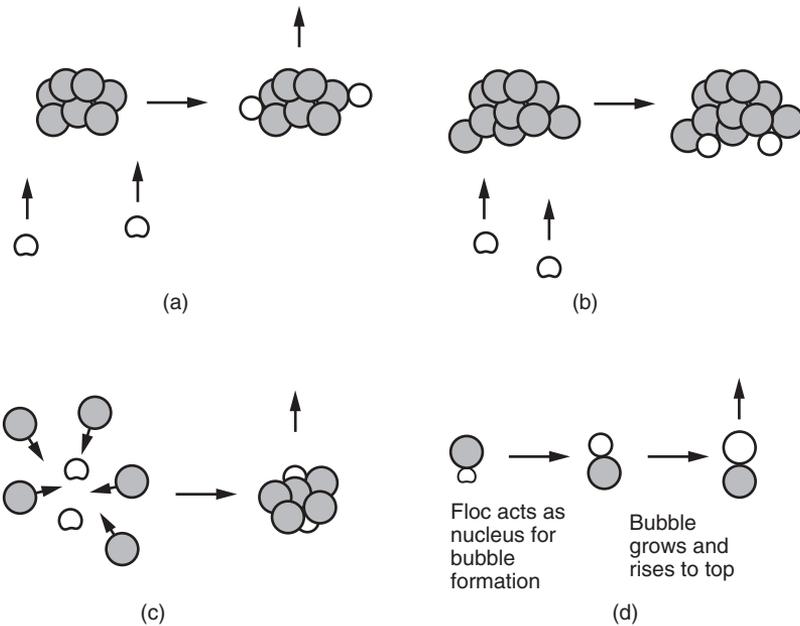

### Comment

The approximate saturation concentration of air can also be determined by considering oxygen and nitrogen separately and then combining the two values. The relationship is not exact because argon is neglected.

Using the computational procedures given in Example 10-9 a plot of the saturation concentration of air versus pressure for various temperatures is presented in Fig. 10-23b. As shown in Fig. 10-23b, the solubility of air in water is reduced at elevated temperatures. In DAF designs in tropical areas, or anywhere where raw-water temperatures routinely exceed 25°C, it is sometimes necessary to adopt higher than normal design recycle rates to ensure sufficient air can be delivered to the process at warmer temperatures.

### FLOC-BUBBLE ATTACHMENT

The mechanisms for floc-bubble attachment are not well understood and may be any of the following four mechanisms individually or in combination, also shown on Fig. 10-24: (1) fine air bubbles adhere to floc in WWB due to electrostatic attraction or other mechanisms (Fig. 10-24a); (2) fine air bubbles become physically entrapped within preformed floc in the WWB (Fig. 10-24b); (3) fine air bubbles become entrapped in floc particles as

**Figure 10-24**

Plausible mechanisms for floc–bubble aggregation: (a) bubbles adhere to preformed floc, (b) bubbles trapped in preformed floc, (c) bubbles trapped as floc forms, and (d) floc acts as nucleus for bubble formation.

they aggregate further within the DAF basin (Fig. 10-24c); and (4) floc particles act as nuclei for bubble formation (Fig. 10-24d).

Because any or all of the above mechanisms may be operative in floc–bubble attachment, it is important to perform at least bench-scale, and ideally pilot-scale, trials to confirm the viability of DAF early in process design. Use of design equations for DAF design is presented in Example 10-10. Additional details on floc–bubble attachment including proposed models can be found in Edzwald (2010) and Gregory and Edzwald (2010).

### Example 10-10 DAF design

A DAF plant is operating at 10 percent recycle with a saturator pressure of 600 kPa (500 kPa gauge). Flocculated water enters the contact zone with a floc particle concentration ( $N_p$ ) of 2500 particles/mL and a floc volume concentration ( $\phi_p$ ) of  $2.5 \times 10^{-6}$  L/L (2.5 ppm). Calculate the air mass concentration ( $C_b$ ), bubble zone volume concentration ( $\phi_b$ ), and bubble number concentration ( $N_b$ ) in the WWB contact zone of the DAF tank and compare the concentrations of bubbles to floc particles. Assume the water temperature is 20°C ( $\rho_{\text{air}} = 1.204 \text{ kg/m}^3 = 1204 \text{ mg/L}$ , see App. B), the

flocculated water has an oxygen deficit of 2 mg/L, the transfer efficiency between the saturator and the point of air release is 90 percent, and the mean bubble diameter is 40  $\mu\text{m}$ . (Adapted from Gregory et al., 1999.)

### Solution

1. Calculate the mass concentration of air in the DAF tank. The dissolved air in the water through the saturator is calculated first. From Example 10-9, the mass of air in the recycle water at 0°C and 600 kPa is about 143.5 mg/L. Based on the air mass balance in the WWB contact zone of the DAF tank, the concentration of air released can be calculated using Eq. 10-48:

$$\begin{aligned} C_b &= \frac{e(C_r - C_{fl})r - k}{1 + r} \\ &= \frac{0.9(143.9 \text{ mg/L} - 24.2 \text{ mg/L})0.10 - 2 \text{ mg/L}}{1 + 0.10} \\ &= 7.98 \text{ mg/L} = 7.98 \text{ g/m}^3 \end{aligned}$$

2. Calculate the bubble volume concentration  $\phi_b$  using Eq. 10-49:

$$\phi_b = \frac{C_b}{\rho_{\text{air}}} = \frac{11.36 \text{ mg/L}}{1200 \text{ mg/L}} = 9464 \times 10^{-6} \text{ L/L} \text{ (9464 ppm)}$$

3. Calculate the bubble number concentration  $N_b$  using Eq. 10-50:

$$\begin{aligned} N_b &= \frac{10^{12} \times 6\phi_b}{\pi d_b^3} = \frac{(10^{12} \mu\text{m}^3/\text{mL})(6)(0.009464 \text{ L/L})}{\pi(40 \mu\text{m})^3} \\ &= 2.8 \times 10^5 \text{ bubbles/mL} \end{aligned}$$

4. Compare the concentrations of bubbles to floc particles. The ratio of the concentration of bubbles to floc particles is calculated for the bubble number concentration and the bubble volume concentration:

- a. Bubble number concentration:

$$\frac{N_b}{N_p} = \frac{2.8 \times 10^5 \text{ bubbles/mL}}{2500 \text{ particles/mL}} = 112$$

Because the ratio of bubbles to particles is high, there is a lot of opportunity for particle collision and attachment:

- b. Bubble volume concentration

$$\frac{\phi_b}{\phi_p} = \frac{9464 \text{ ppm}}{2.5 \text{ ppm}} = 3786$$

Because the ratio of bubble volume to particle volume is high, the floc–bubble density is low, resulting in high rise velocities of the particle–bubble aggregate.

### Comment

The calculation may be a best-case scenario because it was assumed that there is no loss of air between the saturator and the DAF contact tank.

### FLOC–BUBBLE SEPARATION (FLOTATION) ZONE

In the floc–bubble separation zone the removal of free air bubbles and floc–bubble aggregates is based on Hazen’s sedimentation theory (Edzwald, 2010). The flow through the separation zone is assumed to be plug flow in the vertical direction, neglecting the horizontal flow that occurs over the end of the baffle and below the float layer. Under ideal conditions, referring to Fig. 10-22b, the following relationships must apply (Edzwald, 2010):

$$v_b \geq v_{hl} = \frac{Q + Q_r}{A_s} \quad (10-53)$$

$$v_{fb} \geq v_{hl} = \frac{Q + Q_r}{A_s} \quad (10-54)$$

where  $v_b$  = rise rate of air bubble, m/h  
 $v_{hl}$  = downward vertical velocity based on hydraulic loading rate, m/h  
 $Q$  = flow rate to be treated, m<sup>3</sup>/h  
 $Q_r$  = recycle flow rate, m<sup>3</sup>/h  
 $A_s$  = cross-sectional area of separation zone perpendicular to flow, m<sup>2</sup>  
 $v_{fb}$  = rise rate of floc–bubble aggregate, m/h

Clearly, the rise rate for air bubbles and floc–bubble aggregates must be greater than the downward velocity due to the hydraulic loading rate. A number of theories have been advanced to explain the removals achieved under less than ideal conditions that often exist within the separation zone including the effects of stratified flow that can occur below the float (sludge) layer. The flow characteristics within the separation zone have also been modeled using computational fluid dynamics (Edzwald, 2010).

### Design Considerations for DAF Systems

Important design considerations for DAF systems, such as shown on Fig. 10-25, include the basin layout and geometry, recycle systems, sub-natant removal systems, and float removal systems. Each of these design considerations is discussed below.

(a)

(b)

**Figure 10-25**

Views of typical dissolved air flotation units: (a) rectangular type with a chain and flight system for float removal and (b) circular type (used for small systems) with a skimming arms for float removal

#### **BASIN LAYOUT AND GEOMETRY**

The design hydraulic loading rate fixes the total surface area available for flotation in the basin. Basin geometry is a balance between the most cost-effective geometry of the individual basins and the total number of basins in the plant. A summary of design parameters and recommended values is given in Table 10-9. Some alternative DAF systems are also reviewed in this section.

##### *Basin length*

Basin length is restricted typically to less than 11 m from the headwall to the float beach (see Fig. 10-22) to control the density of the bubble blanket. The bubble blanket formed in the contact zone is typically thick but becomes thinner as it flows through the contact zone. Restricting the length of the overall basin prevents the blanket from becoming too thin, which would cause the buoyancy of the float layer to be reduced or even lost, potentially resulting in resuspension of float into the subnatant.

##### *Basin width*

Once the basin length is fixed, the width of the basin is selected based on the design loading rate, while considering mechanical equipment and backmixing. Structurally spanning large widths may not be practical, and standard mechanical equipment may not be available to fit large widths. Narrow basins are also preferred to reduce backmixing by promoting plug flow through the basin. A length-to-width ratio ( $L/W$ ) slightly greater

**Table 10-9**

Typical design criteria for a DAF clarification system

Design Parameter	Unit	Value
<b>Flocculation Process</b>		
Number of basins	Minimum number	2
Number of stages	Number	2
Water depth	m	3.5–4.5
Basin length-to-width ratio	Ratio	1
Detention time, large plants	min	10–15 <sup>a</sup>
Detention time, small package plants	min	20
Energy input range, G	s <sup>-1</sup>	50–100
<b>Basin Design for Rectangular Configuration</b>		
Number of basins	Minimum number	2
Surface hydraulic loading rate, conventional, based on separation zone	m/h	10–20
Surface hydraulic loading rate, high rate, based on separation zone	m/h	40–45
Basin length, from headwall to float beach (separation zone)	m	<11
Basin length-to-width ratio	—	1–1.25
Surface area	m <sup>2</sup>	90–110
Maximum hydraulic capacity for single basin	m <sup>3</sup> /s	0.25–0.5
Basin cross-flow velocity	m/h	18–100
Basin depth	m	2.5–3
Contact zone detention time	s	60–240
Contact zone hydraulic loading rate	m/h	35–100
Baffle clearance velocity	m/h	55
Contact zone baffle angle	deg to horizontal	60–90
<b>Recycle System</b>		
Recycle ratio	% of influent flow	6–12
Recycle system pressure	kPa (gauge)	400–700
Nozzle spacing	m	0.2–0.3
Saturator hydraulic loading rate	m/h	60–80
Saturator packing depth	m	1.0–1.5
Injection nozzles	Fixed-orifice nozzles recommended	
Air loading	g air/m <sup>3</sup> raw water	6–10
Air bubble size	μm	10–100
Bubble concentration	bubbles/mL	1.0–2.0 × 10 <sup>5</sup>
Raw-water bubble number–particle number ratio	Dimensionless	10:1–200:1
Bubble volume concentration	ppm	3500–8000

**Table 10-9** (Continued)

Design Parameter	Unit	Value
Flocculated water bubble–volume to particle volume ratio	Dimensionless	350:1–8000:1
Recycle pump	Centrifugal	Provides one stand-by pump per recycle system
Air compressor	Oil-lubricated rotary screw type, with good posttreatment for particulate and oil removal; oil-free compressors not recommended due to maintenance requirements	
<b>Float Removal</b>		
System type	Mechanical or hydraulic. Choice of type is site specific, but should include cost implications on residuals-handling systems. For mechanical skimming, reciprocating scrapers are recommended.	
<b>Subnatant Removal</b>		
Type of removal system	Perforated pipe laterals or underflow end wall. Special underdrain systems consisting of a false bottom and plenum

<sup>a</sup>Flocculation times as low as 5 min with high surface loading rates have been demonstrated (Edzwald, 2010; Gregory and Edzwald, 2010).

than 1.0 is recommended for full-scale DAF basins. In some new high-rate DAF systems, as described at the end of this section, the length is less than the width.

#### *Basin depth*

Although in theory basin depth should not impact solids removal, in practice it is important to control cross-flow velocity to limit scouring of float from underneath. Recommended basin depths and cross-flow velocities are listed in Table 10-9.

#### *Baffle placement*

The inlet baffle placement should create a contact zone volume large enough to provide good floc–bubble contact time (see Table 10-9), but not so large as to encourage short circuiting. Key parameters governing placement of the baffle are the distance from the headwall to the baffle at floor level, the angle of inclination of the baffle, and the height of the baffle, which defines the clearance between the top of the baffle and the water surface. Criteria ranges for baffle placement are listed in Table 10-9. The lower range of the criteria and baffle angles of at least 75° are recommended for basins with higher hydraulic loading rates to ensure that the bubble cloud will entirely fill the contact zone. If an excessive contact zone length

(or a low baffle angle) is selected, the potential exists for raw-water short circuiting within the zone, whereby water flows along the bottom of the contact zone and up the face of the baffle wall. Circulatory patterns in the contact zone may result in less desirable floc–bubble interaction.

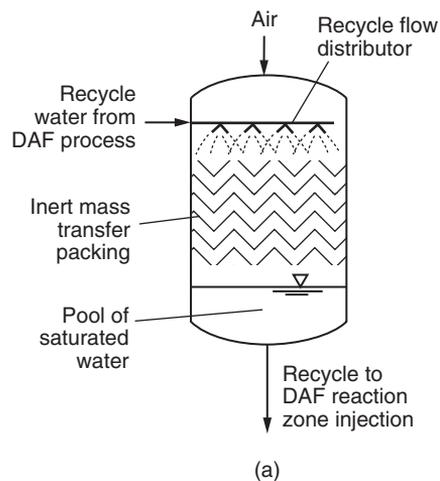

### RECYCLE SYSTEMS

The recycle system is comprised of the saturator, the injection system manifold with orifice nozzles, the recycle flow pressurization pump, an air compressor, and associated piping. An effective DAF recycle system provides the required quantity of air while using as little recycle water as possible, minimizing unnecessary turbulence in the contact zone and keeping pumping costs down. Typical operating pressures optimal for generating microbubbles while minimizing capital cost for saturator vessels are listed in Table 10-9. Additional details on recycle system design are presented below.

#### *Saturator vessel*

The saturator is typically packed with an inert mass transfer media (see Fig. 10-26a) to enhance saturation efficiency (Rees et al., 1979) and is designed based upon surface hydraulic loading (recycle flow divided by superficial area). Higher loading rates tend to cause flooding of the packed bed and significant loss of efficiency. Recycle water is drawn from the DAF effluent collector and pumped into the saturator near the top, where a flow distribution header sprays the water over the entire superficial area of the vessel.

The recycle water trickles downward, forming a thin film on the media and maximizing surface area for transfer of air into the water. A separate air connection at the top of the vessel maintains the saturator at a relatively

**Figure 10-26**  
Typical DAF saturator:  
(a) schematic cross  
section and  
(b) photograph.

(a)

(b)

constant operating pressure. The packed bed rests on a perforated plate, below which saturated water collects in a clearwell at the base of the vessel. With the vessel discharge open to the recycle injection manifolds in the DAF basin, the pressure in the saturator provides the force necessary to drive injection of the saturated fluid back into the basin.

#### *Injection manifolds*

One or more injection manifolds are mounted within the basin contact zone either at floor level or just above the point where the raw water is introduced. Each manifold is fitted with fixed-orifice nozzles spaced at 8 to 12 even intervals across the basin width to release the pressure-forming microbubbles across the superficial area of the contact zone.

#### *Fixed-orifice nozzles*

Several manufacturers have devised proprietary fixed-orifice nozzles for generating bubbles in the ideal size range. These nozzles usually share two common principles (Haarhoff and Rykaart, 1995):

- The nozzles utilize some means for rapidly reducing the pressure from the saturator pressure to atmospheric pressure. The rapid pressure drop causes immediate formation of air bubbles, potentially in an uncontrolled fashion.
- Immediately downstream of the pressure release, some form of impingement or rapid change in direction of flow shears the newly formed bubbles and breaks them down into the desired size range.

Needle valves may be used for generating bubbles; however, they are substantially more difficult to adjust to ensure an even balance of recycle flow across the basin and are therefore not recommended. Fixed-orifice nozzles provide a passive means to balance this flow and are generally not prone to fouling due to solids once the plant is operating.

#### *Head loss in manifold systems*

Once saturation of the recycle stream has been achieved, water is delivered to the recycle injection manifolds with as little head loss as possible, as any loss of head will result in the premature formation of bubbles, which leads to bubble coalescence. From a design standpoint, several approaches to limit head loss are recommended:

- The saturator vessel should be kept elevated so the water level in the saturator clearwell is above the water level in the basin. If the saturator is placed too low, a reduction in static head as the recycle travels toward the injection point will result in air precipitation.
- The saturator should be placed as close as possible to the injection point, and interconnecting piping downstream of the saturator should be designed to keep velocities low and with a minimum of fittings.

**SUBNATANT REMOVAL**

Clarified water, or subnatant, from the separation zone of the DAF basin is removed at a submerged location near the basin floor. An important design consideration for the subnatant removal system is the variation of the hydraulic profile through the basin at different flow rates. A discussion of the two most common approaches to separating the subnatant from the separation zone follows.

*Underflow baffle*

An underflow baffle wall may be used at the end of the basin, allowing subnatant to flow under the baffle across the full width of the basin. Systems with an underflow baffle typically have significant downward velocities at the end of the basin. The downward-flow velocities occur in an area of the basin where float concentrations are highest and bubble cloud densities are lowest, so the potential exists for resuspension of float at the end of the basin.

*Perforated-pipe laterals*

A series of parallel, perforated-pipe laterals (false floor) across the floor of the basin are used to evenly withdraw subnatant. In theory, the perforated-pipe or false-floor approach offers an even withdrawal of subnatant; however, in practice, there is about 0.3 m of head loss with a perforated-pipe lateral system. Usually the laterals can be designed to achieve a reasonably even withdrawal of flow, and operating an individual basin across a fairly narrow range of flows limits water surface level variation.

**FLOAT REMOVAL**

Float may be removed mechanically or hydraulically from a DAF basin. Because float removal occurs at the surface, varying the basin water level may impact the density of sludge removed, especially if the water level varies more than 0.05 to 0.08 m (2 to 3 in.) across the full range of basin operating flows.

*Mechanical float removal*

A surface skimmer is used to scrape the floated solids over a dewatering bench (float beach) and into a hopper from where they can be pumped to residual-handling facilities (see Fig. 10-22a). There are three types of mechanical float-skimming systems: (1) a chain and flight system where flights are mounted across the basin and attached at either side to a continuous chain, as shown on Fig. 10-25a; (2) a reciprocating-type system, where a series of blades are mounted on a carriage and the entire carriage is moved forward when in the scraping mode; and (3) a beach scraper, where a drum with a number of blades is fixed at the far end of the DAF tank at the beach. As the drum rotates, the blades sweep the float over the beach plate.

### *Hydraulic float removal*

When the float is removed hydraulically, the effluent flow is closed off, but the basin is kept on-line so that the water level in the basin rises, causing float to flow over a sludge weir and into the float collection trough. For a hydraulic sludge system, the basin outlet needs to include a convenient point where the effluent flow can be temporarily shut off, using a gate (sluice or slide) or a valve. A hydraulic float removal system is substantially less complex than a mechanical system, typically requiring only a single moving component (gate or valve) on the basin outlet, making this type of system less expensive to install and easier to operate and maintain.

### *Comparison of mechanical and hydraulic float removal systems*

The most significant difference between mechanical and hydraulic systems is the consistency of the sludge product, which impacts the residual-handling system. Because the float separates out as a discrete layer on the surface of the basin, a well-designed mechanical skimmer system can physically remove the float while minimizing carryover of additional liquid. The result is a very thick sludge product that can be removed from the basin using a mechanical skimming system, typically on the order of 2 to 3 percent total solids (percent total solids by weight). By comparison, hydraulic float removal systems allow a significant carryover of water into the float collection trough, producing a sludge that is typically 0.5 percent total solids. The end result is a total sludge volume substantially larger than that produced by mechanical systems.

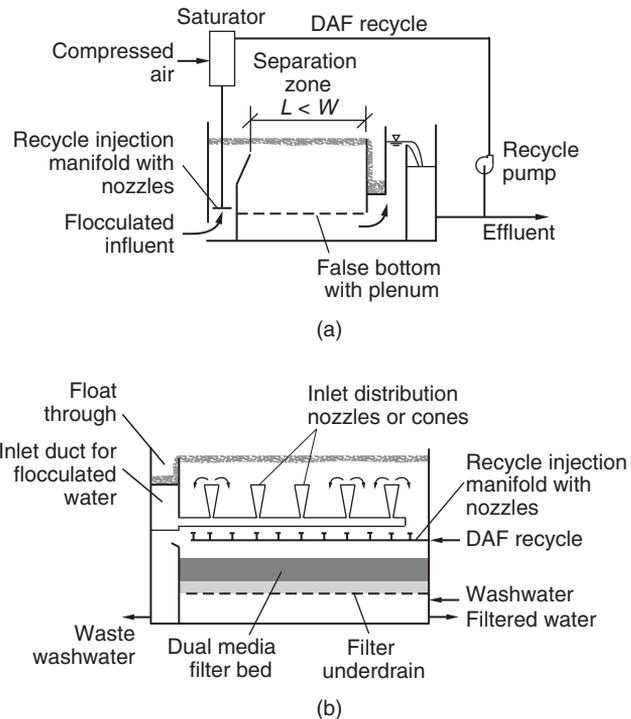

Both mechanical and hydraulic float removal systems commonly make use of spraying systems to help move sludge as required. In mechanical systems, a spray header is typically provided along the length of the float collection trough to assist sludge flow, if required. Hydraulic systems usually do not require this feature; however, spray headers are commonly supplied along both sidewalls of the basin and are used to cut the sludge blanket away from the wall during the desludging cycle.

### **OTHER TYPES OF DAF SYSTEMS**

Over the years since becoming an effective and accepted process for the treatment of water, a number of process variations and proprietary DAF processes have been developed. Two proprietary units are described below: (1) the AquaDAF and (2) the countercurrent dissolved air flotation/filtration (CoCoDAFF) process (Degrémont, 2007).

#### *AquaDAF*

The AquaDAF unit was developed in Finland and is licensed by Infilco-Dergmont. The unit involves the use of an improved proprietary air release manifold system across the entire bottom of the unit to produce a deeper WWB zone (1 to 2 m) in the contact chamber to enhance the coalescence of the air bubbles and aggregation of the coalescence air bubbles with the

**Figure 10-27**

Alternative dissolved air flotation units: (a) AquaDAF with proprietary discharge nozzle system and shorter length to width ratio than conventional DAF unit and (b) CoCoDAFF, which combines a flotation unit with a granular media filter in a single basin.

floc particles. The discharge baffle is curved, which when coupled with a false bottom in the flotation part of the reactor creates a circulation pattern within the unit (see Fig. 10-27). Because of the presence of a deeper WWB zone and the circulation pattern, the rise velocity the resulting air/floc particles is significantly greater than that encountered in conventional DAF units. Because of the increased rise rate, the length of the unit is less than the width of the unit.

#### *CoCoDAFF*

The CoCoDAFF involves placing the dissolved air flotation cell directly above a granular media filter as shown on Fig. 10-27b. This process was developed in the early 1990s by Thames Water to overcome filter operational problems resulting from seasonal algal blooms. Both mono- and dual-media filter beds have been used. As shown in Fig 10-27b, flocculated water is discharged below the surface through a series of special high-flow-rate conical nozzles connected to an inlet manifold. The pressurized recycle water is introduced below the inlet manifold. The air released from the pressurized recycle flow creates a bubble blanket, which moves countercurrent to the water. Flocculent material is removed from the water and floated to the surface as the water moves downward through the bubble blanket. In combined systems, the filter hydraulic loading rate, being

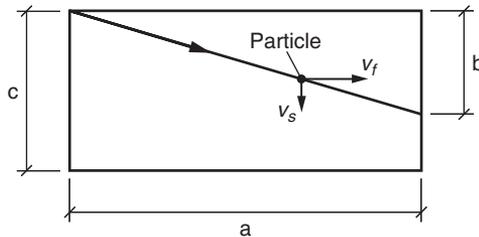

lower than that of the DAF unit, will control the design of the combined flotation–filter unit. When algae are not present or their concentration is low, the DAF portion of the combined system does not need to be operated.

## Problems and Discussion Topics

- 10-1 Calculate the terminal settling velocity and the Reynolds number of the particle given (to be selected by instructor).

Parameter	A	B	C	D	E
Particle diameter, $\mu\text{m}$	50	500	300	150	210
Particle density, $\text{kg}/\text{m}^3$	2650	1050	1050	2600	1700
Water temperature, $^{\circ}\text{C}$	10	15	5	20	15

- 10-2 Estimate the size of sand particle with density of  $2650 \text{ kg}/\text{m}^3$  that would move the same distance in 1 h due to Brownian motion as it would settle in water at  $10^{\circ}\text{C}$  based on Stokes' law.
- 10-3 Consider the particle shown below with the values in the table (to be selected by instructor). Calculate the overflow rate that corresponds to the settling velocity of the particle on the trajectory shown (report your answers in  $\text{m}/\text{h}$  and  $\text{gpm}/\text{ft}^2$ ). If it is desired to achieve complete removal of particles of this size, what adjustment in the length of the basin would be required?

Parameter	A	B	C	D	E
Fluid velocity, $\text{cm}/\text{s}$	20	1.4	0.5	1	0.28
Dimension a, m	4	100	72	80	30
Dimension b, m	0.6	3.5	1.7	0.85	3.6
Dimension c, m	0.9	4.2	3.5	1	4.2

- 10-4 For the particle-settling data shown in Example 10-3, plot the removal efficiency as a function of overflow rate for overflow rates ranging from 0.5 to 4  $\text{m}/\text{h}$ . Determine the overflow rate required to achieve 75 percent removal. If the depth of the basin is 4 m, what is the corresponding detention time?

## 10 Gravity Separation

- 10-5 For the rectangular horizontal-flow sedimentation basin and influent particle-settling characteristics given (to be selected by instructor), calculate the particle removal efficiency and plot the influent and effluent particle concentrations as a function of particle size.

Parameter	A	B	C	D	E
Flow rate, m <sup>3</sup> /d	7,570	19,000	19,000	56,800	56,800
Length, m	30	72	60	100	80
Width, m	5	12	8	18	12

Settling Velocity, m/h	Number of Particles, #/mL				
	A	B	C	D	E
0–0.4	511	511	460	560	255
0.4–0.8	657	657	578	720	314
0.8–1.2	876	876	891	880	454
1.2–1.6	1168	1168	1285	1110	584
1.6–2.0	1460	1460	1748	1320	761
2.0–2.4	1314	1314	1577	1110	639
2.4–2.8	657	657	719	620	321
2.8–3.2	438	438	436	440	219
3.2–3.6	292	292	263	320	141
3.6–4.0	292	292	241	160	116
Total	7665	7665	8198	7240	3804

- 10-6 What are the principal causes of flocculation during sedimentation? Why is flocculation beneficial in a sedimentation tank?
- 10-7 Determine the area of a clarifier required for solids thickening for the parameters given below (to be selected by instructor). The settling velocity of the sludge blanket follows the data given in Table 10-1 and plotted on Fig. 10-8. Also determine  $J_L$ ,  $C_L$ , and  $Q_u$ .

Parameter	A	B	C	D	E
Influent flow rate, m <sup>3</sup> /h	3,000	1,500	2,500	3,300	4,500
Influent solids conc., mg/L	500	800	400	500	800
Underflow solids conc., mg/L	10,000	12,000	14,000	14,000	15,000

- 10-8 A grit chamber is designed to remove sand of 0.08 mm and larger for a design flow of 2.2 m<sup>3</sup>/s (50 mgd). The maximum flow rate is approximately 1.5 times the average flow and the water temperature is 15°C. Assume a typical water depth of 3.5 m for each tank and a factor of safety of 1.5 is to be used. Determine the number and shape of tanks required and their size. Determine the configuration of the diffuser wall.

- 10-9 A water treatment plant is to be designed to treat water with the maximum daily flow and design given below (to be selected by instructor). For the given overflow rate, design a horizontal rectangular sedimentation basin.

Parameter	A	B	C	D	E
Influent flow rate, m <sup>3</sup> /d	15,000	380,000	90,000	220,000	220,000
Overflow rate, m/h	1.10	2.15	2.6	1.65	2.0
Water temperature, °C	10	15	20	20	10

- 10-10 A continuous horizontal flow settling basin is designed to treat a flow rate of 1.1 m<sup>3</sup>/s (25 mgd) and remove floc particles with an average settling velocity of 3.6 m/h. This settling velocity was measured in a laboratory in a quiescent condition at 15°C. Determine the area of the basins and the basin area that needs to be covered with tube settlers. The tube settlers consists of a series of 50-mm (2-in.) square honeycomb cells tilted at a 60° angle. The vertical height of the tube settlers is 0.6 m. Assume a countercurrent flow pattern is used.
- 10-11 Calculate the theoretical settling efficiency ( $v_s/v_0$ ) of parallel square plates, square tubes, hexagons, and circular tubes. The hydraulic diameter, tube length, and angle of the tubes to the horizon are 80 mm, 1.5 m, and 60°. Assume a consistent hydraulic diameter is used because it guarantees that the Reynolds number is the same for the same velocity. Assume a countercurrent flow pattern is used and that any hydraulic problems associated with poor design such as flow distribution and sludge resuspension can be ignored. Note: The hydraulic diameter is equal to two times the hydraulic radius.
- 10-12 Evaluate and compare the settling velocity and rise velocity of a 15- $\mu$ m floc particle that has a density of 1250 kg/m<sup>3</sup> for summer (25°C) and winter (4°C) water temperatures. For the rise velocity calculations assume that the floc attaches to one air bubble that is 30  $\mu$ m in size.
- 10-13 Using the values for the Henry's law constants for oxygen and nitrogen, as given in Table 14-4, verify the values for the amount of air dissolved at 0°C and 101.325 kPa (1 atm) and at 20°C and 600 kPa as determined in Example 10-9.
- 10-14 A DAF plant is operating at 8 percent recycle with a saturator pressure of 650 kPa. Flocculated water enters the contact zone with a floc particle concentration ( $N_p$ ) of 1000 particles/mL and a floc volume concentration ( $\phi_p$ ) of 1.0 ppm. Calculate the air mass concentration ( $c_b$ ), bubble zone volume concentration ( $\phi_b$ ), and bubble number concentration ( $N_b$ ) in the contact zone of the DAF tank and compare the concentrations of bubbles to floc particles.

Assume the water temperature is 15°C ( $\rho_{\text{air}} = 1.2250 \text{ kg/m}^3$ ), the flocculated water has no oxygen deficit, and the mean bubble diameter is 30  $\mu\text{m}$ .

## Terminology for Granular Filtration

---

<b>Term</b>	<b>Definition</b>
Air scour	Optional feature during backwash in which air is introduced into filter underdrains along with backwash water; the vigorous scouring action helps clean deep-bed filters.
Backwash	Process for removing accumulated solids from a filter bed by reversing the water flow.
Bag and cartridge filtration	Pressure driven separation processes that remove particles larger than 1 $\mu\text{m}$ using an engineered porous filtration media consisting of fabric or self-supporting filter elements.
Conventional treatment	Process train consisting of coagulation, flocculation, sedimentation, and filtration.
Contact filtration	Process train consisting of coagulation and filtration.
Depth filtration	Filtration mechanism in which particles accumulate throughout the depth of a granular filter bed by colliding with and adhering to the media. Captured particles can be many times smaller than the pore spaces in the bed.
Diatomaceous earth	Granular material of nearly pure silica, mined from natural deposits of fossilized diatoms that is used as a filtration media in precoat filtration.

<b>Term</b>	<b>Definition</b>
Direct filtration	Process train consisting of coagulation, flocculation, and filtration.
Effective size (ES)	Measure of the size of granular media; the size at which 10 percent of the media has a smaller diameter ( $d_{10}$ ) as determined by a sieve analysis.
Filtration	Removal of particles (solids) from a suspension (two-phase system containing particles and liquid) by passage of the suspension through a porous medium. In granular filtration, the porous medium is a bed of granular material.
Filtration rate	Key process variable; the superficial water velocity through the filter bed, calculated as the flow rate divided by the cross-sectional area of the bed.
In-line filtration	Contact filtration.
Precoat filtration	Granular filtration process in which a fine granular material is introduced into the filter module and collects as a thin cake against a support septum; filtration occurs by straining at the surface of this cake layer.
Rapid filtration	Granular filtration process engineered to achieve filtration rates about 100 times greater than slow sand filtration. Key requirements include coagulation pretreatment, granular media sieved for greater uniformity, and backwashing to remove accumulated particles.
Ripening	Process of granular media conditioning at the beginning of a filter run during which clean media captures particles and becomes more efficient at capturing additional particles. During ripening filter effluent water may not meet quality requirements and must be wasted; typically it is recycled to the head of the plant.
Schmutzdecke	Layer of particles and microorganisms that forms in the top few centimeters of a slow sand filter.
Slow sand filtration	Granular filtration process during which water passes slowly down through a bed of sand. Filtration occurs primarily by straining at the surface of the Schmutzdecke located at the top of the bed.
Specific deposit	Mass of accumulated particles in a filter per unit of filter volume
Straining	Filtration mechanism in which particles are captured at the surface of a filter because they are too large to fit through the pore spaces in the filter.

Term	Definition
Underdrain	Components installed at the base of a filter bed. Underdrains must support the media and evenly collect filter effluent and distribute backwash water (and air) to avoid channeling in the filter bed.
Uniformity coefficient (UC)	Measure of the uniformity of granular media; the ratio of the 60th percentile ( $d_{60}$ ) to the 10th percentile ( $d_{10}$ ) media sizes as determined by a sieve analysis.
Unit filter run volume (UFRV)	Quantity of water that passes through a filter over the course of an entire filter run.

Filtration is widely used for removing particles from water. Filtration can be defined as any process for the removal of solid particles from a suspension (a two-phase system containing particles in a fluid) by passage of the suspension through a porous medium. In granular filtration, the porous medium is a thick bed of granular material such as sand. The most common granular filtration technology in water treatment is *rapid filtration*. The term is used to distinguish it from *slow sand filtration*, an older filtration technology with a filtration rate 50 to 100 times lower than rapid filtration. Key features of rapid filtration include granular media sieved for greater uniformity, coagulation pretreatment, backwashing to remove accumulated particles, and a reliance on *depth filtration* as the primary particle removal mechanism. In depth filtration, particles accumulate throughout the depth of the filter bed by colliding with and adhering to the media. Captured particles can be many times smaller than the pore spaces in the bed.

Nearly all surface water treatment facilities and some groundwater treatment facilities use filtration. Most surface waters contain algae, sediment, clay, and other organic or inorganic particles. Filtration improves the clarity of water by removing these particles. All surface waters also contain microorganisms that can cause illness, and filtration is nearly always required in conjunction with chemical disinfection to assure that water is free of these pathogens. Groundwater is often free of significant concentrations of microorganisms or particles, but may require filtration when other treatment processes (such as oxidation or softening) generate particles that must be removed.

This chapter presents a brief history of granular filtration, a description of the rapid filtration process, properties of filter media, hydraulics of flow through granular media, particulate removal in rapid filtration, and design of rapid filters. A variety of other filtration options and technologies are used in water treatment, including pressure filtration, slow sand filtration, greensand filtration, biologically active filtration, diatomaceous earth filtration, and cartridge or bag filtration. These technologies are introduced

briefly at the end of this chapter. Membrane filtration is another common filtration technology used in water treatment but will be discussed in a different chapter (Chap. 12) because of the substantial differences between granular and membrane filtration technologies. Granular media filters are still the most common type of filters in use today.

## 11-1 Brief History of Filtration

---

Filters have been used to clarify water for thousands of years. Medical lore written in India, dating to perhaps 2000 BC, mentions filtration through sand and gravel as a method of purifying water. Hippocrates advocated filtration through cloth bags in the fourth century BC. The Romans dug channels parallel to lakes to take advantage of natural filtration through soil when using lakes for water supplies. Venice, Italy, stored rainwater in cisterns but drew the fresh water from wells in sand that surrounded the cisterns (Baker, 1948).

The commercialization and patenting of filtration technologies started in France around 1750, using various filter media such as sponges, charcoal, wool, sand, crushed sandstone, or gravel. The practice of filtering surface water through engineered systems and distributing it on a municipal scale began in England and Scotland around 1800. Various filtration concepts were tested, including flow direction (downflow, upflow, and horizontal flow), sand and gravel media graded from smaller to larger sizes, and backwashing by reverse flow. The first modern slow sand filter, designed by James Simpson for the Chelsea Water Works Company in London in 1829, incorporated an underdrain system, graded gravel and sand media, a filtration rate of about 0.12 m/h (0.05 gpm/ft<sup>2</sup>), and cleaning by scraping (Baker, 1948). These design features are still used today.

The first regulation mandating filtration, passed in 1852, required all river water supplied by the Metropolitan District of London to be filtered. The regulation was prompted by rampant pollution in the Thames River and suspicions that cholera was transmitted by water (Fuller, 1933), a suspicion confirmed by Dr. John Snow in his famous investigation of a cholera outbreak in London just 2 years later.

Interest in filtration grew as people realized that it prevented waterborne disease. In 1892, the city of Altona, Germany, largely escaped a cholera epidemic that ravaged neighboring Hamburg. Both cities used the Elbe River as a water supply, but Altona was protected by its slow sand filters even though its water was withdrawn downstream of Hamburg and was contaminated with Hamburg's waste (Hamburg had no filtration system). Similarly, a dramatic reduction in typhoid cases resulted when filters were installed in Lawrence, Massachusetts. Many communities in the United States first began filtering their water supplies during the first couple of decades of the twentieth century.

Rapid filtration originated in the United States during the 1880s. The first municipal plant employing coagulation and other critical elements of rapid filtration was in Somerville, New Jersey, in 1885 (Fuller, 1933). Both slow sand and rapid filters were common in early filter installations (Fuller, 1933), but by the middle of the twentieth century, rapid filters were commonplace and slow sand filters were rarely used.

By the latter part of the twentieth century, most surface waters were filtered before municipal distribution, with rapid filters used in almost all cases (99 percent). Nevertheless, the Surface Water Treatment Rule (SWTR), passed in 1989, was the first regulation in the United States requiring widespread (but not universal) mandatory filtration of municipal water (U.S. EPA, 1989), with the recognition that chemical disinfection alone was insufficient for protozoa such as *Giardia lamblia* and *Cryptosporidium parvum*. Surface water treatment regulations have continued to get more stringent, particularly the remaining utilities with unfiltered surface water supplies that have been under increasing pressure to install filtration. In short, filtration is and will continue to be a central feature in surface water treatment plants.

## 11-2 Principal Features of Rapid Filtration

---

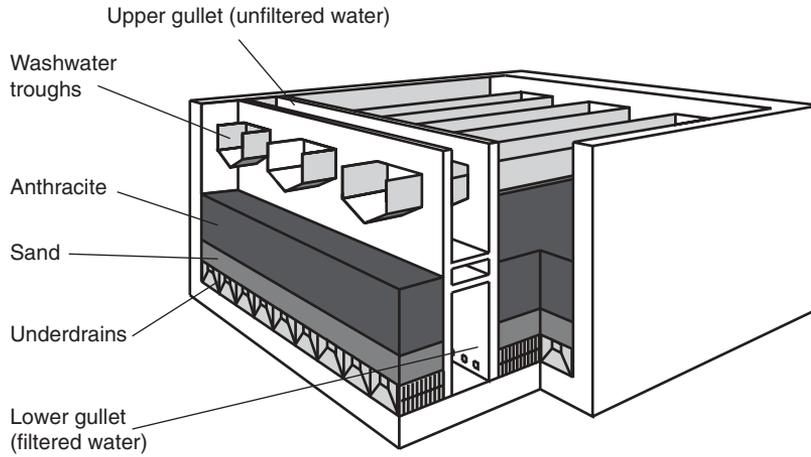

Rapid filtration has several features that allow it to operate at rates up to 100 times greater than slow sand filtration. The most important of these features are (1) a filter bed of granular material that has been processed to a more uniform size than typically found in nature, (2) the use of a coagulant to precondition the water, and (3) mechanical and hydraulic systems to efficiently remove collected solids from the bed.

### **Uniformity of Filter Media**

The filter material in rapid filters is processed to a fairly uniform size. Media uniformity allows the filters to operate at a higher hydraulic loading rate with lower head loss but results in a filter bed with void spaces significantly larger than the particles being filtered. As a result, straining is not the dominant removal mechanism. Instead, particles are removed when they adhere to the filter grains or previously deposited particles. Particles are removed throughout the entire depth of the filter bed by a process called depth filtration, which gives the filter a high capacity for solids retention without clogging rapidly.

### **Coagulation Pretreatment**

Coagulation pretreatment is required ahead of rapid filtration. If particles are not properly destabilized, the natural negative surface charge on the particles and filter media grains cause repulsive electrostatic forces that prevent contact between particles and media. The origin of surface charge on particles in nature and the proper use of coagulants for destabilizing

(a)

(b)

(c)

**Figure 11-1**  
Typical dual-media rapid filter. (a) Schematic representation of dual-media filter. (b) View of an operating rapid filter. Washwater troughs are visible below the water surface. Influent water enters through the central channel, flows through the wall openings for the washwater troughs, and then down through the filter media, which is below the water surface. (c) Rapid filter during the backwash cycle. Washwater flows up through the media, pours over into the troughs, and then runs into the central channel.

particles were discussed in detail in Chap. 9. Properly designed and operated rapid filters can fail quickly if the coagulant feed breaks down or the raw-water quality changes and the coagulant dose is not adjusted accordingly.

A typical configuration for rapid filters is illustrated on Fig. 11-1. The filter bed is contained in a deep structure that is typically constructed of reinforced concrete and open to the atmosphere. The rapid filtration cycle consists of two stages: (1) a filtration stage, during which particles accumulate, and (2) a backwash stage, during which the accumulated material is flushed from the system. During the filtration stage, water flows downward through the filter bed and particles collect within the bed. The filtration stage typically lasts from 1 to 4 days.

During the backwash stage, water flows in the direction opposite to remove the particles that have collected in the filter bed. Efficient removal of collected solids is a key component of rapid filtration systems, so while the backwashing stage is very short compared to the filtration stage, it is a very important part of the filtration cycle.

### Basic Process Description

The physical steps that occur during the backwashing stage include the following: (1) the filter influent and effluent lines are isolated with valves and the backwash supply and waste washwater valves are opened; (2) backwash water, which is potable water produced by the plant, is directed upward through the filter bed; (3) the upward flow flushes captured particles up and away from the bed; and (4) after backwash, the valve positions are reversed and the filter is placed back in service.

Most filters also contain supplemental systems to assist the backwashing process. One option is the surface wash system, which is a fixed grid or rotating system of nozzles that blast the surface of the filter bed to break up any mat of solids that may have formed. Another option is to introduce pressurized air underneath the media with the backwash water. Often the air is introduced while the backwash water flows at a low rate, and the consequent pulsing efficiently scours retained solids from the media. For deep filter beds, both air and surface wash are often provided. The backwashing step typically takes 15 to 30 min.

### **Filtration Effectiveness During the Filtration Stage**

The efficiency of particle capture as reflected by effluent turbidity and head loss varies during the filtration stage (also called a filter run), as illustrated on Fig. 11-2. Filter effluent turbidity during the filter run follows a characteristic pattern with three distinct segments. During the first segment (immediately after backwash), the filter effluent turbidity rises to a peak and then falls. This segment is called filter ripening (or maturation). Ripening is the process of media conditioning and occurs as clean media captures particles and becomes more efficient at collecting additional particles. Some studies indicate that 90 percent of the particles that pass through a well-operating filter do so during the initial stage of filtration (Amirtharajah, 1988). The ripening curve sometimes contains two distinct peaks, the first corresponding to residual backwash water being flushed from the media and the second corresponding to particles from the water column above the backwashed filter. Ripening periods of 15 min to 2 h are possible. The magnitude and duration of the ripening peak can be sizable but can be substantially reduced by proper backwashing procedures, such as minimizing the duration of the backwash stage or using filter aid polymers in the backwash water. Modern filtration plants are designed with a filter-to-waste line, and the water produced during ripening is discharged to waste or recycled to the head of the plant.

The particles captured during ripening improve the overall efficiency of the filter by providing a better collector surface than uncoated media grains. After ripening, effluent turbidity typically can be maintained at a steady-state value below 0.1 NTU. Even though effluent turbidity is essentially constant after ripening, head loss through the filter continuously increases because of the collection of particles in the filter bed. After the period of effective filtration, the filter can experience breakthrough. During breakthrough,

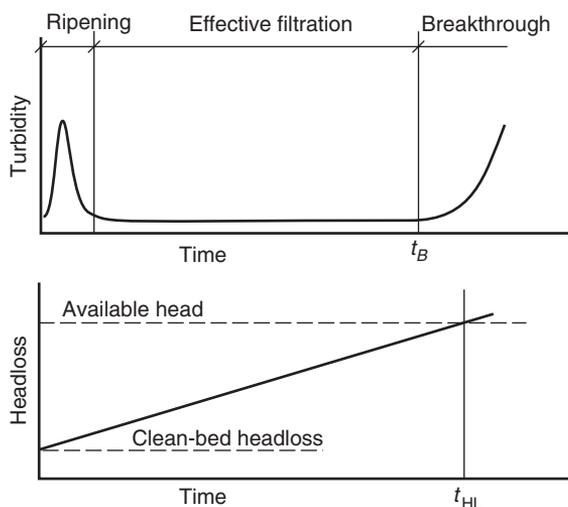

the filter contains so many particles that it can no longer filter effectively and the effluent turbidity increases.

Several events can trigger the end of the filter run and lead to backwash. First, if the filter reaches breakthrough, it must be backwashed to prevent high-turbidity water from entering the distribution system. Second, the head loss can increase beyond the available head through the process. Rapid filters typically operate by gravity and are designed with 1.8 to 3 m (6 to 10 ft) of available head. When head loss exceeds this available head (also called the limiting head), the filter must be backwashed even if it has not reached breakthrough. Some filters do not reach breakthrough or the limiting head within several days. In these cases, utilities backwash filters after a set period to maintain a convenient schedule for plant operators, even though the filter has additional usable capacity.

On Fig. 11-2, the filter reaches breakthrough before reaching the available head, but these events can occur in either order depending on the filter design and raw-water quality. A filter design is optimized when both events occur simultaneously.

Rapid filtration is classified by the level of pretreatment, as presented on Fig. 11-3. The most important factors that determine the required level of pretreatment are the raw-water quality and the preference and resources of the operating utility. Rapid filters are also classified by the number of layers of filter material, as shown in Table 11-1. The common filter materials are sand, anthracite, granular activated carbon (GAC), garnet, and ilmenite. Some are used alone, and others are used only in combination with other media. Additional information on the use and characteristics of these media materials is presented later in the chapter.

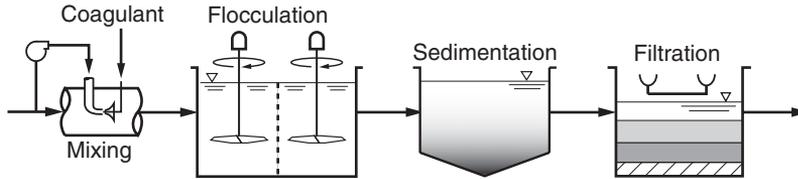

### Classifications of Rapid Filtration Systems

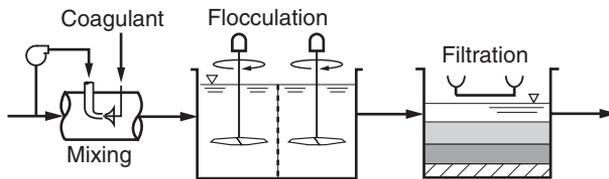

**Figure 11-2**  
Operation of a rapid filter: (a) effluent turbidity versus time and (b) head loss development versus time.

**Conventional filtration.**

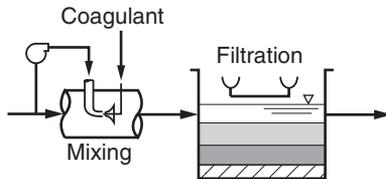

Most common filtration system. Used with any surface water, even those with very high or variable turbidity. Responds well to rapid changes in source water quality.

**Direct filtration.**

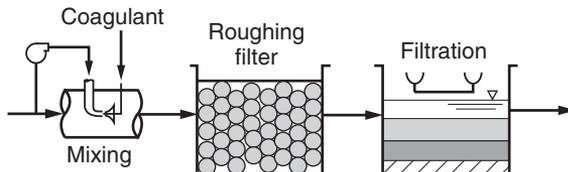

Good for surface waters without high or variable turbidity. Typical source waters are lakes and reservoirs, but usually not rivers. Raw-water turbidity < 15 NTU.

**In-line filtration (also called contact filtration).**

Requires high-quality surface water with very little variation and no clay or sediment particles. Raw-water turbidity < 10 NTU.

**Two-stage filtration.**

Preengineered systems used in small treatment plants (also called package plants). Raw-water turbidity < 100 NTU.

**Figure 11-3**

Classification of rapid filtration by pretreatment level.

**Table 11-1**

Classification of rapid filtration by media type

Filter Classification	Description
Monomedia	One layer of filter material, usually sand. Sand monomedia filters are typically about 0.6–0.76 m (24–30 in.) deep. Sand monomedia filters are an older design and have been largely superseded by other designs.
Deep-bed monomedia	One layer of filter material, usually anthracite or granular activated carbon. Deep-bed monomedia filters are typically 1.5–1.8 m (5–6 ft) deep. They are used to provide greater filtration capacity (longer run time) when feed water of consistent quality can be provided.
Dual media	Two layers of filter media. The older design is 0.45–0.6 m (18–24 in.) of anthracite over 0.23–0.3 m (9–12 in.) of sand, with filtration in the downflow direction. Deep-bed dual-media filters using 1.5–1.8 m (5–6 ft) of anthracite in the top layer are now common. GAC is sometimes used instead of anthracite in the top layer. Dual-media filters are more robust than monomedia filters.
Trimedia or mixed media	Three media, typically anthracite as the top layer, sand as the middle layer, and garnet or ilmenite as the bottom layer. The anthracite layer is typically 0.45–0.6 m (18–24 in.) deep, the sand layer is typically 0.23–0.3 m (9–12 in.) deep, and the garnet or ilmenite layer is 0.1–0.15 m (4–6 in.) deep. These have sometimes been called mixed-media filters when the media properties were selected to promote intermixing rather than the formation of distinct layers.

## 11-3 Properties of Granular Filter Media

---

Granular media filtration is affected by properties of the filter media and the filter bed, including grain size and size distribution, density, shape, hardness, bed porosity, and specific surface area. The types of media used in water filtration and their properties are addressed below.

Naturally occurring granular minerals are mined and processed specifically for use as filter media. The common materials are sand, anthracite coal, garnet, and ilmenite. Anthracite is harder and contains less volatile material than other types of coal. Garnet and ilmenite are heavier than sand and

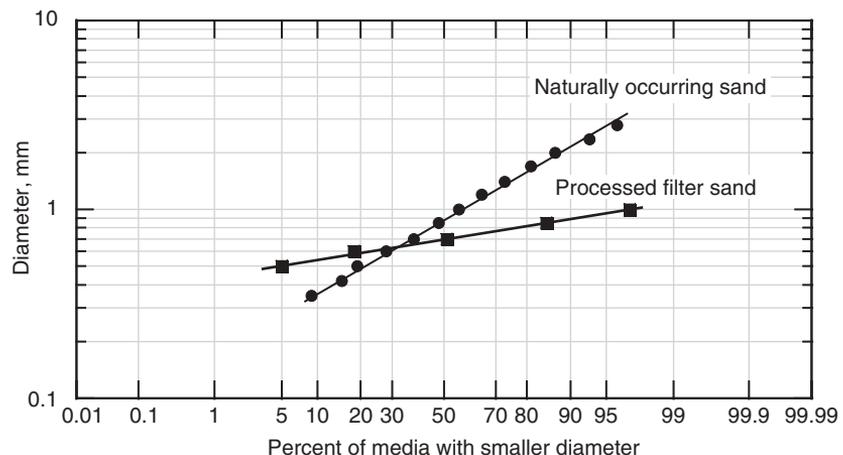

**Materials Used  
for Rapid  
Filtration Media**

are used as the bottom layer in trimedia filters. Garnet is comprised of a group of minerals containing a variety of elements, often appearing reddish or pinkish, and ilmenite is an oxide of iron and titanium. In addition to these four minerals, GAC is sometimes used as a filter material when adsorption and filtration are combined in a single unit process. Standard requirements for filtering materials are described in *ANSI/AWWA B100-01 Standard for Filtering Material* (AWWA, 2001a). Additional information on GAC is provided in Chap. 15.

### Effective Size and Uniformity Coefficient

Filter materials are found in a granular state in nature or must be crushed to the desired size. Naturally occurring granular materials have nearly a lognormal size distribution, meaning that the distribution plots roughly as a straight line on lognormal graph paper. The size distribution is determined by sieve analysis (ASTM, 2001a), in which a sample of material is sifted through a stack of calibrated sieves (ASTM, 2001b), the weight of material retained on each sieve is measured, and the cumulative weight retained is plotted as a function of sieve size. The results of sieve analyses for naturally occurring sand and processed filter media are illustrated on Fig. 11-4. The size distribution of naturally occurring material is broader than desirable for rapid filter media. Thus, rapid filter media is processed to remove the largest (by sieving) and smallest (by washing) grain sizes, producing a narrower size distribution.

In North America, the standard method for characterizing the media size distribution is by effective size and uniformity coefficient. The *effective size* (ES or  $d_{10}$ ) is the media grain diameter at which 10 percent of the media by weight is smaller, as determined by a sieve analysis. The *uniformity coefficient* (UC) is the ratio of the 60th percentile media grain diameter (the diameter at which 60 percent of the media by weight is smaller) to the

**Figure 11-4**  
Size distribution of typical naturally occurring and processed filter sand.

effective size, as shown in the equation

$$UC = \frac{d_{60}}{d_{10}} \quad (11-1)$$

where UC = uniformity coefficient, dimensionless

$d_{10}$  = 10th percentile media grain diameter, mm

$d_{60}$  = 60th percentile media grain diameter, mm

The concept of the effective size was proposed by Allen Hazen in the 1890s because the hydraulic resistance of an unstratified granular bed tends to be unaffected by size variation as long as the effective size remains constant (Fair et al., 1971). Filter media tends to stratify during backwash. Fine grains collect at the top of the filter bed, where they cause excessive head loss and reduce overall effectiveness of the filter bed. Large grains settle to the bottom of the bed and are difficult to fluidize during backwash. A low UC can minimize these effects and is an important factor in the design of rapid filters. The ES and UC of typical filtration materials are provided in Table 11-2, along with typical values of other material properties. Granular activated carbon is typically specified by the maximum and minimum sieve sizes. For instance, an 8 × 20 mesh GAC refers to media that passes through a No. 8 sieve but is retained by a No. 20 sieve. Determination of the ES and UC from sieve data is demonstrated in Example 11-1.

Mathematical models often assume that particles and filter grains are spherical for simplicity, but actual filter grains are not spherical, as shown on Fig. 11-5. The shape of individual grains affects filter design and performance in at least three ways. First, shape affects the size determined by sieve analysis. For spheres, the sieve opening will correspond to the diameter, but for nonspherical media, the sieve opening theoretically corresponds to the largest dimension of the smallest particle cross section (visualize rods going through a sieve lengthwise; the sieve opening corresponds to the largest rod diameter). The grain diameter determined by sieve

## Grain Shape

**Table 11-2**

Typical properties of filter media used in rapid filters<sup>a</sup>

Property	Unit	Garnet	Ilmenite	Sand	Anthracite	GAC
Effective size, ES	mm	0.2–0.4	0.2–0.4	0.4–0.8	0.8–2.0	0.8–2.0
Uniformity coefficient, UC	UC	1.3–1.7	1.3–1.7	1.3–1.7	1.3–1.7	1.3–2.4
Density, $\rho_p$	g/mL	3.6–4.2	4.5–5.0	2.65	1.4–1.8	1.3–1.7
Porosity, $\varepsilon$	%	45–58	N/A	40–43	47–52	N/A
Hardness	Moh	6.5–7.5	5–6	7	2–3	Low

<sup>a</sup>N/A = not available.

### Example 11-1 Determination of effective size and uniformity coefficient

Determine the effective size and uniformity coefficient of the processed filter sand shown on Fig. 11-4.

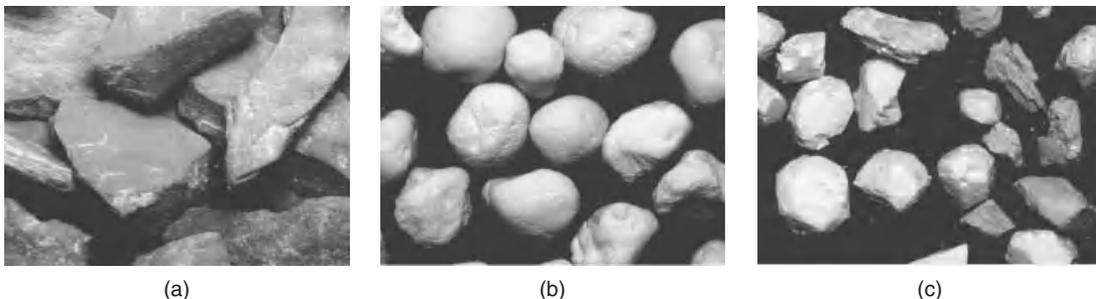

#### Solution

1. Find the 10th percentile line on the x axis and follow it up to the intersection of the line for the processed filter sand. The corresponding value on the y axis is 0.54 mm.
2. The size (y axis) corresponding to the 60th percentile (x axis) for the processed filter sand is 0.74 mm.
3. The effective size is  $ES = d_{10} = 0.54$  mm. The uniformity coefficient is  $UC = d_{60}/d_{10} = 0.74/0.54 = 1.37$ .

#### Comment

Probability paper is not required to determine the effective size and uniformity coefficient. Either an arithmetic scale or a probability scale can be used on the x axis. As long as a smooth curve can be drawn through the data, the  $d_{10}$  and  $d_{60}$  values can be determined. In addition, some spreadsheet software has functions for determining standard deviations and probability functions that can assist with the process of determining ES and UC.

analysis is typically smaller than the diameter of an “equivalent-volume” sphere. Cleasby and Woods (1975) compared size determinations from sieve analysis to equivalent-volume spheres and found that the equivalent-volume sphere diameter was 5 to 10 percent larger than the sieve size for sand and anthracite and 2 percent larger for garnet. Second, shape affects

**Figure 11-5**

Typical filter media: (a) anthracite coal, (b) sand, and (c) garnet. The sand shown is a worn river sand; suppliers may provide worn or crushed sand, depending on the source, which would change the shape factor.

how filter grains pack together in a bed. The porosity (defined below) of a randomly packed bed of spherical beads is typically about 38 percent, but the porosity of beds of filter grains typically ranges from 40 to 60 percent. Third, the hydraulics of flow through a bed of grains with sharp, angular surfaces is different from that through a bed of spherical beads.

Although grain shape has important implications in filter design, there is no easy way to account for it. Throughout filtration literature, grain shape is often characterized by either sphericity ( $\psi$ ) or shape factor ( $\xi$ ), which are interrelated as follows:

$$\psi = \frac{\text{surface area of equivalent-volume sphere}}{\text{actual surface area of grain}} \quad (11-2)$$

$$\xi = \frac{6}{\psi} \quad (11-3)$$

where  $\psi$  = sphericity, dimensionless  
 $\xi$  = shape factor, dimensionless

For spherical grains,  $\psi = 1$  and  $\xi = 6$ . Because a sphere has the minimum surface area of any geometric shape with the same volume, other shapes will have  $\psi < 1$  and  $\xi > 6$  based on the definitions in Eqs. 11-2 and 11-3.

Unfortunately,  $\psi$  and  $\xi$  have limited value in actual practice for several reasons. First, filter media is routinely measured and specified using the diameter determined by sieve analysis, not by equivalent-volume diameter. The equivalent-volume diameter can be determined by counting and weighing a representative number of media grains and calculating volume from the weight and density (Cleasby and Woods, 1975), a tedious procedure that is not done for commercially available filter media. Second, sphericity and shape factors are difficult to measure directly, and indirect means are normally used. The literature values for sphericity of common filter materials, such as the values available in Carman (1937), Cleasby and Fan (1981), and Dharmarajah and Cleasby (1986), were calculated from head loss experiments with the implicit assumption that the head loss equation coefficients (discussed in Sec. 11-4, see Eqs. 11-11 and 11-13) are independent of grain shape characteristics. As a result, many of the sphericity values for filter media available in the literature are really just empirical fitting parameters for head loss rather than true independent measurements of shape. Finally, other variables such as porosity have more impact on design, and arbitrary selection of a value for sphericity does little to improve the accuracy of design equations.

The fluidization and settling velocities of filter media during and after backwash are influenced by material density. Backwash flow requirements are higher for denser materials of equal diameter. In addition, multimedia filters are constructed in a reverse-graded fashion (larger filter grains are near the top of the bed after backwashing) by using materials of

## Material Density

different density. In a dual-media filter, anthracite is above sand because of differences in density. In a trimedia filter, the media are arranged from top to bottom as anthracite, sand, and garnet or ilmenite.

### Material Hardness

Hardness affects the abrasion and breakdown of filter material during the backwash cycle. Hardness is ranked on the Moh table, a relative ranking of mineral hardness (talc = 1, diamond = 10). Sand, garnet, and ilmenite are hard enough to be unaffected by abrasion, but anthracite and GAC are friable, and design specifications must identify minimum hardness values to avoid excessive abrasion. A minimum Moh hardness of 2.7 is often specified for anthracite. The hardness of GAC is evaluated with procedures (the stir-ring abrasion test or the Ro-Tap abrasion test) outlined in *ANSI/AWWA B604-96 Standard for Granular Activated Carbon* (AWWA, 1996).

### Granular Bed Porosity

The filter bed porosity (not porosity of the individual grains) has a strong influence on the head loss and filtration effectiveness in a filter bed. Porosity, or fraction of free space, is the ratio of void space volume to total bed volume and is calculated using the expression

$$\varepsilon = \frac{V_V}{V_T} = \frac{V_T - V_M}{V_T} \quad (11-4)$$

where  $\varepsilon$  = porosity, dimensionless

$V_V$  = void volume in media bed, m<sup>3</sup>

$V_T$  = total volume of media bed, m<sup>3</sup>

$V_M$  = volume of media, m<sup>3</sup>

Filter bed porosity ranges from 40 to 60 percent, depending on the type and shape of the media and how loosely it is placed in the filter bed.

### Granular Bed Specific Surface Area

The specific surface area of a granular bed is defined as the total surface area of the filter material divided by the bed volume and is described by the expression

$$S = \frac{(\text{number of grains})(\text{surface area of each grain})}{\text{bulk volume of filter bed}} \quad (11-5)$$

where  $S$  = specific surface area, m<sup>-1</sup>

For a uniform bed of monodisperse spheres, the specific surface area is given by the expression

$$S = \frac{6(1 - \varepsilon)}{d} \quad (11-6)$$

where  $d$  = diameter of sphere, m

For nonspherical media, Eq. 11-6 is written as

$$S = \frac{6(1 - \varepsilon)}{\psi d} = \frac{\xi(1 - \varepsilon)}{d} \quad (11-7)$$

where  $d$  = equivalent-volume diameter, m

Equation 11-7 is useful only when the equivalent-volume diameter is known.

## 11-4 Hydraulics of Flow through Granular Media

---

The head loss through a clean filter bed and the flow rate needed to fluidize the filter bed during backwashing are discussed in this section. The increase in head loss as particles are captured during filtration is discussed in Sec. 11-5.

An important aspect of hydraulic behavior is the flow regime. The flow regime in granular media is identified by the Reynolds number for flow around spheres, which uses the media grain diameter for the length scale:

$$\text{Re} = \frac{\rho_w v d}{\mu} \quad (11-8)$$

where  $\text{Re}$  = Reynolds number for flow around a sphere, dimensionless

$\rho_w$  = fluid density,  $\text{kg/m}^3$

$v$  = filtration rate (superficial velocity), m/s

$d$  = media grain diameter, m

$\mu$  = dynamic viscosity of fluid,  $\text{kg/m}\cdot\text{s}$

Flow in granular media does not experience a rapid transition from laminar to turbulent, as observed in pipes, but can be divided into four flow regimes (Trussell and Chang, 1999). The low end, called Darcy flow or creeping flow, occurs at Reynolds numbers less than about 1 and is characterized entirely by viscous flow behavior. The next regime, called Forchheimer flow after the first investigator to describe it, occurs at Reynolds numbers between about 1 and 100. Both Darcy flow and Forchheimer flow can be described as steady laminar flow because dye studies demonstrate that the fluid follows distinct streamlines. Forchheimer flow, however, is influenced by both viscous and inertial forces. In purely viscous flow, momentum is transferred between streamlines solely via molecular interactions. In twisting, irregular voids of a granular media bed, however, the fluid must accelerate and decelerate as void spaces turn, contract, and expand. The complex fluid motion through passageways of varying dimensions complicates the momentum transfer between streamlines, leading to an additional component of head loss that can be ascribed to inertial forces. Head loss due to viscous forces is proportional to  $v$  and head loss due to inertial forces is proportional to  $v^2$ . The third regime, a transition zone, has an upper limit Reynolds number between 600 and 800, and full turbulence occurs at higher Reynolds numbers.

Typical rapid filters have Reynolds numbers ranging from 0.5 to 5, straddling the transition between the Darcy and Forchheimer flow regimes. High-rate rapid filters have been designed with filtration rates as high as 33 m/h (13.5 gpm/ft<sup>2</sup>), resulting in a Reynolds number of about 18. Backwashing of rapid filters occurs between Reynolds numbers of 3 and 25, completely in the Forchheimer flow regime.

### Head Loss through Clean Granular Filters

The head loss through a filter increases as particles are retained. The net head available for particle retention is the difference between the available head and the clean-bed head loss.

#### FILTRATION RATE

The filtration rate is the flow rate through the filter divided by the area of the surface of the filter bed. The filtration rate has units of volumetric flux (reported as m/h in SI units, gpm/ft<sup>2</sup> in U.S. customary units) and is sometimes referred to as the superficial velocity because it is the velocity the water would have in an empty filter box (actual average velocity within the bed is higher due to the volume taken up by the filter grains).

#### DARCY FLOW REGIME

In 1856, Henry Darcy published a report stating the relationship between velocity, head loss, and bed depth in granular media under creeping-flow conditions (Darcy, 1856):

$$v = k_p \frac{h_L}{L} \quad (11-9)$$

where  $v$  = superficial velocity (filtration rate), m/s  
 $k_p$  = coefficient, known as hydraulic permeability, m/s  
 $h_L$  = head loss across media bed, m  
 $L$  = depth of granular media, m

Darcy's law contains no mathematical descriptors of the porous material and therefore has no predictive value for filter system design. In 1927, Kozeny (1927a,b) developed an equation to relate granular media hydraulics to properties of the media by postulating an analogy between a bed of granular media and a system of parallel cylindrical channels. Laminar flow through cylindrical tubes is described by Poiseuille's law (Poiseuille, 1841), which can be written as

$$\frac{h_L}{L} = \frac{32\mu v}{\rho_W g d^2} \quad (11-10)$$

where  $g$  = acceleration due to gravity, 9.81 m/s<sup>2</sup>

By equating the bed void volume to total internal channel volume and the media surface area to internal channel surface area, the Kozeny equation can be developed:

$$\frac{h_L}{L} = \frac{\kappa_k \mu S^2 v}{\rho_W g \varepsilon^3} \quad (11-11)$$

where  $\kappa_k$  = Kozeny coefficient, unitless  
 $S$  = specific surface area from Eq. 11-5,  $\text{m}^{-1}$   
 $\varepsilon$  = porosity from Eq. 11-4, dimensionless

The Kozeny coefficient is an empirical coefficient introduced to fit the model results to experimental data. Other experimenters determined the value of  $\kappa_k$  to be about 5 (Carman, 1937; Fair and Hatch, 1933) for spherical media. Carman (1937) and Fair and Hatch (1933) proposed that the value of  $\kappa_k$  was independent of media properties and introduced a correction factor to account for the nonspherical nature of filter grains, Carman using sphericity and Fair and Hatch using the shape factor. Carman's correction factors were calculated from head loss data, which suggests that they might not be independent of  $\kappa_k$ . The origin of Fair and Hatch's shape factors was not clear, and their factors were based on diameter determined by sieve analysis rather than equivalent volume.

#### FORCHHEIMER FLOW REGIME

Subsequent studies demonstrated that head loss in granular media was greater than predicted by Eq. 11-11 when the Reynolds number was greater than 1. Forchheimer (1901) proposed a nonlinear equation that more accurately described head loss with higher velocity or larger media:

$$\frac{h_L}{L} = \kappa_1 v + \kappa_2 v^2 \quad (11-12)$$

where  $\kappa_1$  = permeability coefficient for linear term,  $\text{s/m}$   
 $\kappa_2$  = permeability coefficient for square term,  $\text{s}^2/\text{m}^2$

Ahmed and Sunada (1969) showed that an equation with the form of Eq. 11-12 could be derived from the Navier–Stokes equation with only two assumptions: (1) the medium and the fluid are homogeneous and isotropic and (2) thermodynamic and chemical effects are small.

Ergun (1952) developed an equation with this form to describe head loss through granular media under Forchheimer flow conditions. The result was

$$h_L = \kappa_V \frac{(1 - \varepsilon)^2}{\varepsilon^3} \frac{\mu L v}{\rho_W g d^2} + \kappa_I \frac{1 - \varepsilon}{\varepsilon^3} \frac{L v^2}{g d} \quad (11-13)$$

where  $\kappa_V$  = head loss coefficient due to viscous forces, unitless  
 $\kappa_I$  = head loss coefficient due to inertial forces, unitless

Equation 11-13 is known as the Ergun equation. Ergun (1952) compiled data from 640 experiments covering a range of Reynolds numbers between about 1 and 2000 when the diameter  $d$  was an effective diameter based on specific surface, and proposed values of  $\kappa_V = 150$  and  $\kappa_I = 1.75$  to fit the experimental data. The first term of the Ergun equation is identical to Eq. 11-11 (with substitution of Eq. 11-6) with the exception of the numerical

value of the coefficient. Ergun proposed that the first term in Eq. 11-13 represented viscous energy losses and the second term represented kinetic energy losses, which is consistent with the mathematical construct of the equation. The dependence on  $\mu$ ,  $L$ ,  $v$ ,  $\rho_w$ ,  $g$ , and  $d$  in the first term is consistent with the Poiseuille equation (i.e., laminar flow), while the dependence on these six variables in the second term is consistent flow under turbulent conditions, where kinetic energy losses predominate (Streeter and Wylie, 1979).

#### PRACTICAL CONSIDERATIONS FOR CALCULATION OF CLEAN-BED HEAD LOSS

Although some filters may operate in the Darcy flow regime, the transition between Darcy flow and Forchheimer flow is gradual. Based on past experience, it has been found that equations based on the Forchheimer flow regime can be used to determine the clean-bed head loss over the full range of values of interest in rapid filtration; therefore, Eq. 11-13 is the recommended equation for clean-bed head loss in rapid filters.

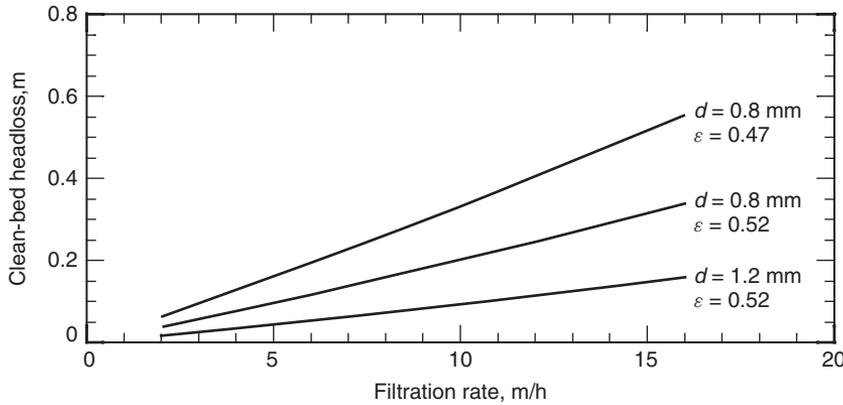

An important issue is the selection of values for each parameter in the clean-bed head loss equation. The coefficients proposed by Ergun are based on an effective diameter that is not easily measured. A more recent study has reexamined head loss through granular media (Chang et al., 1999; Trussell and Chang, 1999; Trussell et al., 1999). For spherical glass beads, the values proposed by Ergun were found to be reasonable. Different values are proposed for sand and anthracite, as shown in Table 11-3 (Trussell and Chang, 1999). The values for the head loss coefficients and porosity in Table 11-3 are based on the use of the effective size as determined by sieve analysis for the diameter (e.g.,  $d = ES$ ) and take media shape into account so that a separate shape factor is not needed. In the absence of pilot data or other site-specific information, the midpoint values in Table 11-3 are recommended for model use.

The sensitivity of clean-bed head loss to filtration rate, porosity, and media diameter is illustrated on Fig. 11-6. The significant impact of filtration rate is evident. In addition, clean-bed head loss doubles as the effective size of anthracite decreases from 1.2 to 0.8 mm, and increases by about 65 percent as porosity declines from 0.52 to 0.47. Head loss is also dependent on temperature because fluid viscosity increases as temperature decreases. The clean-bed head loss at 5°C is 60 to 70 percent higher than at 25°C.

**Table 11-3**  
Recommended parameters for use with Eq. 11-13<sup>a</sup>

Medium	$\kappa_V$	$\kappa_I$	$\epsilon_I$
Sand	110–115	2.0–2.5	40–43
Anthracite	210–245	3.5–5.3	47–52

<sup>a</sup>When effective size as determined by sieve analysis is used for the diameter.

**Figure 11-6**  
Effect of media size, bed porosity, and filtration rate on head loss through a clean granular filter bed. Calculated using Eq. 11-13 for anthracite ( $L = 1$  m,  $T = 15^\circ\text{C}$ ,  $\kappa_V = 228$ ,  $\kappa_I = 4.4$ ).

Fortunately, it is common for water treatment plants to operate at a lower capacity during the winter than during the summer, and the reduction in filtration rate typically counteracts the increase in viscosity. Calculation of clean-bed head loss is demonstrated in Example 11-2.

### Example 11-2 Clean-bed head loss through rapid filter

Calculate the clean-bed head loss through a deep-bed anthracite filter with 1.8 m of  $ES = 0.95$  mm media at a filtration rate of 15 m/h and a temperature of  $15^\circ\text{C}$ .

#### Solution

The head loss through anthracite is calculated first using Eq. 11-13.

- No pilot or site-specific information is given, so midpoint values are selected from Table 11-3;  $\kappa_V = 228$ ,  $\kappa_I = 4.4$ , and  $\epsilon = 0.50$ . Values of  $\rho_W$  and  $\mu$  are available in Table C-1 in App. C ( $\rho_W = 999$  kg/m<sup>3</sup> and  $\mu = 1.14 \times 10^{-3}$  kg/m · s).
- Calculate the first term in Eq. 11-13:

$$\frac{(228)(1 - 0.50)^2(1.14 \times 10^{-3} \text{ kg/m} \cdot \text{s})(1.8 \text{ m})(15 \text{ m/h})}{(0.50)^3(999 \text{ kg/m}^3)(9.81 \text{ m/s}^2)(0.95 \text{ mm})^2(10^{-3} \text{ m/mm})^2(3600 \text{ s/h})} = 0.44 \text{ m}$$

- Calculate the second term in Eq. 11-13:

$$\frac{(4.4)(1 - 0.50)(1.8 \text{ m})(15 \text{ m/h})^2}{(0.50)^3(9.81 \text{ m/s}^2)(0.95 \text{ mm})(10^{-3} \text{ m/mm})(3600 \text{ s/h})^2} = 0.06 \text{ m}$$

4. Add the two terms together:

$$h_L = 0.44 \text{ m} + 0.06 \text{ m} = 0.50 \text{ m} \quad (1.6 \text{ ft})$$

### Comments

A relatively small contribution to head loss comes from the inertial term. The inertial term becomes more important for the larger media and higher velocities used in high-rate rapid filters. If the filter is designed with 2.5 m (8.2 ft) of available head, the clean-bed head loss consumes about 20 percent of the available head. Note that if multiple layers of media are present, the head loss through each layer is additive.

## Backwash Hydraulics

At the end of a filter run, rapid filters are backwashed by filtered water flowing upward through the filter bed. The backwash flow rate must be great enough to flush captured material from the bed, but not so high that the media is flushed out of the filter box. To prevent loss of media, it is important to determine the bed expansion that occurs as the filter media is fluidized, which is a function of the backwash flow rate and can be calculated using head loss equations for fixed beds.

### FORCES ON PARTICLES

The forces on an individual particle (either a particle from the influent or a media grain) in upward-flowing water are exactly the same as were developed for the terminal settling velocity in Chap. 10 (see the free-body diagram on Fig 10-2). The particle will settle (or fail to fluidize) when downward forces predominate, be washed away when upward forces predominate, and remain suspended (fluidized) when the forces are balanced. The downward force is equal to the buoyant weight of the media and the upward force is the drag caused by the backwash flow. As noted in Chap. 10, the sum of forces on a particle is given by the expression

$$\sum F = F_g - F_b - F_d \quad (10-1)$$

where  $F_g$  = gravitational force on a particle, N  
 $F_b$  = buoyant force on a particle, N  
 $F_d$  = drag force on a particle, N

Combining Eqs. 10-1 through 10-4 from Chap. 10 yields the equation

$$\sum F = \rho_P V_p g - \rho_W V_p g - C_d \rho_W A_p \frac{v_s^2}{2} \quad (11-14)$$

where  $\rho_P$  = particle density, kg/m<sup>3</sup>  
 $\rho_W$  = water density, kg/m<sup>3</sup>  
 $V_p$  = volume of particle, m<sup>3</sup>  
 $A_p$  = projected area of particle in direction of flow, m<sup>2</sup>  
 $C_D$  = drag coefficient, unitless  
 $g$  = acceleration due to gravity, 9.81 m/s<sup>2</sup>  
 $v_s$  = settling velocity of the particle, m/s

The drag coefficient is dependent on the flow regime (Clark, 1996). As noted in Chap. 10, the drag coefficient is described by the following expressions:

$$C_d = \frac{24}{\text{Re}} \quad \text{for } \text{Re} < 2 \quad (\text{laminar flow}) \quad (10-10)$$

$$C_d = \frac{18.5}{\text{Re}^{0.6}} \quad \text{for } 2 \leq \text{Re} \leq 500 \quad (\text{transition flow}) \quad (10-11)$$

The fluid velocity required to keep an individual particle suspended can be determined by substituting Eq. 10-10 or Eq. 10-11 into Eq. 11-14 and solving for velocity. As was shown in Chap. 10, the fluid velocity is given as Stokes' law (Eq. 10-13) for laminar flow, and the following expression for transition flow:

$$v_s = \frac{g(\rho_P - \rho_W)d_p^2}{18\mu} \quad (\text{laminar flow}) \quad (10-13)$$

$$v_s = \left[ \frac{g(\rho_P - \rho_W)d_p^{1.6}}{13.9\rho_W^{0.4}\mu^{0.6}} \right]^{1/1.4} \quad (\text{transition flow}) \quad (10-14)$$

The velocity required to suspend an isolated particle in a uniform flow field (i.e., above the filter bed, away from the influences of the bed) may be determined using Eqs. 10-13 or 10-14, as appropriate. Within a filter bed, velocities (and therefore drag forces) are higher due to the volume taken up by the media. The balance of forces on an individual particle is demonstrated in Example 11-3.

### Example 11-3 Forces on suspended particle

A filter is backwashed at 50 m/h at 15°C. Determine whether a 0.1-mm diameter particle of sand will be washed from the filter.

#### Solution

1. Calculate the gravitational force on the particle using the  $F_g$  term from Eq. 10-1. The value for  $\rho_P$  is available in Table 11-2:

$$F_g = \rho_P V_p g = (2650 \text{ kg/m}^3) \left(\frac{\pi}{6}\right) \left(\frac{0.1 \text{ mm}}{10^3 \text{ mm/m}}\right)^3 (9.81 \text{ m/s}^2)$$

$$= 1.36 \times 10^{-8} \text{ kg} \cdot \text{m/s}^2 = 1.36 \times 10^{-8} \text{ N}$$

2. Calculate the buoyant force on the particle using the  $F_b$  term from Eq. 10-1. The value for  $\rho_W$  is available in Table C-1 in App. C:

$$F_b = \rho_W V_p g = (999 \text{ kg/m}^3) \left(\frac{\pi}{6}\right) \left(\frac{0.1 \text{ mm}}{10^3 \text{ mm/m}}\right)^3 (9.81 \text{ m/s}^2)$$

$$= 5.13 \times 10^{-9} \text{ kg} \cdot \text{m/s}^2 = 5.13 \times 10^{-9} \text{ N}$$

3. Calculate the Reynolds number using Eq. 11-8 to determine in what flow regime the particle is:

$$\text{Re} = \frac{\rho_W v d}{\mu} = \frac{(999 \text{ kg/m}^3)(50 \text{ m/h})(0.1 \text{ mm})}{(1.139 \times 10^{-3} \text{ kg/m} \cdot \text{s})(3600 \text{ s/h})(10^3 \text{ mm/m})} = 1.22$$

4. The Reynolds number is less than 2, so Eq. 10-10 can be used to calculate drag forces:

$$C_d = \frac{24}{\text{Re}} = \frac{24}{1.22} = 19.7$$

$$F_d = C_d \rho_W A_p \frac{v_s^2}{2} = \frac{19.7(999 \text{ kg/m}^3)}{2} \left(\frac{\pi}{4}\right) \left(\frac{0.1 \text{ mm}}{10^3 \text{ mm/m}}\right)^2 \left(\frac{50 \text{ m/h}}{3600 \text{ s/h}}\right)^2$$

$$= 1.49 \times 10^{-8} \text{ N}$$

5. Calculate the sum of the forces:

$$\sum F = F_g - F_b - F_d = 1.36 \times 10^{-8} \text{ N} - 5.13 \times 10^{-9} \text{ N} - 1.49 \times 10^{-8} \text{ N}$$

$$= -6.43 \times 10^{-9} \text{ N}$$

The net force is negative (upward), so the particle will be flushed away with the backwash water.

**BED EXPANSION AND POROSITY**

A state of equilibrium between gravitational and drag forces is established in the filter bed. During backwash, the velocity in a filter bed is higher than for an isolated particle due to the presence of the media, causing higher drag forces that lift the media. As the media rises, increasing porosity reduces the velocity until the drag force is balanced by the gravitational force. The relationship between bed expansion and porosity is described in the following equation and on Fig. 11-7:

$$\frac{L_E}{L_F} = \frac{1 - \varepsilon_F}{1 - \varepsilon_E} \quad (11-15)$$

where  $L_E$  = depth of expanded bed, m  
 $L_F$  = depth of bed at rest (fixed bed), m  
 $\varepsilon_E$  = porosity of expanded bed, dimensionless  
 $\varepsilon_F$  = porosity of bed at rest (fixed bed), dimensionless

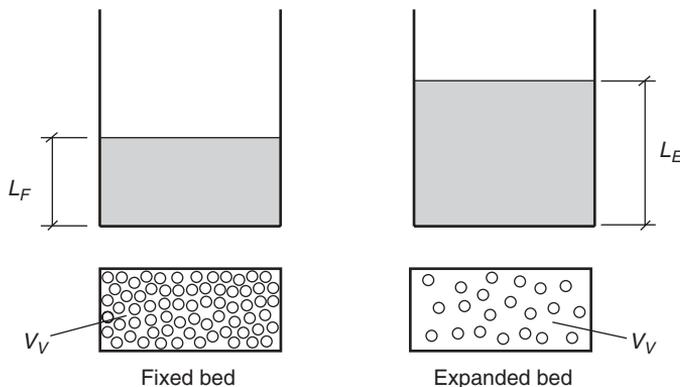

The drag force on the media exerts an equal and opposite force on the water, which is manifested as head loss. Head loss through a fluidized bed is calculated as the gravitational force (fluidized weight) of the entire bed, as shown in the expression

$$F_g = mg = (\rho_p - \rho_w)(1 - \varepsilon) a L g \quad (11-16)$$

where  $F_g$  = weight of the entire filter bed, N  
 $a$  = cross-sectional area of filter bed, m<sup>2</sup>

The weight of the bed must be divided by the filter area to convert the weight of the bed to units of pressure (i.e., convert N to N/m<sup>2</sup>) and divided by  $\rho_w g$  to convert units of pressure (N/m<sup>2</sup>) to units of head (m) as follows:

$$h_L = \frac{F_g}{a \rho_w g} = \frac{(\rho_p - \rho_w)(1 - \varepsilon)L}{\rho_w} \quad (11-17)$$

**Figure 11-7**

Fixed and expanded beds during backwashing of rapid filters. During filtration, the media grains are touching each other, but when media are fluidized during backwashing, the void volume increases, causing an overall expansion of the bed.

Akgiray and Saatçi (2001) demonstrated that the Eq. 11-13 is equally valid for fixed and expanded beds. Thus, in a fluidized bed, the head loss due to the weight of the media is equal to the head loss calculated from Eq. 11-13. Equating Eqs. 11-13 and 11-17 yields the expression

$$\kappa_V \frac{(1-\varepsilon)^2}{\varepsilon^3} \frac{\mu L v}{\rho_w g d^2} + \kappa_I \frac{1-\varepsilon}{\varepsilon^3} \frac{L v^2}{g d} = \frac{(\rho_p - \rho_w)(1-\varepsilon)L}{\rho_w} \quad (11-18)$$

An analytical solution for Eq. 11-18 in terms of  $v$  would allow the backwash velocity to be calculated directly for any set of filter conditions. Equation 11-18 can be seen to be a quadratic equation in  $v$  with a multitude of other terms, but it can be solved directly by making use of the Reynolds number. Equation 11-18 can be rearranged as follows after incorporating Eq. 11-8:

$$\kappa_I / \text{Re}^2 + \kappa_V (1-\varepsilon) \text{Re} - \beta = 0 \quad (11-19)$$

$$\beta = \frac{g \rho_w (\rho_p - \rho_w) d^3 \varepsilon^3}{\mu^2} \quad (11-20)$$

where  $\beta$  = backwash calculation factor, dimensionless

Equation 11-19 is a quadratic equation in terms of  $\text{Re}$ . One root of Eq. 11-19 is necessarily negative because both  $\kappa_I$  and  $\kappa_V$  are positive. The remaining meaningful solution of the quadratic equation is

$$\text{Re} = \frac{-\kappa_V (1-\varepsilon) + \sqrt{\kappa_V^2 (1-\varepsilon)^2 + 4\kappa_I \beta}}{2\kappa_I} \quad (11-21)$$

Once the Reynolds number is obtained from Eq. 11-21, the velocity that will maintain the bed in an expanded state corresponding to a specific porosity value can be determined from Eq. 11-8. The minimum fluidization flow rate can be calculated by determining the velocity that produces head loss equal to the buoyant weight of the media at the fixed-bed porosity. The minimum fluidization velocity is a function of grain size, with smaller particles fluidizing at lower velocity. The backwash rate must be above the minimum fluidization velocity of the largest media, typically taken as the  $d_{90}$  diameter (Cleasby and Logsdon, 1999). After fluidization, head loss may decrease slightly because the media grains are no longer in contact and extremely small or dead-end void spaces disappear. Akgiray and Saatçi (2001) performed an analysis using equivalent-volume diameters and sphericity factors and recommended Ergun's values of  $\kappa_I = 150$  and  $\kappa_V = 1.75$  for fixed beds but that  $\kappa_V = 1.0$  fit the data better for expanded beds. The problems associated with equivalent-volume diameters and sphericity factors have been discussed previously. Thus, the values of  $\kappa_I$  and  $\kappa_V$  from Table 11-3 are recommended for backwash expansion calculations. Calculation of the backwash flow rate to achieve a certain level of bed expansion is illustrated in Example 11-4.

### Example 11-4 Backwash flow rate for bed expansion

Find the backwash flow rate that will expand an anthracite bed by 30 percent given the following information:  $L_F = 2$  m,  $d = 1.3$  mm,  $\rho_p = 1700$  kg/m<sup>3</sup>,  $\varepsilon = 0.52$ , and  $T = 15^\circ\text{C}$ .

#### Solution

1. Calculate  $L_E$  that corresponds to a 30 percent expansion:

$$L_E = L_F + 0.3L_F = 2 \text{ m} + 0.3(2 \text{ m}) = 2.6 \text{ m}$$

2. Calculate  $\varepsilon_E$  using Eq. 11-15:

$$\varepsilon_E = 1 - \left[ \frac{L_F}{L_E} (1 - \varepsilon_F) \right] = 1 - \left[ \left( \frac{2 \text{ m}}{2.6 \text{ m}} \right) (1 - 0.52) \right] = 0.63$$

3. Calculate  $\beta$  using Eq. 11-20. Values of  $\rho_w$  and  $\mu$  are available in Table C-1 in App. C.

$$\begin{aligned} \beta &= \frac{g\rho_w(\rho_p - \rho_w)d^3\varepsilon^3}{\mu^2} \\ &= \frac{(9.81 \text{ m/s}^2)(999 \text{ kg/m}^3)(1700 - 999 \text{ kg/m}^3)(0.0013 \text{ m})^3(0.63)^3}{(1.139 \times 10^{-3} \text{ kg/m} \cdot \text{s})^2} \\ &= 2910 \end{aligned}$$

4. Calculate Re using Eq. 11-21. Because no pilot or site-specific data are given, use values of  $\kappa_V$  and  $\kappa_I$  from midpoint values from Table 11-3 (e.g.,  $\kappa_V = 228$  and  $\kappa_I = 4.4$ ):

$$\begin{aligned} \text{Re} &= \frac{-\kappa_V(1 - \varepsilon) + \sqrt{\kappa_V^2(1 - \varepsilon)^2 + 4\kappa_I\beta}}{2\kappa_I} \\ &= \frac{-228(1 - 0.63) + \sqrt{(228)^2(1 - 0.63)^2 + 4(4.4)(2910)}}{2(4.4)} = 17.9 \end{aligned}$$

5. Calculate  $v$  using Eq. 11-8:

$$\begin{aligned} v &= \frac{\mu \text{ Re}}{\rho_w d} = \frac{(1.139 \times 10^{-3} \text{ kg/m} \cdot \text{s})(17.9)(3600 \text{ s/h})}{(999 \text{ kg/m}^3)(0.0013 \text{ m})} \\ &= 56.5 \text{ m/h} \quad (22.6 \text{ gpm/ft}^2) \end{aligned}$$

Alternatively, it is frequently necessary to determine the bed expansion that occurs for a specific backwash rate. Equation 11-18 is a cubic equation in porosity, which was analytically solved by Akgiray and Saatçi (2001). Akgiray and Saatçi showed that two roots of the cubic equation are complex numbers, leaving only one meaningful solution as follows:

$$\varepsilon = \sqrt[3]{X + (X^2 + Y^3)^{1/2}} + \sqrt[3]{X - (X^2 + Y^3)^{1/2}} \quad (11-22)$$

where  $X$  = backwash calculation factor, dimensionless

$Y$  = backwash calculation factor, dimensionless

The factors  $X$  and  $Y$  are defined as

$$X = \frac{\mu v}{2g(\rho_p - \rho_w)d^2} \left( \kappa_V + \frac{\kappa_I \rho_w v d}{\mu} \right) \quad (11-23)$$

$$Y = \frac{\kappa_V \mu v}{3g(\rho_p - \rho_w)d^2} \quad (11-24)$$

The targeted expansion rate is about 25 percent for anthracite and about 37 percent for sand (Kawamura, 2000). The procedure for calculating the expansion of media during backwashing is demonstrated in Example 11-5.

### Example 11-5 Filter bed expansion during backwash

Find the expanded bed depth of a sand filter at a backwash rate of 40 m/h given the following information:  $L = 0.9$  m,  $d = 0.5$  mm,  $\rho_p = 2650$  kg/m<sup>3</sup>, and  $T = 15^\circ\text{C}$ .

#### Solution

1. Calculate  $X$  using Eq. 11-23. Values of  $\rho_w$  and  $\mu$  are available in Table C-1 in App. C. Because no pilot or site-specific data are given, use values of  $\kappa_V$  and  $\kappa_I$  from midpoint values in Table 11-3 (e.g.,  $\kappa_V = 112$  and  $\kappa_I = 2.25$ ):

$$\begin{aligned} X &= \frac{\mu v}{2g(\rho_p - \rho_w)d^2} \left( \kappa_V + \frac{\kappa_I \rho_w v d}{\mu} \right) \\ &= \frac{(1.14 \times 10^{-3} \text{ kg/m} \cdot \text{s})[(40 \text{ m/h})/(3600 \text{ s/h})]}{2(9.81 \text{ m/s}^2)(2650 - 999 \text{ kg/m}^3)[0.5 \text{ mm}/(10^3 \text{ mm/m})]^2} \\ &\quad \times \left[ 112 + \frac{(2.25)(999 \text{ kg/m}^3)[(40 \text{ m/h})/(3600 \text{ s/h})][0.5 \text{ mm}/(10^3 \text{ mm/m})]}{1.14 \times 10^{-3} \text{ kg/m} \cdot \text{s}} \right] \\ &= 0.1921 \end{aligned}$$

2. Calculate  $Y$  using Eq. 11-24:

$$Y = \frac{k_V \mu v}{3g(\rho_p - \rho_w)d^2}$$

$$= \frac{(112)(1.14 \times 10^{-3} \text{ kg/m} \cdot \text{s})(40 \text{ m/h})(10^3 \text{ mm/m})^2}{3(9.81 \text{ m/s}^2)(2650 - 999 \text{ kg/m}^3)(0.5 \text{ mm})^2(3600 \text{ s/h})} = 0.1168$$

3. Calculate porosity using Eq. 11-22:

$$\varepsilon_E = \sqrt[3]{X + (X^2 + Y^3)^{1/2}} + \sqrt[3]{X - (X^2 + Y^3)^{1/2}}$$

$$= \sqrt[3]{0.1921 + [(0.1921)^2 + (0.1168)^3]^{1/2}}$$

$$+ \sqrt[3]{0.1921 - [(0.1921)^2 + (0.1168)^3]^{1/2}} = 0.57$$

4. Calculate the expanded bed depth using Eq. 11-15. Because no site-specific porosity value is given, the fixed-bed porosity is taken from Table 11-3 and is assumed to be  $\varepsilon_F = 0.42$ .

$$L_E = L_F \frac{1 - \varepsilon_F}{1 - \varepsilon_E} = 0.9 \text{ m} \left( \frac{1 - 0.42}{1 - 0.57} \right) = 1.21 \text{ m}$$

5. Calculate the percent expansion of the bed:

$$\left( \frac{L_E}{L_F} - 1 \right) \times 100 = \left( \frac{1.21 \text{ m}}{0.9 \text{ m}} - 1 \right) \times 100 = 34\%$$

### Comment

The bed expansion under the example conditions is 34 percent, which is about equal to the desired expansion rate of 37 percent for sand.

Backwash hydraulics depends on the viscosity of water, which varies with temperature. To achieve the same expansion, it is necessary to use a higher backwash rate in summer, when the water is warmer, than the backwash rate used when the water is cold.

Several aspects of rapid filter design and operation result directly from requirements for effective backwashing. These include selection of a low uniformity coefficient to minimize stratification, skimming to remove fines, and selecting media for dual- and multimedia filters.

### STRATIFICATION

Stratification is an important side effect of backwashing of rapid media filters. As shown in Eq. 10-14, the settling velocity of individual grains of filter media depends on diameter, with larger grains requiring a larger

fluidization velocity. When a graded media filter bed (of constant grain density) is backwashed at a uniform rate, the smallest particles fluidize most and rise to the top of the filter bed, while the largest particles collect near the bottom of the bed.

Stratification has several adverse effects on filter performance. First, the accumulation of small grains near the top of the bed causes excessive head loss in the first few centimeters of bed depth (because head loss is a function of grain size). Second, the ability of a filter to remove particles is also a function of grain size (as will be presented subsequently), so small grains at the top of a bed cause all particles to be filtered in the first few centimeters of bed depth, which means the entire bed depth is not being used effectively.

The method for minimizing stratification is proper selection of filter media. The uniformity coefficient determines the stratification of the media. Low values of the uniformity coefficient are recommended specifically to minimize stratification of the filter bed during backwashing. A uniformity coefficient less than 1.4 is recommended for all rapid filter media, and uniformity coefficient values less than 1.3 are becoming common.

#### REMOVAL OF FINES

Stratification is particularly problematic if the media has excessive fines (particles considerably smaller than the effective size), even if a low uniformity coefficient has been specified. Fines are normally removed by backwashing and skimming immediately after the installation of new media. After media installation, backwashing normally proceeds at a low rate, just above the minimum fluidization velocity to bring as many fines as possible to the top of the bed, which are then skimmed with a flat-bladed shovel after the filter is drained. It is usually necessary to repeat the backwashing and skimming several times to remove the fines. Multimedia filters should be backwashed and skimmed after each layer of media is installed.

#### MULTIMEDIA FILTERS

Backwash hydraulics have important implications for the selection of media in dual- and trimedia filters. The media in multimedia filters must be matched so that all media fluidize at the same backwash rate. Otherwise, one media may be washed out of the filter during attempts to fluidize the other media, or alternatively, one media may fail to fluidize. Fluidization of media can be balanced by selecting a ratio of grain sizes that is matched to the ratio of grain densities. During backwash, the settling velocity is in the transition flow regime. Equating an equivalent fluidization velocity for two media in Eq. 10-14 and solving for the ratio of particle sizes yield the expression

$$\frac{d_1}{d_2} = \left( \frac{\rho_2 - \rho_w}{\rho_1 - \rho_w} \right)^{0.625} \quad (11-25)$$

where  $d_1$  = grain diameter of one filter medium, m  
 $d_2$  = grain diameter of a second filter medium, m  
 $\rho_1$  = density of medium with diameter  $d_1$ , kg/m<sup>3</sup>  
 $\rho_2$  = density of medium with diameter  $d_2$ , kg/m<sup>3</sup>

If the two media have approximately the same uniformity coefficient, the effective size can be used in Eq. 11-25.

#### INTERMIXING

Proper selection of media and proper backwashing procedures result in the layers of media staying segregated, with only a few centimeters of intermixing. Two layers of media tend to stay segregated when the bulk densities of the two layers are different. Bulk density is a function of the grain density, water density, and bed porosity (Cleasby and Woods, 1975), as shown in the expression

$$\rho_B = \rho_p(1 - \varepsilon) + \rho_w\varepsilon \quad (11-26)$$

where  $\rho_B$  = bulk density of bed, kg/m<sup>3</sup>

The vigorous agitation of media during backwashing can cause intermixing. Segregation of media types is maintained by reducing the backwash rate gradually at the end of the backwash cycle, which allows the media to segregate before the backwash cycle is terminated.

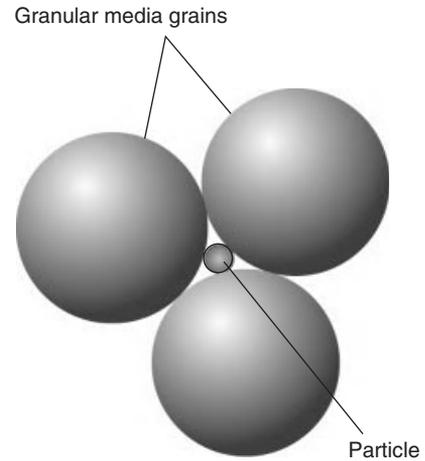

The size and uniformity coefficient of media for trimedia filters are sometimes selected to encourage intermixing rather than segregation. Filters with media that is intermixed are called *mixed-media filters* and are thought to have a better distribution of media, from coarse grains on the top of the bed to fine grains at the bottom, which would minimize the porosity of the filter bed, sacrificing head loss but improving removal.

## 11-5 Particle Removal in Rapid Filtration

---

Filters can remove particles from water by several mechanisms. When particles are larger than the void spaces in the filter, they are removed by straining. When particles are smaller than the voids, they can be removed only if they contact and stick to the grains of the media. Transport to the media surface occurs by interception, sedimentation, and diffusion, and attachment occurs by attractive close-range molecular forces such as van der Waals forces.

Straining causes a cake to form at the surface of the filter bed, which can improve particle removal but also increases head loss across the filter. Rapid filters quickly build head loss to unacceptable levels if a significant cake layer forms. In addition, filtration at the surface leaves the bulk of the rapid filter bed unused. Consequently, rapid filters are designed to minimize straining and encourage depth filtration.

**Figure 11-8**

Capture of spherical particle by spherical media grains. If the ratio of particle diameter to media diameter is greater than 0.15, the particle will be strained by the media. If it is smaller, straining is not possible and particle capture must occur by other means. For typical rapid filtration, straining is limited to particles about 80  $\mu\text{m}$  and larger.

### Straining

A bed of granular media can strain particles smaller than the grain size. For spherical media, a close-packed arrangement will cause straining when the ratio of particle diameter to grain diameter is greater than 0.15; smaller particles can pass through the media, as shown in Fig. 11-8. The effective size of the smallest media specified in rapid filters is typically around 0.5 mm, although some trimedia filters use garnet or ilmenite with an effective size as small as 0.2 mm. With the use of engineered media that minimizes the quantity of finer grains, straining becomes insignificant for particles smaller than about 30 to 80  $\mu\text{m}$ , depending, of course, on the shape and variability of the media and how it packs together. The vast majority of particles in the influent to rapid filters are smaller, particularly when sedimentation is used ahead of filtration. For example, viruses can be more than 1000 times smaller than particles that would be strained in a conventional filter, and clearly would not be removed without transport and attachment mechanisms.

### Depth Filtration

In depth filtration, particles are removed continuously throughout the filter through a process of transport and attachment to the filter grains. Particle removal within a filter is dependent on the concentration of particles, similar to a first-order rate equation (Iwasaki, 1937), as described by

$$\frac{\partial C}{\partial z} = -\lambda C \quad (11-27)$$

where  $\lambda$  = filtration coefficient,  $\text{m}^{-1}$

$C$  = mass or number concentration of particles,  $\text{mg/L}$  or  $\text{L}^{-1}$

$z$  = depth in filter,  $\text{m}$

If the filtration coefficient was known, it would be possible to calculate the effluent particle concentration from a filter. Unfortunately, filtration

is a complex process, and the filtration coefficient can vary in both time and depth in the filter and depend on properties of the filter bed (grain shape and size distribution, porosity, depth), influent suspension (turbidity, particle concentration, particle size distribution, particle and water density, water viscosity, temperature, level of pretreatment), and operating conditions (filtration rate).

Two types of models have evolved to explain rapid filter behavior. Fundamental (or microscopic) models examine the importance of actual transport and attachment mechanisms. Phenomenological (or macroscopic) models attempt to explain the physical progression of the filtration cycle, through ripening, effective filtration, and breakthrough, though they do so with empirical parameters obtained from site-specific pilot studies rather than fundamental mechanisms. Phenomenological models are useful for evaluating pilot data and can be used to predict filter performance for conditions that were not specifically addressed within a pilot study. Because of the complexity of filtration mechanisms and the wide variation in source water properties, neither type of model can predict filter performance without site-specific pilot studies; nevertheless, they provide insight and understanding into the filtration process.

Fundamental filtration models examine the relative importance of mechanisms that cause particles to contact media grains. They can explain how particles are removed during depth filtration and the importance of various design and operating parameters under time-invariant conditions. For instance, fundamental filtration models are used later in this section to demonstrate the advantages of dual-media over monomedia filters and the importance of a low uniformity coefficient. Fundamental filtration models can also be used to examine the relative impact of varying other parameters on filter performance, such as porosity, filtration rate, or temperature. For these reasons, fundamental filtration models are valuable to a student acquiring a conceptual understanding of the filtration process.

Although they assist with conceptual understanding, fundamental filtration models are not very effective at quantitatively predicting the effluent turbidity in actual full-scale filters for the following reasons: (1) the models are based on an idealized system in which spherical particles collide with spherical filter grains; (2) the hydrodynamic variability and effect on streamlines introduced by the use of angular media are not addressed; (3) the models predict a single value for the filtration coefficient, which does not change as a function of either time or depth, whereas in real filters the filtration coefficient changes with both time and depth as solids collect on the media; and (4) the models assume no change in grain dimensions or bed porosity as particles accumulate. For these reasons, fundamental depth filtration models are often called clean-bed filtration models, and experimental validation generally focuses on the initial performance of laboratory filters (with spherical particles and media grains).

### **Fundamental Depth Filtration Theory**

### Yao Filtration Model

The basic model for water treatment applications was presented by Yao et al. (1971). Yao et al.'s theory is based on the accumulation of particles on a single filter grain (termed a "collector"), which is then incorporated into a mass balance on a differential slice through a filter. The accumulation on a single collector is defined as the rate at which particles enter the region of influence of the collector multiplied by a transport efficiency factor and an attachment efficiency factor. The transport efficiency  $\eta$  and the attachment efficiency  $\alpha$  are ratios describing the fraction of particles contacting and adhering to the media grain, respectively, as described by the equations

$$\eta = \frac{\text{particles contacting collector}}{\text{particles approaching collector}} \quad (11-28)$$

$$\alpha = \frac{\text{particles adhering to collector}}{\text{particles contacting collector}} \quad (11-29)$$

where  $\eta$  = transport efficiency, dimensionless  
 $\alpha$  = attachment efficiency, dimensionless

The mass flow of particles approaching the collector is the mass flux through the cross-sectional area of the collector:

$$\text{Mass flow to one collector} = vC \frac{\pi}{4} d_c^2 \quad (11-30)$$

where  $v$  = superficial velocity, m/s  
 $C$  = concentration of particles, mg/L  
 $d_c$  = diameter of collector (media grain), m

The model development was based on an isolated single collector in a uniform-flow field, so the velocity in Eq. 11-30 is the filtration rate.

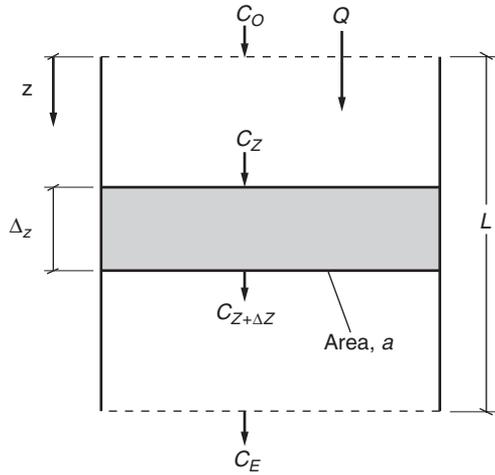

The accumulation of particles on a single collector is applied to a mass balance in a filter using a differential element of depth as the control volume, as shown on Fig. 11-9. The number of collectors in the control volume must be determined, which is the total volume of media within the control volume divided by the volume of a single collector:

$$\text{Number of collectors} = \frac{(1 - \varepsilon) a \Delta z}{(\pi/6) d_c^3} \quad (11-31)$$

where  $\varepsilon$  = porosity  
 $a$  = cross-sectional area of filter bed, m<sup>2</sup>  
 $\Delta z$  = incremental unit of depth in filter, m

The total accumulation of particles within the control volume is the product of the number of collectors and the accumulation on a single isolated collector. These terms can then be applied to a mass balance on the differential element:

$$[\text{accum}] = [\text{mass in}] - [\text{mass out}] \pm [\text{rxn}] \quad (11-32)$$

**Figure 11-9**  
Differential element of filter bed for filtration models.

Generation or loss of particles due to reactions (i.e., production of biomass or consumption of particles via chemical or biological activity) is not included in the model. Diffusion is negligible compared to convective flux, so the mass balance can be written as

$$\left( vC \frac{\pi}{4} d_c^2 \eta \alpha \right) \left[ \frac{(1 - \epsilon) a \Delta z}{(\pi/6) d_c^3} \right] = QC_Z - QC_{Z+\Delta Z} = -va(C_{Z+\Delta Z} - C_Z) \quad (11-33)$$

where  $Q$  = flow through filter,  $m^3/s$

Taking the limit as  $\Delta z$  goes to zero, Eq. 11-33 can be rearranged as

$$\frac{dC}{dz} = \frac{-3(1 - \epsilon)\eta\alpha C}{2d_c} \quad (11-34)$$

Equation 11-34 has the same form as Eq. 11-27 and defines the filter coefficient as

$$\lambda = \frac{3(1 - \epsilon)\eta\alpha}{2d_c} \quad (11-35)$$

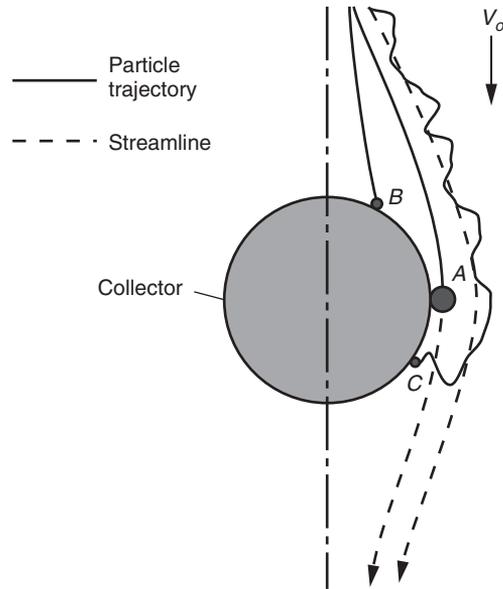

If the parameters in Eq. 11-35 ( $\epsilon$ ,  $\eta$ ,  $\alpha$ , and  $d_c$ ) are constant with respect to depth in the filter, Eq. 11-34 can be integrated to yield the expression

$$C = C_O \exp \left[ \frac{-3(1 - \epsilon)\eta\alpha L}{2d_c} \right] \quad (11-36)$$

where  $C_O$  = particle concentration in filter influent,  $mg/L$

$L$  = depth of filter,  $m$

The next step in the development of the Yao model is to evaluate the mechanisms that influence the transport of particles to the media surface and the forces that influence attachment to the media.

**Figure 11-10**

Particle transport mechanisms in fundamental filtration theory: (a) interception, particle A follows streamline but collides with the collector because of the proximity between the streamline and the collector; (b) sedimentation, particle B deviates from the streamline and collides with the collector because of gravitational forces; (c) diffusion, particle C collides with collector due to random Brownian motion.

## Transport Mechanisms

The mechanisms for transporting particles to media grains are shown on Fig. 11-10. Water approaching a spherical collector in a uniform-flow field under laminar flow conditions follows streamlines to either side of the collector. Some particles will contact the collector because they follow a fluid streamline that passes close to the grain, while others must deviate from their fluid streamline to reach the collector surface. Details for each transport mechanism are as follows.

### INTERCEPTION

Particles remaining centered on fluid streamlines that pass the collector surface by a distance of half the particle diameter or less will be intercepted. For laminar flow, spherical particles, and spherical collectors, particle transport by interception is given by the following expression (Yao et al., 1971):

$$\eta_I = \frac{3}{2} \left( \frac{d_p}{d_c} \right)^2 \quad (11-37)$$

where  $\eta_I$  = transport efficiency due to interception, dimensionless  
 $d_p$  = diameter of particle, m

As shown in Eq. 11-37, interception increases as the ratio of particulate size to collector size increases. For 10- $\mu\text{m}$  particles passing through a filter with 0.5-mm sand,  $\eta_I < 10^{-3}$ . In other words, only about one of a thousand possible collisions with a single collector due to interception will actually occur. However, a particle will pass thousands of collectors during its passage through a filter bed, increasing the chance of being removed somewhere in the filter bed.

**SEDIMENTATION**

Particles with a density significantly greater than water tend to deviate from fluid streamlines due to gravitational forces. The collector efficiency due to gravity has been shown to be the ratio of the Stokes settling velocity (see Chap. 10) to the superficial velocity (Yao et al., 1971), as shown in the expression

$$\eta_G = \frac{v_S}{v_F} = \frac{g(\rho_p - \rho_w) d_p^2}{18\mu v_F} \quad (11-38)$$

where  $\eta_G$  = transport efficiency due to gravity, dimensionless  
 $v_S$  = Stokes' settling velocity, m/s  
 $v_F$  = filtration rate (superficial velocity), m/s

**DIFFUSION**

Particles move by Brownian motion and will deviate from the fluid streamlines due to diffusion. The transport efficiency due to diffusion is given by the following expression (Levich, 1962):

$$\eta_D = 4 \text{Pe}^{-2/3} \quad (11-39)$$

$$\text{Pe} = \frac{3\pi\mu d_p d_C v}{k_B T} \quad (11-40)$$

where  $\eta_D$  = transport efficiency due to diffusion, dimensionless  
 $\text{Pe}$  = Peclet number, dimensionless  
 $k_B$  = Boltzmann constant,  $1.381 \times 10^{-23}$  J/K  
 $T$  = absolute temperature, K ( $273 + ^\circ\text{C}$ )

The Peclet number is a dimensionless parameter describing the relative significance of advection and dispersion in mass transport and is discussed further in Chap. 6. For physically similar systems, a lower value of the Peclet number implies greater significance of diffusion. The formulation of the Peclet number in Eq. 11-40 uses the Stokes–Einstein equation (see Chap. 7) to relate the diffusion coefficient to the diameter of a spherical particle. In rapid filtration, diffusion is most significant for particles less than about  $1 \mu\text{m}$  in diameter.

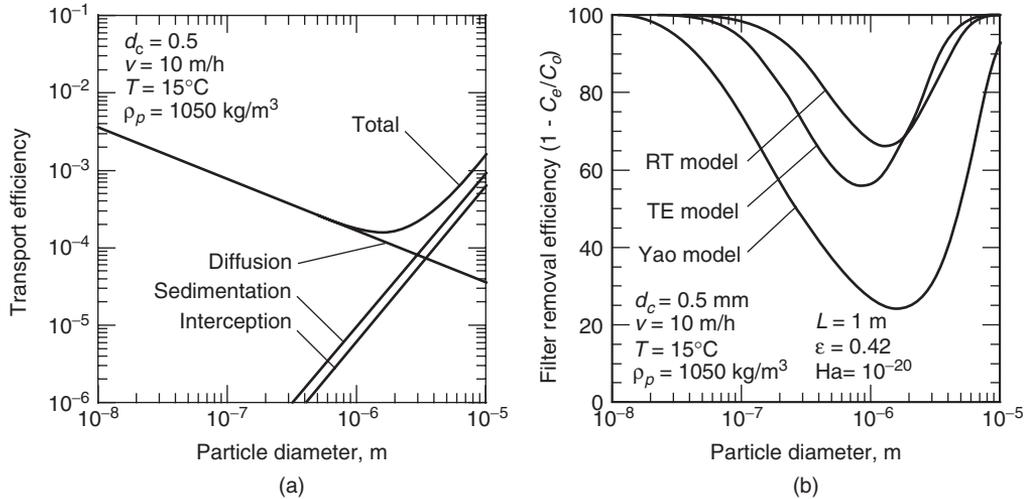

**TOTAL TRANSPORT EFFICIENCY**

The relative importance of these various mechanisms for transporting the particle to the surface depends on the physical properties of the filtration system. The Yao model assumes that the transport mechanisms are additive:

$$\eta = \eta_I + \eta_G + \eta_D \quad (11-41)$$

where  $\eta$  = total transport efficiency, dimensionless

The importance of each mechanism can be evaluated as a function of system properties. The effect of particle diameter on the importance of

**Figure 11-11**

Predictions of fundamental filtration models: (a) importance of each transport mechanism on particles of different size as predicted by the Yao model and (b) comparison of predictions by each model for removal efficiency.

each mechanism is shown on Fig. 11-11a. Small particles are efficiently removed by diffusion, whereas larger particles are removed mainly by sedimentation and interception. The Yao model predicts that the lowest removal efficiency occurs for particles of about 1 to 2  $\mu\text{m}$  in size, which has been verified experimentally (Yao et al., 1971).

### Advanced Fundamental Filtration Models

The Yao filtration model frequently underpredicts the number of collisions between particles and collectors when compared to experimental data. Several groups of researchers have tried to refine the Yao model by using a different flow regime or incorporating additional transport mechanisms. Rajagopalan and Tien (1976) developed a fundamental depth filtration model (the RT model) that (1) used a sphere-in-cell model of granular media, (2) accounted for the attraction between the collectors and particles caused by van der Waals forces (for interception and sedimentation only), and (3) accounted for reduced collisions due to viscous resistance of the water between the particle and collector. Following Rajagopalan and Tien's work, Tufenkji and Elimelech (2004) expanded the correlation further (the TE model) and more fully integrated van der Waals forces and hydrodynamic interactions into all transport mechanisms. The RT and TE models are semiempirical expressions that were correlated with the results of a numerical simulation model. The equations for the individual transport mechanisms in the Yao, RT, and TE models, along with the underlying expressions, are summarized in Table 11-4. In each case, the total transport efficiency is expressed by Eq. 11-41. The filter removal

**Table 11-4**

Transport mechanism equations in the Yao, RT<sup>a</sup>, and TE fundamental filtration models

Mechanism	Yao, Habibian, and O'Melia	Rajagopalan and Tien <sup>a</sup>	Tufenkji and Elimelech
Interception	$\eta_I = \frac{3}{2} N_R^2$ (11-37)	$\eta_I = A_S \left( \frac{4}{3} N_A \right)^{1.8} N_R^{1.5/8}$ (11-43)	$\eta_I = 0.55 A_S N_A^{1/8} N_R^{1.675}$ (11-46)

efficiency predicted by each model under comparable conditions is shown on Fig. 11-11b. The Hamaker constant is a parameter used in describing van der Waals forces. The theory necessary to calculate a value for the Hamaker constant is beyond the scope of this text, but the value ranges from  $10^{-19}$  to  $10^{-20}$  J (Hiemenz and Rajagopalan, 1997).

Fundamental filtration models can be used to examine the effect of important variables on filter performance, as shown in Example 11-6.

### Example 11-6 Application of the TE Model

Use the TE model to examine the effect of media diameter (ranging from 0.4 to 2 mm in diameter) on the removal of 0.1- $\mu$ m particles in a filter bed of monodisperse media under the following conditions: porosity  $\varepsilon = 0.50$ , attachment efficiency  $\alpha = 1.0$ , temperature  $T = 20^\circ\text{C}$  (293.15 K), particle density  $\rho_p = 1050 \text{ kg/m}^3$ , filtration rate  $v = 15 \text{ m/h}$ , bed depth  $L = 1.0 \text{ m}$ , Hamaker constant  $Ha = 10^{-20} \text{ J}$  ( $10^{-20} \text{ kg} \cdot \text{m}^2/\text{s}^2$ ), and Boltzmann constant  $k_B = 1.381 \times 10^{-23} \text{ J/K}$  ( $1.381 \times 10^{-23} \text{ kg} \cdot \text{m}^2/\text{s}^2 \cdot \text{K}$ ).

#### Solution

1. Calculate  $N_R$  for a media diameter of 0.4 mm using Eq. 11-49:

$$N_R = \frac{d_p}{d_c} = \frac{1 \times 10^{-7}}{4 \times 10^{-4}} = 2.5 \times 10^{-4}$$

2. Calculate  $N_G$  using Eq. 11-50. The values of  $\rho_w$  and  $\mu$  are available in Table C-1 in App. C:

$$\begin{aligned} N_G &= \frac{g(\rho_p - \rho_w)d_p^2}{18\mu v_F} \\ &= \frac{(1050 - 998 \text{ kg/m}^3)(9.81 \text{ m/s}^2)(1 \times 10^{-7} \text{ m})^2 (3600 \text{ s/h})}{18(1 \times 10^{-3} \text{ kg/m} \cdot \text{s})(15 \text{ m/h})} \\ &= 6.76 \times 10^{-8} \end{aligned}$$

3. Calculate Pe for a media diameter of 0.4 mm using Eq. 11-40:

$$\begin{aligned} Pe &= \frac{3\pi\mu d_p d_c v}{k_B T} \\ &= \frac{3\pi(1 \times 10^{-3} \text{ kg/m} \cdot \text{s})(1 \times 10^{-7} \text{ m})(4 \times 10^{-4} \text{ m})(15 \text{ m/h})}{(1.381 \times 10^{-23} \text{ kg} \cdot \text{m}^2/\text{s}^2 \text{ K})(293.15 \text{ K})(3600 \text{ s/h})} \\ &= 3.89 \times 10^5 \end{aligned}$$

4. Calculate  $N_A$  using Eq. 11-51:

$$N_A = \frac{Ha}{3\pi\mu d_p^2 v} = \frac{(1 \times 10^{-20} \text{ kg} \cdot \text{m}^2/\text{s}^2)(3600 \text{ s/h})}{3\pi(1 \times 10^{-3} \text{ kg/m} \cdot \text{s})(1 \times 10^{-7} \text{ m})^2(15 \text{ m/h})}$$

$$= 2.54 \times 10^{-2}$$

5. Calculate  $N_{vdW}$  using Eq. 11-52:

$$N_{vdW} = \frac{Ha}{k_B T} = \frac{1 \times 10^{-20} \text{ kg} \cdot \text{m}^2/\text{s}^2}{(1.381 \times 10^{-23} \text{ kg} \cdot \text{m}^2/\text{s}^2)(293.15 \text{ K})} = 2.47$$

6. Calculate  $\gamma$  using Eq. 11-53:

$$\gamma = (1 - \varepsilon)^{1/3} = (1 - 0.50)^{1/3} = 0.7937$$

7. Calculate  $A_S$  using Eq. 11-54:

$$A_S = \frac{2(1 - \gamma^5)}{2 - 3\gamma + 3\gamma^5 - 2\gamma^6}$$

$$= \frac{2[1 - (0.7937)^5]}{2 - 3(0.7937) + 3(0.7937)^5 - 2(0.7937)^6} = 21.46$$

8. Calculate  $\eta_I$  using Eq. 11-46:

$$\eta_I = (0.55)(21.46)(2.54 \times 10^{-2})^{1/8} (2.5 \times 10^{-4})^{1.675}$$

$$= 6.91 \times 10^{-6}$$

9. Calculate  $\eta_G$  using Eq. 11-47:

$$\eta_G = (0.22)(2.5 \times 10^{-4})^{-0.24} (2.47)^{0.053} (6.76 \times 10^{-8})^{1.11}$$

$$= 1.86 \times 10^{-8}$$

10. Calculate  $\eta_D$  using Eq. 11-48:

$$\eta_D = (2.4)(21.46)^{1/3} (2.50 \times 10^{-4})^{-0.081}$$

$$\times (2.47)^{0.052} (3.89 \times 10^5)^{-0.715} = 1.38 \times 10^{-3}$$

11. Calculate  $\eta$  using Eq. 11-41:

$$\eta = 6.91 \times 10^{-6} + 1.86 \times 10^{-8} + 1.38 \times 10^{-3} = 1.39 \times 10^{-3}$$

12. Calculate  $C/C_0$  using Eq. 11-36:

$$\frac{C}{C_0} = \exp \left[ \frac{-3(1 - 0.50)(1.39 \times 10^{-3})(1.0)(1 \text{ m})}{2(4 \times 10^{-4} \text{ m})} \right] = 0.074$$

13. Set up a computation table to determine particle removal for other diameters. Repeat steps 1 through 12 for additional media sizes between 0.4 and 2.0 mm. These calculations are best done with a spreadsheet. The results are as follows:

Media Diameter (mm)	$C/C_0$	Log Removal
0.4	0.074	1.13
0.6	0.262	0.58
0.8	0.434	0.36
1.0	0.560	0.25
1.2	0.650	0.19
1.4	0.716	0.15
1.6	0.764	0.12
1.8	0.801	0.10
2.0	0.830	0.08

### Comment

The initial removal of small particles is highly sensitive to media size. While these particles are removed relatively efficiently by 0.4-mm-diameter media, removal drops dramatically as the media size increases.

As particles approach the surface of the media, short-range surface forces begin to influence particle dynamics. The attachment efficiency varies from a value of zero (no particles adhere) to a value of 1.0 (every collision between a particle and collector results in attachment). The attachment efficiency is affected by London–van der Waals forces, surface chemical interactions, electrostatic forces, hydration, hydrophobic interactions, or steric interactions (Tobiason and O’Melia, 1988; O’Melia, 1985; O’Melia and Stumm, 1967). Laboratory studies have found values of attachment efficiency ranging from about 0.002 to 1.0 (Chang and Chan, 2008; Elimelech and O’Melia, 1990; Tobiason and O’Melia, 1988). A number of correlations have been developed to relate the attachment efficiency value to properties of the collectors, particles, and solution (Chang and Chan, 2008; Bai and Tien, 1999; Elimelech, 1992). A key property that makes attachment unfavorable is the presence of repulsive electrostatic forces.

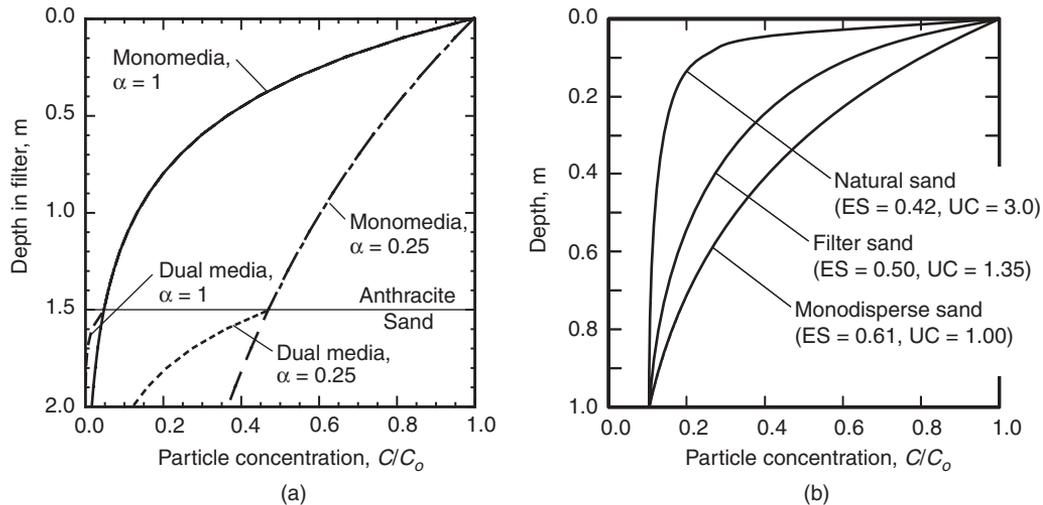

### Attachment Efficiency

In water treatment, the interest is not so much the ability to predict the value of the attachment efficiency when attachment conditions are unfavorable, but to modify the system so that attachment is as favorable as possible, that is, an attachment efficiency value very nearly 1.0. The most important factor in achieving high attachment efficiency is eliminating the repulsive electrostatic forces; that is, proper destabilization of particles by coagulation. The need for a high attachment efficiency is exactly why coagulation is a critical part of rapid filtration. Particle stability and destabilization by coagulation was discussed in Chap. 9.

### Predicting Filter Performance

The RT model has been used to demonstrate the value of dual-media filter beds when poorly pretreated water enters the filter (O'Melia and Shin, 2001). A similar analysis is shown on Fig. 11-12a. When water is properly conditioned ( $\alpha = 1.0$ ), both the monomedia and dual-media filters perform well. When the water is not properly conditioned ( $\alpha = 0.25$ ), both filters perform worse, but the degradation of quality is much more dramatic with the monomedia filter, suggesting that dual-media filters are more robust during periods of inadequate chemical pretreatment.

Similarly, the TE model can be used to demonstrate the effect of specifying filter media with a low uniformity coefficient. The particle concentrations through three filter beds with different UC values, but the same filter effluent quality are shown on Fig. 11-12b. The monodisperse media (i.e., UC = 1.0) has a constant filter grain size through the depth of the bed, but the two polydisperse media have been stratified by backwashing,

**Figure 11-12**

(a) Effect of attachment efficiency on effluent from monomedia and dual-media filters, as predicted by the RT model and  
 (b) effect of media uniformity on solids penetration in filter bed, as predicted by the TE model.

sending the smallest grains to the top and the largest grains to the bottom. Stratification increases the removal efficiency near the top of the bed. As a result, nearly all of the particles are removed near the top of the bed with the natural sand ( $UC = 3.0$ ), whereas the particles are distributed throughout the monodisperse bed. In addition, the rapid collection of particles at the top of the natural sand bed will lead to clogging and onset of straining as an additional removal mechanism, leading to rapid head loss buildup and short filter runs. Thus, a low uniformity coefficient leads to a more effective use of the entire depth of the filter bed, less straining and cake formation at the top of the bed, and longer filter runs.

As filtration progresses, the media bed physically changes due to the accumulation of particles. Thus, filtration efficiency changes with time, a phenomenon not addressed in the fundamental filtration models. More sophisticated models have been developed to incorporate time-dependent phenomena, such as ripening (Darby et al., 1992), but current models are unable to predict changes in particle removal or head loss when design or operating conditions change. To examine the change in filter performance as solids collect within the filter bed, phenomenological filter models have been developed.

The primary function of phenomenological filtration models is to explore the progression of a filter run and the change in performance as solids collect within the filter. Performance variables of interest include (1) the duration of ripening and water quality during ripening, (2) the water quality during the effective filtration cycle, (3) the time to breakthrough, and (4) the time to limiting head.

### Phenomenological Depth Filtration Models

#### PHENOMENOLOGICAL MODEL DEVELOPMENT

The mathematical formulation of phenomenological filtration models is based on the same overall mass balance through the filter bed that was used for the fundamental filtration models, using Eq. 11-32 to describe the accumulation of solids in a differential element of depth in the filter bed, as shown on Fig. 11-9. Phenomenological models do not focus on the accumulation of particles on a single collector but instead consider the increase of mass within the differential element. The basic mass balance equation for phenomenological models is developed with the following simplifying assumptions: (1) although particles are present in the interstitial fluid and at the surface of the media, the accumulation of particles in the interstitial fluid is negligible compared to the accumulation of particles on the media; (2) the number of particles entering and exiting the element by diffusion is negligible; and (3) the generation or loss of particles due to reaction is ignored. Thus, the mass balance for a differential element is described by the expression

$$\frac{\partial \sigma}{\partial t} = -v_F \frac{\partial C}{\partial z} \quad (11-55)$$

where  $\sigma$  = specific deposit, mass of accumulated particles per filter bed volume, mg/L  
 $t$  = time, s

Phenomenological models are empirical and based on experimental data using the specific deposit as a master variable. By combining Eqs. 11-27 and 11-55, the basic form of the phenomenological model can be developed as

$$\frac{\partial \sigma}{\partial t} = \lambda v_F C \quad (11-56)$$

As noted earlier, filter performance changes as a function of time as solids collect in the filter bed. Thus, the filtration coefficient is normally expressed as a function of the specific deposit. For instance, filter efficiency improves as a filter ripens, and the filtration capabilities of the clean media are quickly superseded by the filtration capabilities of the retained particles. Ripening can be viewed as a condition that increases the value of the filtration coefficient as solids are collected in the filter bed. Thus, the filtration coefficient could be expressed as follows (Iwasaki, 1937):

$$\lambda = \lambda_0 + k\sigma \quad (11-57)$$

where  $\lambda_0$  = initial filtration coefficient,  $m^{-1}$   
 $k$  = filtration rate constant,  $L/mg \cdot m$

As solids accumulate in the filter, the value of the filtration coefficient increases, leading to greater capture of solids and a lower concentration of particles in the filter effluent. Removal efficiency increases with depth during ripening and is dependent on the size and charge of particles in the water and other factors (Kim and Lawler, 2008; Kim et al., 2008). Consequently, the value of the filtration coefficient must be calculated as a function of depth because solids do not collect uniformly throughout the entire depth of the filter.

Breakthrough is a decrease of the filtration coefficient that causes an increase in effluent turbidity, which is opposite to what occurs when particles are being captured in the filter. A filtration coefficient that initially increases (ripening) and eventually decreases to zero (breakthrough) can be expressed in several forms, such as (Tien, 1989)

$$\lambda = \lambda_0 + k\sigma - \frac{k_T \sigma^2}{\varepsilon_0 - \sigma/\rho_P} \quad (11-58)$$

where  $k_T$  = breakthrough rate constant,  $L^2/mg^2 \cdot m$   
 $\varepsilon_0$  = initial porosity, dimensionless

Filtration models must account for ripening and breakthrough and must also consider other processes such as detachment of previously attached particles. A number of filtration models have been proposed over the years and have been summarized elsewhere in the filtration literature (Tien, 1989; Tien and Payatakes, 1979).

A solution to a phenomenological model allows the particle concentration at any depth in the filter bed as well as the effluent concentration to be calculated at any point in time. Unfortunately, phenomenological model equations are complex and not easily solved. The rate of particle capture at any point in the filter bed is dependent on the quantity of previously captured solids, which in turn varies with bed depth (more solids collect at the top of the bed because the concentration of solids is higher near the top of the bed, in accordance with Eq. 11-56) and filtration time. Development of a phenomenological model involves the simultaneous solution of Eqs. 11-27 and 11-55 under conditions where  $\lambda$  is a function of the specific deposit, which in turn varies in both space and time. The filter rate coefficient  $\lambda$  is also site specific because of variations in local water quality, characteristics of the particles, characteristics of the media, stratification, and operating parameters. Because determining the filter rate coefficient is complex, phenomenological models are frequently solved numerically, although analytical solutions are possible depending on the complexity of the equation for  $\lambda$ .

#### STEADY-STATE PHENOMENOLOGICAL MODEL

A simplified phenomenological model can be developed to allow easier analysis of pilot data. The basic assumptions of a simplified phenomenological model are (1) the specific deposit is averaged over the entire filter bed, (2) solids accumulate at a steady rate over the entire filter run (the reduced accumulation of solids during ripening is ignored, under the legitimate assumption that the relatively small quantity of solids retained in the bed during ripening has little impact on the specific deposit over the entire filter run), and (3) head loss increases at a constant rate. With these assumptions, the specific deposit can be determined by performing a mass balance over the entire bed:

$$\sigma_t V = C_O Q t - C_E Q t \quad (11-59)$$

where  $\sigma_t$  = specific deposit at time  $t$ , mg/L  
 $V$  = bed volume, m<sup>3</sup>  
 $C_O$  = influent concentration, mg/L  
 $C_E$  = effluent concentration, mg/L

Dividing by the filter bed area and rearranging yields an expression for the specific deposit as a function of time:

$$\sigma_t = \frac{v_F (C_O - C_E) t}{L} \quad (11-60)$$

where  $L$  = filter bed depth, m

The specific deposit increases at a steady rate as solids accumulate in the filter bed. Pilot filters can be operated until breakthrough occurs, and the

value of the specific deposit at breakthrough can be related to the time to breakthrough by the expression

$$\sigma_B = \frac{v_F(C_O - C_E)t_B}{L} \quad (11-61)$$

where  $\sigma_B$  = specific deposit at breakthrough, mg/L  
 $t_B$  = time to breakthrough, h

Equation 11-61 can be rearranged and expressed as a function of  $t_B$ :

$$t_B = \frac{\sigma_B L}{v_F(C_O - C_E)} \quad (11-62)$$

Specific deposit depends on process parameters (influent water quality, filtration rate, bed depth, media diameter, etc.). The value of the specific deposit at breakthrough can be recorded for a number of pilot filter runs in which these process parameters are varied. A regression analysis of the data can determine the dependence of the specific deposit at breakthrough,  $\sigma_B$ , on the process parameters (Kavanaugh et al., 1977). The dependence of the specific deposit varies because of site-specific conditions and can be determined only by analyzing pilot data.

Similarly, the rate of head loss buildup has been observed to depend on the rate of solids deposition in a filter. If  $h_{L,O}$  is the clean-bed head loss determined from the Ergun equation (Eq. 11-13) and head loss increases at a constant rate, then the head loss at any time during the filtration run can be determined using the expression (Ives, 1967)

$$h_{L,t} = h_{L,O} + k_{HL}\sigma_t \quad (11-63)$$

where  $h_{L,t}$  = filter head loss at time  $t$ , m  
 $h_{L,O}$  = initial head loss, m  
 $k_{HL}$  = head loss increase rate constant, L · m/mg

Like the specific deposit, the head loss increase rate constant depends on site-specific conditions and process parameters. Some evidence suggests that filtration rate is an important factor in determining the type of deposit that forms. Higher filtration rates tend to cause particle to penetrate more deeply into the bed, spreading the deposit over a larger area of the bed. In addition, higher filtration rates lead to more compact deposits whereas lower filtration rates tend to form more open, porous deposits (Veerapnani and Weisner, 1997; Weisner, 1999). Compact deposits can be characterized by a higher fractal dimension (spheres have a fractal dimension of 3 whereas lines have a fractal dimension of 1). The rate of head loss increase as the deposit accumulates (i.e., the head loss increase rate constant  $k_{HL}$ ) appears to be higher for deposits with a low fractal dimension; thus, low filtration rates cause a faster increase in head loss than high filtration rates for the same specific deposit. Quantitative models relating the rate of head loss increase to the characteristics of the deposit have not been successfully developed, and the head loss increase rate constant is best determined

through a pilot study. Incorporating Eq. 11-60 and rearranging yields an expression for the rate constant:

$$k_{HL} = \frac{(h_{L,t} - h_{L,o})L}{v_F(C_O - C_E)t} \quad (11-64)$$

Once the rate constant for head loss buildup is determined, it can be used to determine the specific deposit that can be accumulated before reaching the limiting head as follows:

$$t_{HL} = \frac{(H_T - h_{L,o})L}{k_{HL}v_F(C_O - C_E)} \quad (11-65)$$

where  $t_{HL}$  = time to limiting head, h  
 $H_T$  = total available head, m

Once dependence of the specific deposit at breakthrough and the rate of head loss buildup on process parameters are determined, the phenomenological model can be used to determine the duration of filter runs and whether filter runs are limited by breakthrough or limiting head. Use of the simplified phenomenological model to analyze pilot data is shown in Example 11-7.

### Example 11-7 Determination of optimum media size from pilot data

Four pilot filters with different effective sizes of anthracite ( $UC < 1.4$ ,  $\rho = 1700 \text{ kg/m}^3$ ) were operated over multiple runs. The results are summarized in the table below. The media depth in each filter was 1.8 m, the filtration rate was 15 m/h, and the temperature was relatively constant at 20°C. Based on turbidity, you can assume the solids concentration was constant at 2.2 mg/L in the influent and negligible in the effluent.

Media ES (mm)	No. of Runs	Ave. Eff. Turbidity (NTU)	Ave. Time to Breakthrough (h)	Ave. Initial Head (m)	Ave. Final Head (m)
0.73	7	0.08	55	0.77	3.35
0.88	6	0.07	49	0.56	2.38
1.02	9	0.08	41	0.44	1.87
1.23	8	0.13	38	0.29	1.44

Determine: (a) the relationship between specific deposit at breakthrough ( $\sigma_B$ ) and the media ES, (b) the relationship between the head loss rate constant ( $k_{HL}$ ) and the media ES, and (c) the required available head and optimal media size if the full-scale system is to have a design run length of at least 48 h.

**Solution**

- Any type of equation that relates media ES to  $\sigma_B$  and  $k_{HL}$  and results in a linear graph can be used. Often the relationships between the media ES and  $\sigma_B$  or  $k_{HL}$  can be described by a power function, and that type of equation is used in this example. Thus:

$$\sigma_B = b_1 (d)^{m_1} \quad \text{and} \quad k_{HL} = b_2 (d)^{m_2}$$

To find the value of the coefficients  $b$  and  $m$ , take the log of each equation and plot  $\log(\sigma_B)$  and  $\log(k_{HL})$  as a function of  $\log(d)$ . The slope of the straight line is  $m$  and the intercept is  $\log(b)$ :

$$\log(\sigma_B) = \log(b_1) + m_1 \log(d)$$

and

$$\log(k_{HL}) = \log(b_2) + m_2 \log(d)$$

- Calculate the necessary values for the first effective size
  - Calculate  $\log(d)$

$$\log(d) = \log(0.73 \text{ mm}) = -0.137$$

- Calculate  $\sigma_B$  using Eq. 11-61

$$\begin{aligned} \sigma_B &= \frac{v(C_0 - C_E) t_B}{L} = \frac{(15 \text{ m/h})(2.2 - 0 \text{ mg/L})(55 \text{ h})}{1.8 \text{ m}} \\ &= 1008 \text{ mg/L} \end{aligned}$$

- Calculate  $\log(\sigma_B)$

$$\log(\sigma_B) = \log(1008) = 3.00$$

- Calculate  $k_{HL}$  using Eq. 11-64

$$k_{HL} = \frac{(3.35 - 0.77 \text{ m})(1.8 \text{ m})}{15 \text{ m/h}(2.2 - 0 \text{ mg/L})(55 \text{ h})} = 0.00256 \text{ L} \cdot \text{m/mg}$$

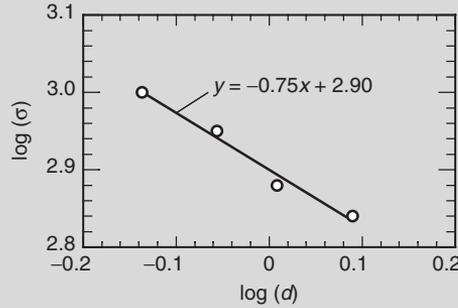

- Calculate  $\log(k_{HL})$

$$\log(k_{HL}) = \log(0.00256) = -2.59$$

- Repeat step 2 for the remaining effective sizes. The results are summarized in the following table:

ES	$\log(d)$	$\sigma_B$	$\log(\sigma_B)$	$k_{HL}$	$\log(k_{HL})$
0.73	-0.137	1008	3.00	0.00256	-2.59
0.88	-0.056	898	2.95	0.00203	-2.69
1.02	0.0086	752	2.88	0.00190	-2.72
1.23	0.090	697	2.84	0.00165	-2.78

4. Plot  $\log(\sigma_B)$  against  $\log(d)$ .

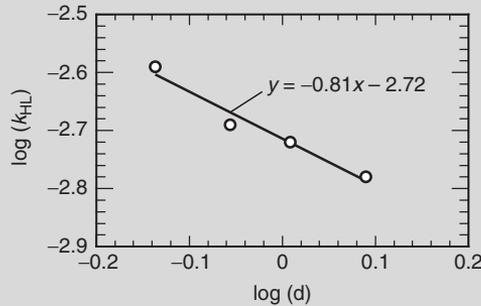

5. Perform a linear regression of the data (shown in the graph in step 4 using the Excel trendline function) and determine the slope and intercept of the regression line. From the graph in step 4,  $m_1 = -0.75$  and  $\log(b_1) = 2.90$ . Therefore,  $b_1 = 794$ . The relationship between  $\sigma_B$  and  $d$  is

$$\sigma_B = 794 (d)^{-0.75} \quad (1)$$

when the units of  $\sigma_B$  are mg/L and the units of  $d$  are mm.

6. Plot  $\log(k_{HL})$  against  $\log(d)$ .

7. Perform a linear regression of the data (shown in the graph in step 6 using the Excel trendline function) and determine the slope and intercept of the regression line. From the graph in step 6,  $m_2 = -0.81$  and  $\log(b_2) = -2.72$ . Therefore,  $b_2 = 0.00191$ . Thus, the relationship between  $k_{HL}$  and  $d$  is

$$k_{HL} = 0.00191 (d)^{-0.81} \quad (2)$$

when the units of  $k_{HL}$  are L·m/mg and the units of  $d$  are mm.

8. Calculate the required size to reach 48 h before breakthrough by substituting Eq. 1 above into Eq. 11-62 and solving for the media size.

$$t_B = \frac{794 (d)^{-0.75} L}{v_F(C_O - C_E)}$$

$$(d)^{-0.75} = \frac{t_B v_F (C_O - C_E)}{794 L} = \frac{(48 \text{ h})(15 \text{ m/h})(2.2 - 0 \text{ mg/L})}{794(1.8 \text{ m})} = 1.108$$

$$d = (1.108)^{1/-0.75} = 0.87 \text{ mm}$$

9. Calculate the required head to reach 48 h before reaching the limiting head by substituting Eq. 2 above into Eq. 11-65 and solving for the available head.

$$t_{HL} = \frac{(H_T - h_{L,0})L}{0.00181 (d)^{-0.81} v_F(C_O - C_E)}$$

$$H_T = \frac{t_{HL} 0.00181 (d)^{-0.81} v_F(C_O - C_E)}{L} + h_{L,0}$$

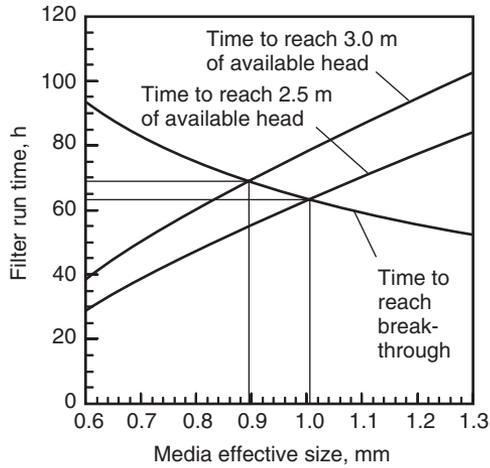

$$= \frac{(48 \text{ h})(0.00181)(0.87 \text{ mm})^{-0.81}(15 \text{ m/h})(2.2 - 0 \text{ mg/L})}{1.8 \text{ m}} + 0.53 \text{ m}$$

$$= 2.3 \text{ m}$$

where the initial head loss was calculated with Eq. 11-13 (the Ergun equation; see Example 11-2).

#### OPTIMIZATION

For a given set of design and operating conditions, optimum water production occurs when the time to reach limiting head is equal to the time to breakthrough provided the run length is adequate. Phenomenological filtration models can be used to optimize filtration design by allowing the engineer to vary design parameters until the time to breakthrough and limiting head are equal. Optimization of the filter design presented in Example 11-7 for two conditions of available head with respect to media size is shown on Fig. 11-13. Increasing the media depth will tend to increase the time to reach breakthrough ( $t_B$ ) but decrease the time to reach the limiting head ( $t_{HL}$ ). For 2.5 m of available head, the optimum design is achieved at a media size of 1.0 mm. An increase in available head to 3.0 m would have no effect on the run length if the media stayed the same size but would increase the run length by about 5 h if the media effective size were decreased to 0.90 mm.

**Figure 11-13**

Optimization of media size with respect to time to breakthrough and time to limiting head.

The effect of significant design parameters on  $t_B$  and  $t_{HL}$  is summarized in Table 11-5. The effects summarized in Table 11-5 can be predicted from the theory presented earlier in the chapter and have generally been observed in actual filter operation. These design variables will influence filter performance, and thus  $t_B$  and  $t_{HL}$ , based on the rate of particulate capture and the rate of head loss increase. Some of the design variables, such as media size, media depth, and flow rate, are subject to designer selection. The limits of media size should be chosen to minimize interlayer mixing, which tends to decrease porosity and thereby lead to a rapid increase in head loss (decrease in  $t_{HL}$ ) (Cleasby and Woods, 1975). Other variables, such as influent solids concentration, will depend upon the location of the filter in the process scheme. Variables such as floc strength and deposit

**Table 11-5**

Effect of design parameters on time to breakthrough and limiting head loss

Parameter	Effect of Parameter Increase on	
	Time to Breakthrough, $t_B$	Time to Limiting Head Loss, $t_{HL}$
Effective size	Decrease	Increase
Media depth	Increase	Decrease
Filtration rate	Decrease	Decrease
Influent particle concentration	Decrease	Decrease
Floc strength	Increase	Decrease
Deposit density	Decrease	Decrease
Porosity	Decrease	Increase

density are difficult to control, but the use of polymers can be employed to improve floc strength.

### **Particle Detachment**

Particle removal in granular filters is not an irreversible process, and detachment of particles may occur during the filtration cycle. Several studies have examined the breakthrough phenomenon and noted that it may be due to a decrease in particle capture or an increase in detachment, with evidence suggesting that the latter may be the dominant cause (Moran et al., 1993). Detachment occurs when there are perturbations to the system (Bergendahl and Grasso, 2003) but may occur at a low rate during steady-state filtration in the absence of perturbations. Perturbations may include changes in hydraulic forces or changes in water quality, including ionic strength and pH (Amirtharajah and Raveendran, 1993; Raveendran and Amirtharajah, 1995).

Detachment occurs when the forces shearing the particles away from the media grain are greater than the adhesive forces holding the particle. The primary forces between particles and media grains include van der Waals forces, electric double-layer interactions, Born repulsion, and hydration and hydrophobic forces (Raveendran and Amirtharajah, 1995). Under constant-flow (shear) conditions, detachment increases as pH increases or ionic strength decreases. Under constant chemical conditions, detachment increases as hydraulic shear increases. Models suggest that the shear stress from hydraulic perturbations has a greater effect on large particles than on smaller colloids (Bergendahl and Grasso, 2003). In addition, experimental evidence suggests that solids aggregate on the filter media (in a manner analogous to the aggregation of solids during flocculation) and that the aggregated flocs can then detach from the media (Darby and Lawler, 1990; Kau and Lawler, 1995; Moran et al., 1993).

Experimental research has not produced a quantitative model describing particle attachment and detachment mathematically. It is evident, however, that changes in filtration rate or influent water quality can have negative effects on filter performance and lead to the detachment of previously retained particles as well as changes in the ability to retain new particles, resulting in higher effluent turbidity. For these reasons, granular filters perform best when operated under constant conditions and when any changes are made gradually.

## 11-6 Rapid Filter Design

---

Preliminary design of rapid filters consists of the following:

1. Setting performance criteria, such as effluent turbidity, filter run length, recovery, and unit filter run volume (UFRV)
2. Selecting process design criteria, such as required level of pretreatment; filter media type, size, and depth; filtration rate; number of filters; and available head

3. Selecting a method for flow distribution and control
4. Selecting major process components, including backwashing systems, underdrains, wash troughs, and process piping

These topics are considered in the following sections.

The primary performance criteria for rapid filter design are the effluent water quality, the length of the filter run, and the recovery (i.e., the ratio of net to total water filtered). Filter design must also consider nonperformance criteria, such as minimizing capital and operation and maintenance (O&M) costs, reliability, and ease of maintenance.

## Performance Criteria

### EFFLUENT WATER QUALITY

Filter performance is primarily monitored by measuring effluent turbidity. To be in compliance with current U.S. regulations, the turbidity must be measured in the combined filter effluent at least every 4 h and at least 95 percent of the measurements must be below 0.3 NTU (maximum 1 NTU) (U.S. EPA, 2006). Most utilities set a design turbidity goal below the regulated limits, with a typical goal being 0.1 NTU. Additional information about the measurement and interpretation of turbidity values is presented in Chap. 2. Facilities can get additional credit for *Cryptosporidium* removal by achieving lower turbidity levels or by achieving low levels in the effluent from each individual filter.

A second method of measuring effluent water quality is particle counts. Particle counters provide both the number and size distribution of particles in water. Some utilities have installed particle counters and set water quality goals for particles, but there are no standard methods for the measurement of particles or regulatory requirements for the number of particles in filtered water. Additional information about particle counters is presented in Chap. 2.

### FILTER RUN LENGTH

The length of the filter run dictates how often backwashes must be performed and has an impact on recovery. Since operators either perform backwashes manually or supervise automated backwash procedures, the frequency of backwashing has a direct impact on the amount of labor involved in filter operation. Typically, the minimum desirable filter run length is about 1 day, with filter designs that produce a filter run length between 1 and 4 days being common. Design parameters that can affect the length of a filter run are presented in Table 11-5.

### RECOVERY

Recovery is the ratio between the net and total quantity of water filtered. Portions of the filtered water are used for backwashing and discharged as filter-to-waste volume, so the net water production is lower than the total

volume of water processed through the filter. Recovery is evaluated using the concepts of unit filter run volume (UFRV) and unit backwash volume (UBWV) (Trussell et al., 1980). The UFRV is the volume of water that passes through the filter during a run, and the UBWV is the volume required to backwash the filter, defined as

$$\text{UFRV} = \frac{V_F}{a} = v_F t_F \quad (11-66)$$

$$\text{UBWV} = \frac{V_{\text{BW}}}{a} = v_{\text{BW}} t_{\text{BW}} \quad (11-67)$$

$$\text{UFWV} = \frac{V_{\text{FTW}}}{a} = v_F t_{\text{FTW}} \quad (11-68)$$

where UFRV = unit filter run volume,  $\text{m}^3/\text{m}^2$   
 UBWV = unit backwash volume,  $\text{m}^3/\text{m}^2$   
 UFWV = unit filter-to-waste volume,  $\text{m}^3/\text{m}^2$

$V_F$  = volume of water filtered during one filter run,  $\text{m}^3$

$V_{\text{BW}}$  = volume of water required to backwash one filter,  $\text{m}^3$

$V_{\text{FTW}}$  = volume of water discharged as filter-to-waste,  $\text{m}^3$

$v_F$  = filtration rate (superficial velocity),  $\text{m}/\text{h}$

$v_{\text{BW}}$  = backwash rate,  $\text{m}/\text{h}$

$t_F$  = duration of filter run,  $\text{h}$

$t_{\text{BW}}$  = duration of backwash cycle,  $\text{h}$

$t_{\text{FTW}}$  = duration of filter-to-waste period,  $\text{h}$

$a$  = filter cross-sectional area,  $\text{m}^2$

The ratio of net to total water filtered is the recovery:

$$r = \frac{V_F - V_{\text{BW}} - V_{\text{FTW}}}{V_F} = \frac{\text{UFRV} - \text{UBWV} - \text{UFWV}}{\text{UFRV}} \quad (11-69)$$

where  $r$  = recovery, expressed as a fraction

Filters should be designed for a recovery of at least 95 percent. Typical wash water quantities are about  $8 \text{ m}^3/\text{m}^2$  ( $200 \text{ gal}/\text{ft}^2$ ). Thus, to achieve a recovery greater than 95 percent, a UFRV of at least  $200 \text{ m}^3/\text{m}^2$  ( $5000 \text{ gal}/\text{ft}^2$ ) is required. Calculation of the parameters for net water production is demonstrated in Example 11-8.

Utility operators sometimes use excessive backwash rates or time in the belief that cleaning the media thoroughly will result in longer filter runs or lower effluent turbidity. Excessive backwashing, however, is counterproductive because it lowers the recovery and can result in longer ripening periods, which further reduce recovery.

## Process Design Criteria

Design criteria are established to meet the performance requirements, given the source water quality and site-specific constraints.

### Example 11-8 Calculation of parameters for net water production

A filter is operated at a rate of 12.5 m/h for 72 h, of which 30 min was discharged as filter-to-waste volume. After filtration, it is backwashed at a rate of 40 m/h for 15 min. Calculate the UFRV, UBWV, UFWV, and recovery.

#### Solution

1. Calculate UFRV using Eq. 11-66:

$$\text{UFRV} = (12.5 \text{ m/h})(72 \text{ h}) = 900 \text{ m} = 900 \text{ m}^3 / \text{m}^2$$

2. Calculate UBWV using Eq. 11-67:

$$\text{UBWV} = (40 \text{ m/h})(0.25 \text{ h}) = 10 \text{ m} = 10 \text{ m}^3 / \text{m}^2$$

3. Calculate UFWV using Eq. 11-68:

$$\text{UFWV} = (12.5 \text{ m/h})(0.5 \text{ h}) = 6.25 \text{ m} = 6.25 \text{ m}^3 / \text{m}^2$$

4. Calculate recovery using Eq. 11-69:

$$r = \frac{(900 - 10 - 6.25) \text{ m}^3 / \text{m}^2}{900 \text{ m}^3 / \text{m}^2} = 0.982 = 98.2\%$$

#### FILTER TYPE

Classifications of rapid filters were presented on Fig. 11-3 (by level of pretreatment) and in Table 11-1 (by type of media). The level of pretreatment is typically based on raw-water quality. In borderline cases, pilot studies can verify whether a lower level of pretreatment is effective (i.e., direct filtration instead of conventional treatment).

The selection of monomedia versus dual-media filters is also based on raw-water quality and pilot study data. Deep-bed monomedia anthracite filters have a low rate of head loss accumulation, a high capacity for solids retention, and long filter runs. Dual-media filters, however, can provide a more robust design when filters are subjected to influent water that has not been properly conditioned, as was shown with the RT model on Fig. 11-12a. Thus, monomedia filters may be appropriate in situations when the raw-water quality is fairly constant and predictable, and dual-media filters may be more appropriate for variable water supplies. Deep-bed dual-media filters might be an attractive option when robustness and long filter runs are needed with variable water supplies.

#### FILTRATION RATE

Filtration rate influences the required area of the filter beds, clean-bed head loss, rate of head loss accumulation, distribution of solids collection in

the bed, effluent water quality, and run length. Filters are typically designed to treat the maximum plant capacity at the design filtration rate with at least one filter out of service for backwashing. A low filtration rate increases the capital cost because it increases the required area of the filter beds, whereas a high filtration rate can increase the clean-bed head loss and decrease the length of the filter runs. Typically, the highest filtration rate that yields good filter performance is recommended. In filtering floc resulting from alum or ferric coagulation with polymeric coagulant aids, reasonable filter run lengths with no degradation of effluent quality can generally be achieved up to 25 m/h (10 gpm/ft<sup>2</sup>). Filter effluent quality tends to degrade at filtration rates above 12.5 m/h (5 gpm/ft<sup>2</sup>) with weak chemical floc such as alum floc without polymer or poorly flocculated biological floc. Higher filtration rates tend to increase solids penetration (if media size is properly selected), and the rate of head loss accumulation may be slower at higher rates because of more efficient use of the filter bed.

Filtration rates are often subject to regulatory limits. For instance, West Coast states restrict the filtration rate to 15 m/h (6 gpm/ft<sup>2</sup>) or less, unless pilot testing demonstrates a higher rate is justified (Kawamura, 1999). Most rapid-filtration plants have design filtration rates between 5 and 15 m/h (2 and 6 gpm/ft<sup>2</sup>), although some high-rate rapid filters have been constructed with filtration rates as high as 33 m/h (13.5 gpm/ft<sup>2</sup>).

#### **NUMBER AND DIMENSIONS OF FILTERS**

The number of filters is influenced by the overall capacity of the plant, the maximum dimensions of a single filter, the effect of filtration rate changes during backwashing, and economic considerations. Most water treatment plants have a minimum of four filters, although small plants may have as few as two.

A small number of filters can reduce cost by minimizing the number of components, but a large number of filters minimizes the filtration rate change on the remaining filters when one is taken out of service for backwash. With only two filters, the filtration rate in one filter would double when the other was backwashed. As noted in Sec. 11-5, significant changes in the filtration rate can have adverse effects on filter performance by causing particle detachment and increasing effluent turbidity.

The maximum dimensions of a single filter are generally determined by the economic sizing of the filter backwash facility and possible difficulties in providing uniform distribution of backwash water over the entire filter bed. The practical maximum size of a typical high-rate gravity filter is about 100 m<sup>2</sup> (1100 ft<sup>2</sup>).

#### **AVAILABLE HEAD**

The head for filtration is the difference between the clean-bed head loss and the available head in the structure. Because rapid filters typically operate

by gravity, the available head is dependent on the elevation of the filter building relative to upstream and downstream structures (sedimentation basins and clearwells). Selection of the available head involves a trade-off between longer filter runs (greater available head) and economics (smaller available head). Due to construction costs, filter designs rarely provide more than 2 to 3 m (6.5 to 10 ft) of available head through the filter bed.

#### **FILTER MEDIA**

The selection of filter media is critical to meeting the performance criteria established for the treatment plant. Selection of filter media involves a trade-off between filtration efficiency (smaller media captures particles better) and head loss (larger media minimizes head loss).

The primary design criteria for filter media are the ES and UC. As noted earlier, a low UC is important for effective utilization of the entire filter bed. The ES must be selected in concert with other design parameters, such as filtration rate and filter depth. Factors such as clean-bed head loss as calculated in Sec. 11-4 must be considered along with effluent quality.

Filter depth and media size are interrelated. Some design engineers recommend a rule-of-thumb relationship, the ratio of depth to effective size ( $L/d$  ratio), to be between 1000 and 2000. As described in Secs. 11-4 and 11-5, head loss and particle removal are not simple inverse relationships of media diameter. Thus, the  $L/d$  ratio can provide some general guidance on the adequacy of a particular design, but it cannot be used to predict that two filters with the same  $L/d$  ratio will perform identically, particularly if they are composed of different media.

As a result of many years of successful operation of rapid filters, it is frequently possible to design an effective rapid-filtration system using the principles presented in this chapter without the use of pilot testing. In situations where higher filtration rates are warranted, pilot testing may be necessary to verify acceptable performance or satisfy regulatory agencies.

A typical rapid-filtration pilot plant is shown on Fig. 11-14. The pilot equipment typically consists of a feed pump, acrylic columns with an inside diameter of 0.1 to 0.15 m (4 to 6 in), and associated piping, valves, and instrumentation. In general, the diameter of the column should be at least 50 times the diameter of the media (Lang et al., 1993). The most common variables to be considered in a filtration pilot study are media size, media depth, and filtration rate. In addition, mono- and dual-media filters are often compared in pilot studies. For each pilot experiment, it is important to collect data on (1) clean-bed head loss, (2) filtration rate, (3) duration and magnitude of ripening, (4) influent and effluent turbidity, (5) water temperature, (6) time to breakthrough, and (7) head loss at the end of the filter run. It is normally desirable to collect some of these data continuously, particularly the turbidity, filtration rate, and head loss data.

#### **Pilot Testing**

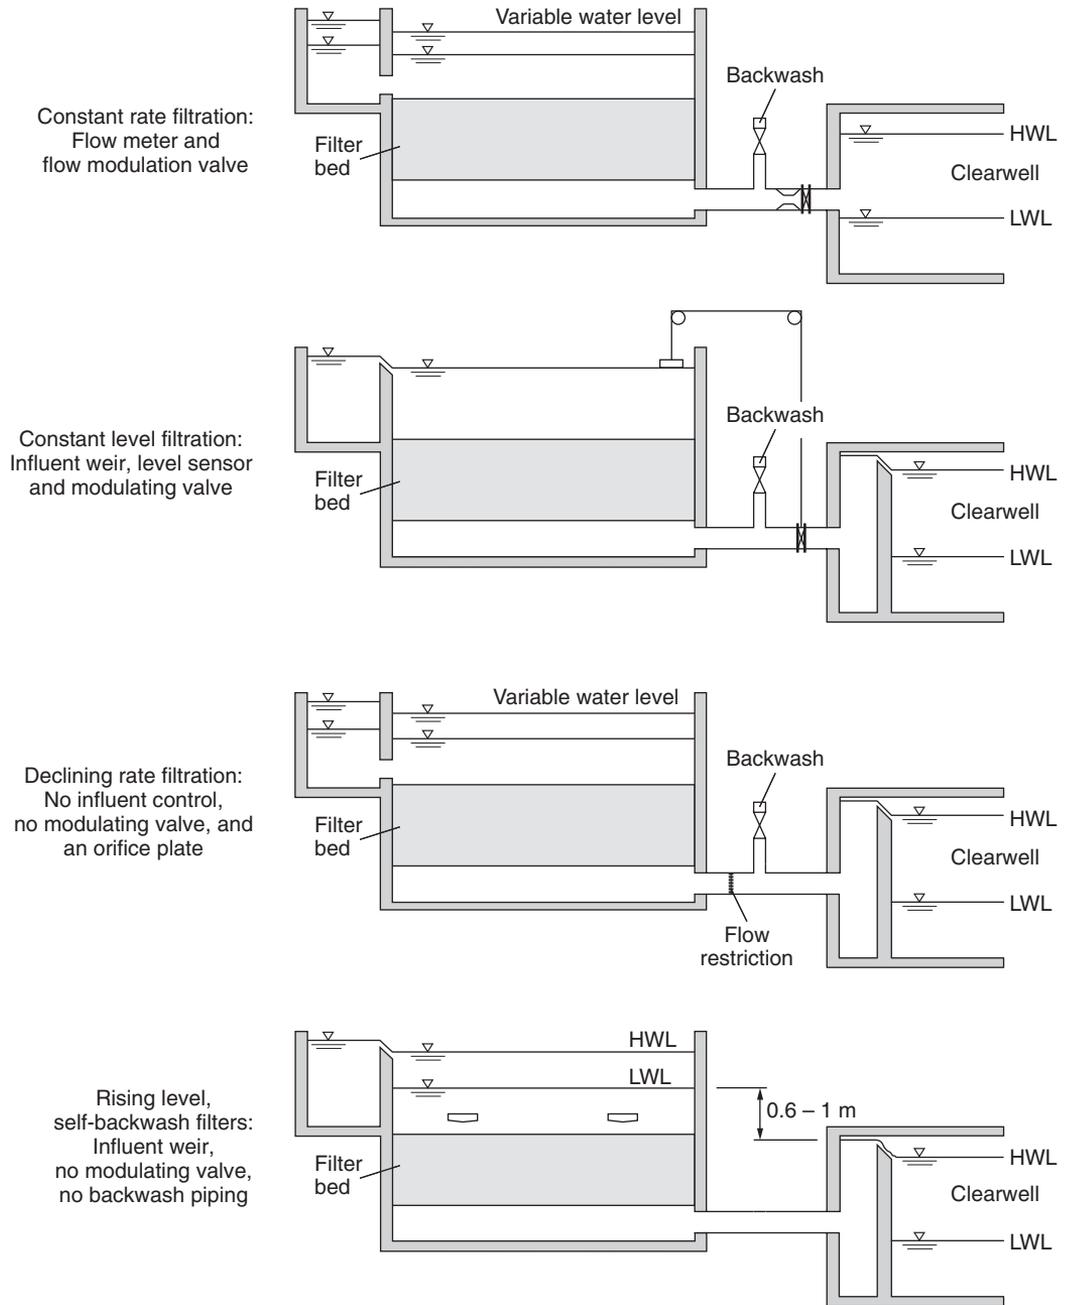

**Figure 11-14**  
Typical rapid granular filter pilot plant and associated facilities. The filters are the tall Plexiglas columns near the front of the photograph.

### Flow Control

Flow control is an important part of any filter system. Filter flow control can be accomplished in a variety of ways, and texts and design manuals describe four or five different control strategies (Cleasby and Logsdon, 1999; Kawamura, 2000). All systems for flow control have advantages and disadvantages but must accomplish three objectives: (1) control the filtration rate of individual filters, (2) distribute flow among individual filters, and (3) accommodate increasing head loss. Figure 11-15 shows several options for filter control systems.

Three basic methods are used for controlling filtration rates and distributing the flow to individual filters: (1) modulating control valve, (2) influent weir flow splitting, and (3) declining-rate filtration (no active flow control or distribution). The features of these methods are described in Table 11-6.

As noted earlier, the total available head in a gravity rapid filter system is fixed by the water elevation in the upstream and downstream structures (i.e., sedimentation basins and clearwells). The head loss through the filter bed increases as the filter collects solids, so provisions must be made to accommodate the variation in head loss. Three basic strategies are used: (1) maintain constant head above the filter (e.g., constant water level) and vary the head in the filter effluent by modulating a control valve;

**Figure 11-15**  
Rapid granular filter flow control strategies.

**Table 11-6**  
Filter control options for distributing flow to filters and controlling filtration rate

	<b>Modulating Control Valve</b>	<b>Influent Weir Flow Splitting</b>	<b>Declining Rate Filtration</b>
<b>Description</b>	Effluent piping from each filter has a flowmeter and modulating control valve. The control system calculates a flow setpoint for each filter (from total flow and number of filters in service, or an influent level indicator) and automatically adjusts the control valve until the signal from the flowmeter matches the setpoint.	Water from a common influent channel flows to each filter over a weir. Water splits equally to all operating filters. When a filter is removed from service for backwashing, the flow is automatically distributed to the remaining filters.	Water from a common influent channel flows to each filter without any devices to measure or control the flow. All filters operate at the same head loss but different filtration rates. The flow is greatest in the cleanest filters and declines as solids accumulate. The common water level rises as all filters accumulate solids and then falls after the dirtiest (i.e., longest operating) filter is backwashed. After backwash, the filter that had been producing the lowest flow now produces the highest flow.
<b>Advantages</b>	Maximum flexibility and control. No need for influent weirs or orifices that can cause turbulence that can break fragile floc and degrade filter performance.	Simple and effective. No sophisticated instrumentation required. Total flow always divided evenly with each filter having the same filtration rate. Filtration rate changes gradually as water level rises or drops.	Simple. No instrumentation required. May be appropriate in developing countries or remote locations.
<b>Disadvantages</b>	Greatest complexity. Without proper maintenance, components can break down and lead to poor filter control. Valve movement in discrete steps can repeatedly overshoot target position, resulting in the valve “hunting” for the right position and causing large swings in the filtration rate, which can cause particle detachment and an increase in effluent turbidity (see Sec. 11-5).	Floc may break up and degrade filter performance if floc is fragile or if drop over weir is large (drop can be minimized by proper design and floc can be strengthened by using polymers during coagulation or flocculation).	No indication of the flow rate in any individual filter is provided. No way to control the filtration rate. The filtration rate at the beginning of a filter run may greatly exceed the design filtration rate. The high filtration rate during the filter-to-waste (FTW) period can waste water. Flow restrictors in FTW piping can reduce water loss but may cause particle detachment during increase in filtration rate with the FTW period is over.

(2) maintaining constant head in the filter effluent and vary the head upstream of the filter (allowing the water level to rise); and (3) maintaining nearly constant head loss and allowing the filtration rate to decline as solids accumulate in the bed (declining-rate filtration). Declining rate filtration was described in Table 11-6, and the features of the other two methods are described in Table 11-7.

It should be evident from Tables 11-6 and 11-7 that all flow control methods have advantages and disadvantages. No method is clearly superior

**Table 11-7**

Filter control options for accommodating the increase in head loss in a rapid granular filter during filtration

	Constant Level	Rising Water Level
Description	The water column above the filter is maintained near the maximum level. When head loss in the filter bed is low (immediately after backwash), an effluent valve is maintained in a nearly closed position. As head loss builds up in the filter, the valve gradually opens so that the total head loss across the filter bed and effluent valve stays constant. The effluent valve is controlled by an effluent flowmeter or a level transmitter. Head loss is monitored with a differential-pressure transmitter.	Filter effluent piping is configured to keep the filter bed submerged, typically with a filter effluent control weir with an elevation just above the top of the filter bed. When head loss in the filter bed is low, the water level is just above the top of the filter bed. As head loss builds up in the filter, the water level in the filter box gradually increases.
Used with (see Table 11-6)	Influent weir flow splitting. Modulating control valve.	Influent weir flow splitting.
Advantages	The filter box can be shorter (minimizing construction costs) than for rising water level systems because no head is lost over an effluent control weir, and even more height can be saved if there is no influent flow splitting weir. Minimizes cascade over the influent weir, when one is present.	Simple. No individual flow meters or modulating control valves on filters. Changes in filtration rate occur gradually because it takes time for the water level in the filter box to rise or fall.
Disadvantages	With no effluent control weir, poor design can lead to potential for negative pressure in the filter bed (see section on negative pressure in filter beds).	The influent weir must be above the maximum water level in the filter boxes to feed all filters equally. If the influent water cascades into the filter box from a large height, the top of the filter bed may be disturbed or the floc may be broken up by turbulence.

to the others. Selection is typically made on the basis of designer and owner preferences. Cost, complexity, and reliability are important issues. Whichever method is used, proper design is important because poor flow control can have a significant negative impact on filter performance.

## Backwashing Systems

Backwashing is an indispensable part of rapid filtration. Improper or inadequate backwashing is one of the most frequent causes of problems in filters. Backwash criteria are established based on the flow rates necessary to fluidize the media and carry away deposited solids. The design equations for calculating these backwash rates were presented in Sec. 11-4. Alternatives for backwashing and backwash water delivery systems are discussed below.

### ALTERNATIVES FOR BACKWASHING

Backwashing consists of upflowing water and a supplemental scouring system. The typical options for supplemental scouring systems are (1) fixed-nozzle surface wash, (2) rotating-arm surface wash, and (3) air scour. Supplemental scouring causes vigorous agitation of the bed and causes collisions and abrasion between media grains that break deposited solids loose from the media grains. Once the solids are separated from the media grains, the upflowing wash water can flush the solids from the filter. Design criteria for water-jet-type surface wash systems and air scour washing systems are shown in Table 11-8.

### SURFACE WASH SYSTEMS

Surface wash systems typically have water nozzles on a rotating header or on a fixed pipe grid located just above the surface of the bed. Subsurface

**Table 11-8**

Typical design criteria for supplemental backwash systems

Criteria	Units	Fixed-Nozzle Surface Wash	Rotating-Arm Surface Wash	Air Scour
Surface wash water flow rate	m/h	7–10	1.2–1.8	—
	gpm/ft <sup>2</sup>	2.8–4	0.5–0.7	—
Air flow rate	m <sup>3</sup> /m <sup>2</sup> · h	—	—	36–72
	scfm/ft <sup>2</sup>	—	—	2–4
Pressure at discharge point	bar	0.5–0.8	5–7	0.3–0.5
	psi	7.2–11.6	73–100	4.3–7.3
Duration of washing	min	4–8	4–8	8–15
Backwash water flow rate	m/h	30–60	30–60	15–45
	gpm/ft <sup>2</sup>	12–24	12–24	6–18

agitators or dual-arm agitators (with one set of nozzles above the bed and a second set located near the interface in a dual- or multimedia bed) are also available but are not common. Surface wash systems typically start operation 1 to 2 min before the backwash water starts flowing and continue for 5 to 10 min after the bed is fluidized. As the media fluidizes, it rises above the level of the nozzles, so the surface wash system is able to provide vigorous agitation of the fluidized media. Surface wash systems are effective for cleaning traditional filters with depths of 0.6 to 0.9 m (2 to 3 ft) but are less effective for cleaning deep-bed filters.

#### **AIR SCOUR SYSTEMS**

Air scour systems are necessary for cleaning deep-bed filters. Air and water are introduced simultaneously at the bottom of the filter bed for a portion of the backwash cycle followed by a water-only wash for the remainder of the cycle. The method of air introduction depends on the type of underdrain and support system used. Most modern underdrain systems can introduce air through the underdrains along with the water. When the filter design includes support gravel, however, air must be introduced through a piping system located just above the support gravel to prevent dislodging the gravel.

The most effective air scouring occurs when the water is flowing between 25 and 50 percent of the minimum fluidization velocity (Amirtharajah, 1993). At this water flow rate, the air forms cavities within the media that subsequently collapse (a phenomenon that has been called *collapse pulsing*), causing a substantial amount of agitation of the bed. With no water flow, air moves through the media as bubbles or channels with little movement of the media. At water flow rates above 75 percent of the minimum fluidization velocity, the air moves with the water as bubbles.

Air scour provides such vigorous agitation that media can be lost if air is flowing while waste wash water is being discharged from the filter. Thus, the common procedure for using air scour is to (1) drain the water to a level about 150 mm (6 in.) above the top of the media, (2) start the water air at appropriate rates for collapse pulsing, (3) continue the air scour while the water level gradually rises in the filter box, (4) terminate the air flow rate just before the water level reaches the lip of the wash water troughs, (5) increase the backwash water rate to a fluidization velocity and continue to wash the filter for several more minutes to flush solids from the bed, and (6) terminate backwash water slowly to allow dual-media filters to re-stratify. This procedure typically allows several minutes for air scour, which is sufficient for cleaning the bed. Additional details of the air scour process are available in Amirtharajah (1993).

#### **BACKWASH WATER DELIVERY SYSTEMS**

Backwashing requires a large volume of water to flow through the filter in a short time. Backwash rates typically range from 30 to 60 m/h (12 to

24 gpm/ft<sup>2</sup>) for 10 to 20 min. Backwash water can be delivered to the filter through one of three methods: (1) backwash pumps, (2) an elevated backwash water tank, or (3) a head difference between the effluent channel and filter box. These systems are described in Table 11-9. Most filters require between 2 and 4 m (6.6 and 13 ft) of static head at the filter bottom, although many backwash systems are designed to provide up to 10 m (33 ft) of head at the pump or elevated tank, with the remaining head being dissipated by delivery piping, a throttling valve, and a flow controller to ensure a relatively constant backwash rate.

**Table 11-9**  
Backwash water delivery systems

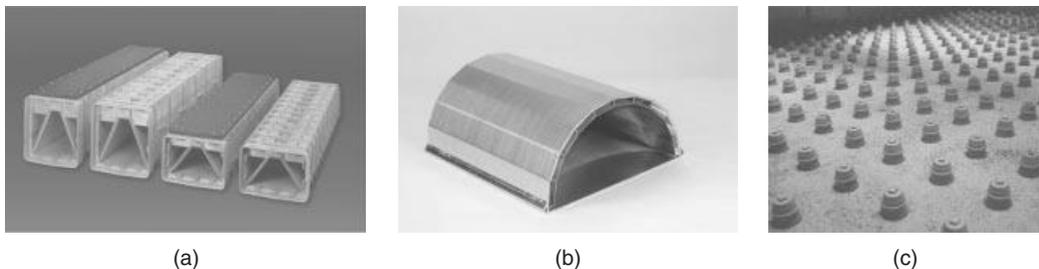

<b>Water Supply</b>	<b>Backwash Pumps</b>	<b>Elevated Tank</b>	<b>Effluent Channel (Self-Backwashing Filter)</b>
Description	Pumps, sized to provide the entire backwash flow, withdraw water from the filter effluent channel or finished water clearwell and provide it directly to the filter bottom.	Small pumps withdraw water from the filter effluent channel or finished water clearwell and send it to an elevated tank. The minimum water level in the tank is typically 9–12 m (30–40 ft) above the filter media. During backwash, water flows from the tank to the filters by gravity.	Filter effluent flows to a common effluent channel whose water elevation is controlled by a weir set several feet above the top of the media. During backwash, the water level in the filter box drops so that the head in the effluent channel is sufficient to provide the necessary backwash flow. This type of filter is often called a self-backwashing filter.
Advantages	Provides the maximum amount of control over backwash flow rates.	Smaller pumps are required because the volume of water required for backwash can be pumped to the tank over a period of hours.	Simplicity of design and operation; no pumps required.
Disadvantages	Large pumps are required.	Backwash flow rate can decline as water level in the elevated tank declines.	Less control over backwash flow rates. Deep filter box is required to provide sufficient head for filtering (maximum water level in filter to water level in effluent channel) and sufficient head for backwashing (water level in effluent channel to minimum water level in filter).

## Filter System Components

Filters can be designed with a wide variety of configurations and various alternatives for the positioning of influent and effluent channels and piping. Detailed design of the structural aspects of filters is beyond the scope of this text, and students are referred to several references for detailed design, such as Kawamura (1975a,b,c, 1999, 2000). The primary components of a filter, other than the media, control system, and backwashing systems, are the underdrains and wash troughs.

### FILTER SUPPORT MEDIA AND UNDERDRAINS

The function of filter underdrains is to support the filter media, collect and convey filtered water away from the filter system, and distribute backwash water and air. The underdrains must capture and distribute water uniformly to avoid localized variations in filtration rate or backwash rate that would jeopardize the effectiveness of the filter. Historically, a common design was a grid of perforated pipes overlain by several layers of gravel. The perforated pipe collects filtered water and distributes backwash water, and the gravel prevents the filter media from entering the perforations and provides additional distribution of backwash water. The gravel is installed in several layers, each 75 to 150 mm (3 to 6 in.) thick. The gravel on the bottom is typically 40 to 60 mm (1.5 to 2.5 in.) in diameter, and each overlying layer has stones of smaller diameter, with the top layer having an effective size of 0.8 to 2.0 mm (known as torpedo sand). Each layer is able to physically retain the overlying layer (recall from Fig. 11-8 that smaller grains can be physically retained by larger grains if the ratio of sizes is larger than about 0.15). A wide variety of other systems have been used, including false bottoms with strainers, underdrain blocks, precast concrete underdrains, teepee-type underdrains, and porous plates. Examples of underdrains are shown on Fig. 11-16. Uniform backwash flow distribution, durability, and cost are the three most important factors in selecting filter underdrains.

**Figure 11-16**

Typical filter underdrains: (a) Type S and SL with and without integral media support (IMS) cap (courtesy F. B. Leopold Company, Inc.), (b) direct retention underdrain system (courtesy Johnson Screens), and (c) nozzle-type underdrain system (courtesy of Ondeo-Degremont).

Modern underdrains typically have porous plates or fine mesh screens that can retain the filter media directly without the layers of gravel. Eliminating the gravel reduces the height of the filter box by about 0.5 m (1.6 ft). In addition, gravel can be dislodged by surges in backwash water or air scour.

To achieve an even distribution of backwash flow, (1) the orifice openings should be small enough to introduce a controlling loss of head and (2) the flow velocity in the pipe or channel in the underdrain system should be reasonably low and uniform throughout the entire filter area. Head loss in the underdrain system during backwash ranges from 0.1 to 3 m (0.3 to 10 ft) depending on the type of underdrain and backwash rates. For a false-bottom-type underdrain system, the required head loss is low (0.1 m for some systems) because the pressure is constant throughout the plenum if the inlet is properly designed. Perforated pipe grid systems use small orifices to create the necessary head loss to provide even distribution of backwash water.

#### WASH TROUGHS

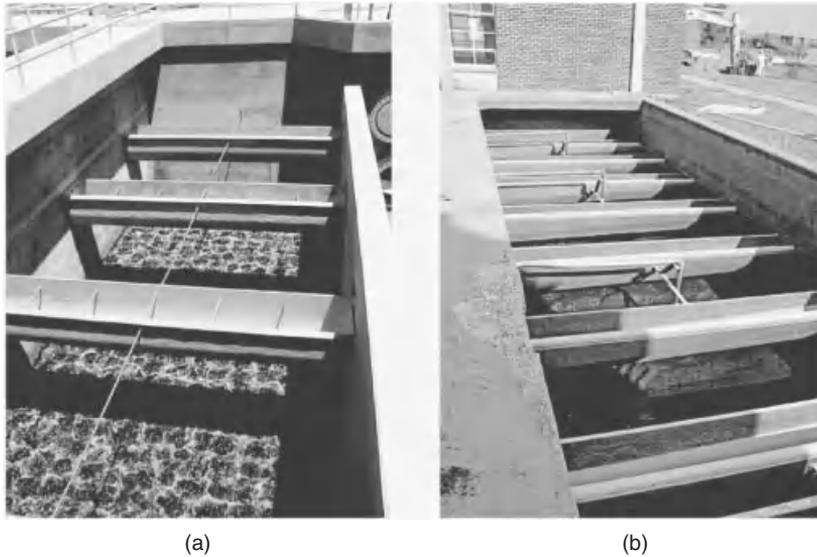

Wash troughs provide a channel to collect the waste washwater so that dislodged suspended matter will be carried away without losing filter media. Backwash troughs are nearly universal in filtration plants in the United States but are typically not used in Europe, where waste washwater flows over a single overflow weir or side-channel weirs.

Wash troughs are generally of two basic types: (1) troughs with a shallow but wide cross section and a slight V-shaped bottom and (2) deeper troughs with a U-shaped cross section. The bottom of the wash trough should not be flat because froth and suspended matter are often trapped under the trough bottom and may never be washed out. Typical wash troughs are shown on Fig. 11-17. If the troughs are located close to the top of the filter bed, it may be difficult to provide sufficient depth to fluidize the media without losing media. In these cases, troughs can be modified to retain media while allowing suspended solids to flow to the wash troughs (Kawamura, 2000; Kawamura et al., 1997).

The troughs should have enough capacity to carry the maximum expected wash rate without flooding. A uniform flow over the lip of the trough can be guaranteed if the trough lips behave as free-flowing weirs along their entire length. Weirs should also provide a free-fall to the main collection outlet gullet. The bottom of the trough may be either horizontal or sloping. Spacing and dimensions of troughs can be obtained from standard design texts (Kawamura, 2000) or from manufacturer's literature.

#### **Negative Pressure in Filter Beds**

During filtration, the hydraulic gradient (head loss per unit depth) can be greater near the top of the bed because of the greater collection of solids near the top of the bed (Darby and Lawler, 1990). If the hydraulic gradient is greater than the static head gradient, low or even negative pressure

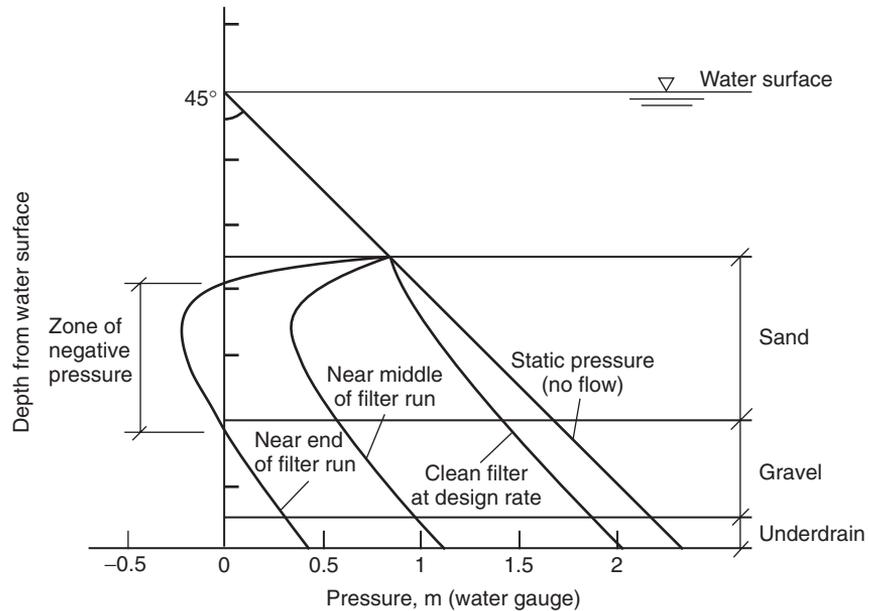

**Figure 11-17**  
Typical filter washwater troughs: (a) plastic adjustable type and (b) cast-in-place concrete type (see also Fig. 1-1e in Chap. 1).

(below atmospheric pressure) can develop in the filter bed. The pressure within a filter bed and the potential for negative pressure development are depicted on Fig. 11-18. Negative pressure can cause bubbles to form as dissolved gases (oxygen and nitrogen) and come out of solution. Bubbles can be trapped by the media and cause a dramatic increase in head loss, a phenomenon called air binding.

Air binding can be avoided with proper filter design. A weir in the effluent channel that maintains sufficient water depth over the media can prevent the problem, but with proper understanding of the hydraulics of the filtration process, it is not necessary to provide an excessive water depth (Monk, 1984).

Filters produce two waste streams. The filter-to-waste water is water that has been fully treated through the water treatment plant but does not meet effluent requirements such as turbidity. Because filter-to-waste water is fully treated, it may be recycled to the head of the plant for retreatment instead of being sent to the waste washwater recovery system. The second waste stream is the waste washwater produced from filter backwashing, which contains the accumulated solids from a filter run and can have significant concentrations of microorganisms such as *Giardia* and *Cryptosporidium*. Waste washwater is regulated by the Filter Backwash Recycling Rule (U.S. EPA, 2001) and should typically be treated before being recycled to the head of the plant or discharged to a receiving stream. Additional details on the treatment and ultimate disposition of filter waste streams are discussed in Chap. 21.

## Residual Management

**Figure 11-18**  
Pressure development within filter bed during filtration. (Adapted from Kawamura, 2000).

## 11-7 Rapid Filter Design Example

A new water treatment plant is to be built to treat water from a river in Arkansas. The average turbidity in the river is typically about 40 NTU but will frequently spike to 150 NTU during storm events. The plant is to have a capacity of 230,000 m<sup>3</sup>/d (60 mgd). The owners and engineers have set the target effluent turbidity to be 0.1 NTU. Other treatment plants upstream of the proposed site have been successful at treating the water with dual media sand/anthracite filters. Pilot testing similar to that presented in Example 11-7 has been conducted.

The process design criteria that need to be determined are:

1. Type of filtration process (conventional, direct, or contact filtration)
2. Type of filter bed (monomedia or dual media)
3. Type of flow control
4. Media size (ES and UC)
5. Media depth
6. Filtration rates with all filters in service and with one out of service
7. Available head
8. Number and size of filters
9. Backwash rate
10. UFRV and recovery

**Solution**

Pretreatment requirements for the filtration process can be influenced by raw water quality, regulatory agency requirements, and the experience and preference of the operators. In this case, the turbidity spikes to 150 NTU dictate that the appropriate rapid granular filtration process is conventional filtration (see Fig 11-3). Based on successful pilot testing, deep-bed monomedia filters containing 1.8 m (6 ft) of anthracite are selected.

As noted earlier, several options are available for flow control in filters and no one method has clear advantages over the other methods. Selection is based on engineer and owner preferences with respect to cost, complexity, and reliability. For this design, the engineers have chosen the influent weir split, constant level flow control system.

The principles presented in this chapter demonstrate that media effective size, media depth, filtration rate, and available head are interrelated. None of these design parameters can be set without considering the impact of the others. The goal for selecting these parameters is to minimize capital and operating costs while achieving the effluent turbidity goal. The regulatory limit on turbidity is 0.3 NTU but a typical goal is to keep effluent turbidity below 0.1 NTU. Many combinations of size, depth, and rate can achieve this turbidity goal. Capital costs are reduced by minimizing the required filter area, which is accomplished by operating at the highest possible filtration rate. The cost of media does not change significantly as the size changes. The depth of the bed is only a portion of the overall structure depth, so an increase in media depth causes only a moderate increase in capital cost. However, capital costs increase almost linearly as the filter area increases. Operating costs are minimized by decreasing the frequency of backwashing; thus, long filter runs are desirable.

Increasing the filtration rate will moderately reduce the time to breakthrough but significantly reduce the time to reach the available head. The reduced time to reach the available head at a higher rate is almost entirely due to the higher clean-bed head loss. Clean-bed head loss is also sensitive to media diameter. Thus, increasing the media diameter can compensate for the reduced run length resulting from a higher filtration rate. As noted earlier, smaller media captures particles better, so an increase in media effective size might reduce effluent quality. Equation 11-36 demonstrates that filter effluent turbidity improves as the media depth increases, so an increase in media effective size can be compensated for by increasing the media depth.

Using data from the pilot plant shown in Example 11-7 and the optimization graph shown on Fig 11-13, the engineers design the system with 2.5 m (8.2 ft) of available head. To get the longest filter runs at this condition, the optimal media effective size is about 1.0 mm. From the other pilot information, the filtration rate is 15 m/h (6.1 gpm/ft<sup>2</sup>) and the media depth is 1.8 m (6 ft). With this filter bed design, filter runs of about 62 h are expected. The uniformity coefficient is specified to be below 1.4 to minimize stratification after backwashing.

With the media specifications and filtration rate set, the number of filters and filtration area can be determined. The required filter area is based on the capacity and filtration rate:

$$A = \frac{Q}{v_F} = \frac{230,000 \text{ m}^3/\text{d}}{(15 \text{ m/h})(24 \text{ h/d})} = 640 \text{ m}^2 (6900 \text{ ft}^2)$$

Capital costs are minimized by using the lowest possible number of filters (reducing valves, piping connections, etc). Because the largest practical size of a filter is about  $100 \text{ m}^2$  ( $1100 \text{ ft}^2$ ), the required filter area could be met with seven filters. It is necessary to operate at full capacity while one filter is backwashing or out of service for maintenance, so eight filters are required. The area of each filter is

$$A_F = \frac{230,000 \text{ m}^3/\text{d}}{(15 \text{ m/h})(24 \text{ h/d})(7)} = 91 \text{ m}^2 (980 \text{ ft}^2)$$

The dimensions of individual filters are determined by options for components such as underdrains and wash troughs. For this plant, filters were configured to have two cells separated by a central gullet (the channel that provides water flow), with each cell being  $10 \text{ m} \times 4.55 \text{ m}$  ( $32.8 \text{ ft} \times 15 \text{ ft}$ ).

The effective filtration rate when all filters are in service is

$$v_F = \frac{230,000 \text{ m}^3/\text{d}}{(91 \text{ m}^2)(24 \text{ h/d})(8)} = 13.2 \text{ m/h} (5.4 \text{ gpm}/\text{ft}^2)$$

The slightly lower filtration rate when all filters are in service will have a positive effect on the length of filter runs.

Backwash flow requirements are determined using principles shown in Example 11-4. A 1.8-m (6-ft) bed of 1.0 mm anthracite with a density of  $1700 \text{ kg}/\text{m}^3$  and porosity of 0.50 can be expanded by 25 percent at a temperature of  $20^\circ\text{C}$  using a normal backwash flow rate of  $38.6 \text{ m/h}$  ( $15.8 \text{ gpm}/\text{ft}^2$ ). The required backwash flow rate is

$$Q_B = v_{BW}A_F = (38.6 \text{ m/h})(91 \text{ m}^2) = 3500 \text{ m}^3/\text{h} (15,400 \text{ gpm})$$

Backwash pumps are frequently specified with additional capacity to accommodate occasional as more vigorous backwashing or changes in temperature. Twenty-five percent additional capacity is specified in this plant.

The unit filter run volume at design capacity is determined with Eq. 11-66:

$$\text{UFRV} = v_F t_F = (6 \text{ m/h})(62 \text{ h}) = 372 \text{ m}^3/\text{m}^2 (9100 \text{ gal}/\text{ft}^2)$$

Because a deep-bed monomedia filter is specified, collapse-pulse backwashing will be necessary. The expected volume of backwash water based on a backwash flow rate of  $12 \text{ m/h}$  for 5 min followed by a flow of  $38.6 \text{ m/h}$  for 10 min is  $676 \text{ m}^3$  ( $23,900 \text{ ft}^3$ ). Including a filter-to-waste period of 30 min

(found during the pilot study), the net water recovery is determined from Eqs. 11-66 to 11-69:

$$\text{UFWV} = v_F t_{FTW} = (6 \text{ m/h})(0.5 \text{ h}) = 3 \text{ m}^3/\text{m}^2 \text{ (74 gal/ft}^2\text{)}$$

$$\text{UBWV} = \frac{V_{\text{BW}}}{a} = \frac{676 \text{ m}^3}{91 \text{ m}^2} = 7.4 \text{ m}^3/\text{m}^2 \text{ (182 gal/ft}^2\text{)}$$

$$r = \frac{372 - 7.4 - 3}{372} \times 100 = 97.2\%$$

The UFRV and recovery meet typical goals for granular media filters. The design parameters for this filter system are summarized in Table 11-10.

## 11-8 Other Filtration Technologies and Options

This chapter has focused on gravity-driven rapid filtration because that is the most common granular filtration technology used in water treatment. Several other filtration options, however, are used in specific applications. The following filtration options are briefly introduced in this section: pressure filtration, biologically active filtration, slow sand filtration, greensand

**Table 11-10**

Summary of design criteria for rapid filter design example

Parameter	Units	Value
Filter type	—	Conventional, deep-bed monomedia
Flow control	—	Influent weir split, constant level
Number	—	8
Inside dimensions	m · m	10 × 4.55 × 2 cells
Media surface area (each filter)	m <sup>2</sup>	91
Media surface area (total)	m <sup>2</sup>	728
Maximum available head	m	2.5
Filtration rate (at plant design flow rate)		
One filter off-line	m/h	15
All filters in service	m/h	13.2
Filter media		
Type	—	Anthracite
Depth	m	1.8
Effective size	mm	1.0
Uniformity coefficient	—	<1.4
Density	—	1700
Backwash criteria		
Maximum rate	m/h	48.2
Normal rate	m/h	38.6
Duration	min	15

filtration, diatomaceous earth filtration, and bag or cartridge filtration. Membrane filtration is discussed in Chap. 12.

### Pressure Filtration

Pressure filtration is largely similar to gravity-driven rapid filtration with the exception that the filter is housed in a pressure vessel. Filter media used, pretreatment requirements, mechanisms for filtration, backwashing requirements, and other features of gravity-driven rapid filtration are applicable to pressure filters. Design equations and procedures are similar. An example of a pressure filter system is shown on Fig. 11-19. The primary advantage of a pressure filtration system is that the water remains under continuous pressure; that is, any excess pressure in the influent water (beyond that needed to overcome the head loss in the filter bed and piping) is available in the filtered water. Because of this, the filter effluent can be delivered to the point of use without additional pumping facilities.

A key disadvantage of pressure filters is that it is not easy to observe the filtration process, backwash process, or condition of the filter bed. Sudden changes in pressure can disturb the media and lead to channeling and poor filtration. Because poor filter conditions might be difficult to detect and compromise filtration effectiveness, some state regulatory agencies do not allow pressure filters to be used for surface water treatment, where prevention of waterborne illness is a primary concern (GLUMRB, 2007). Pressure filters can be suitable for groundwater applications. An example of an appropriate use for pressure filters is for iron and manganese removal from well water (see Chap. 20). The well pump can supply the head for the filter and deliver the water to the distribution system. Pressure filters are also used in tertiary wastewater treatment, swimming pools, and industrial applications.

**Figure 11-19**

Typical pressure filters. The vessels in the left foreground are pressure filters, right foreground are cartridge filters, and background are GAC contactors.

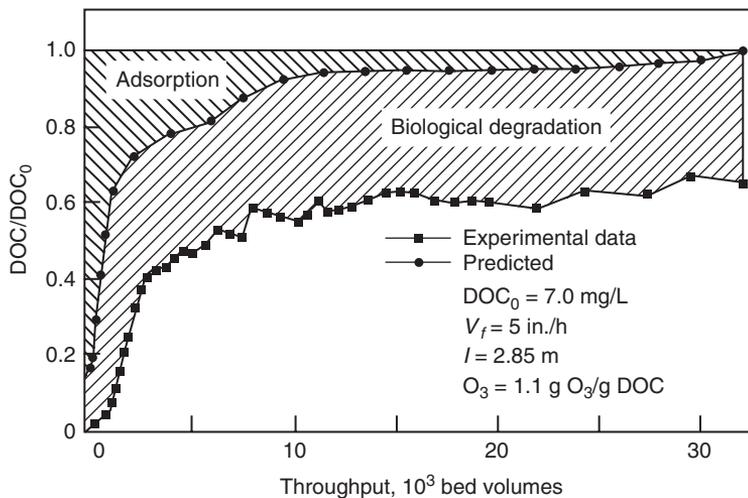

## Biologically Active Filtration

Biologically active filtration, or biofiltration, incorporates biological activity into the granular filtration process. Heterotrophic bacteria colonize the surface of the media, forming a biofilm that is able to degrade some organic compounds and micropollutants, such as phenol, trichlorobenzene, ozonation by-products, ammonia, and odor-causing compounds such as geosmin and MIB. Biofiltration can improve water quality by decreasing the potential for bacterial regrowth in distribution systems, decreasing DBP formation during final disinfection, decreasing chlorine demand, and decreasing chlorine potential (Urfer et al, 1997).

Biofiltration is frequently used after ozonation because ozone can break down large recalcitrant humic acid molecules to smaller, more biologically degradable compounds. Without biofiltration, this increase in biodegradable organic matter (BOM) may encourage regrowth in the distribution system. With biofiltration, DOC removal of 35 to 40 percent may be possible, as shown on Fig 11-20. Thus, ozonation and biofiltration might be considered as a coupled process.

In Europe, dedicated biofilters using GAC media are sometimes installed following a conventional filtration process. In the United States, granular media filters are typically configured to accomplish both biodegradation and particle filtration in a single process. A thorough review of the use of biofiltration in water treatment is provided in Urfer et al. (1997).

Several factors affect the removal of BOM with biological filtration. These include (1) BOM type and concentration, (2) filter media type (i.e., GAC, anthracite, and/or sand), (3) water temperature, and (4) empty bed contact time (EBCT) through the filter. Depending on these factors, steady-state biological performance will be reached within a maximum period of 1 to 2 months.

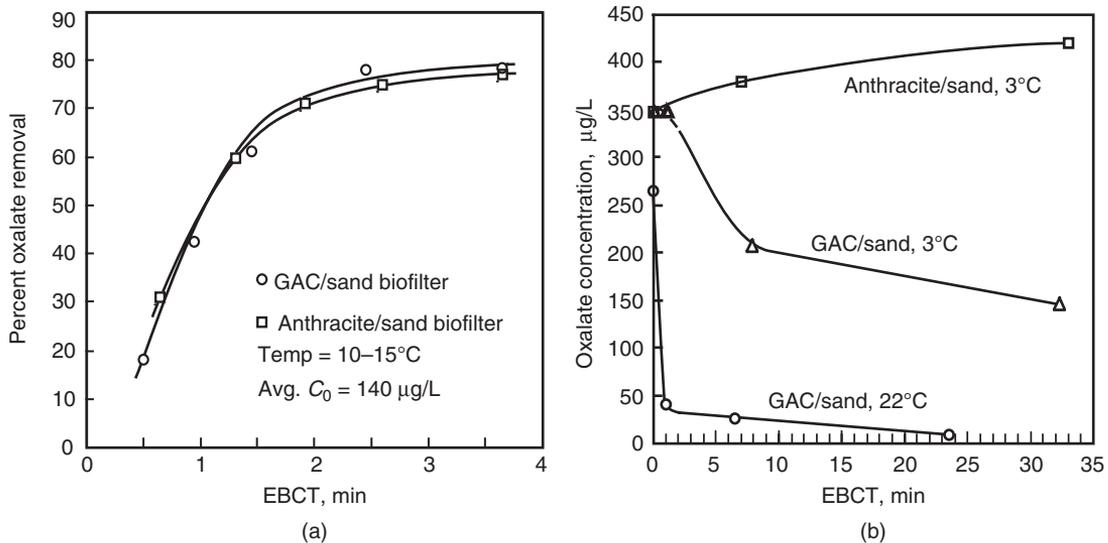

**Figure 11-20**  
DOC removal by adsorption and biodegradation during biofiltration of an ozonated humic acid solution (Adapted from Sontheimer and Hubele, 1987).

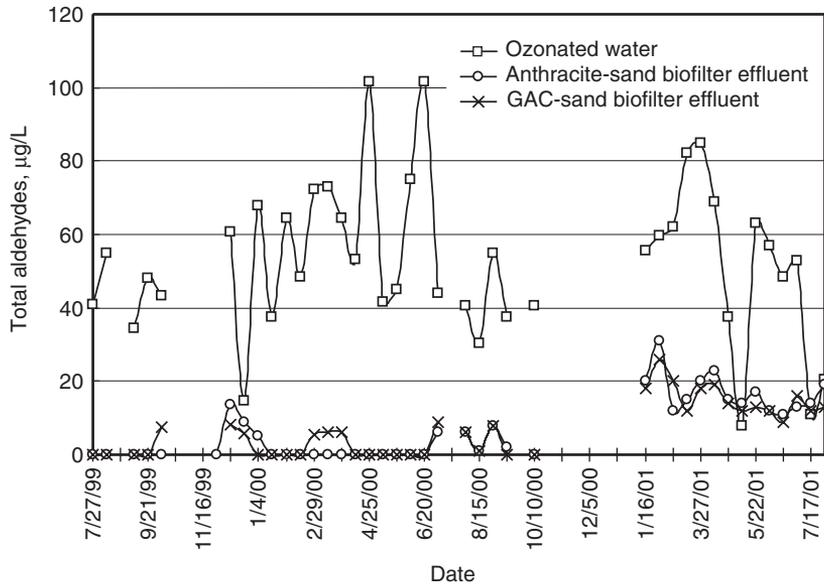

**BIOFILTRATION MEDIA**

Sand, anthracite, and GAC have all been used as biofilter media and some studies suggest that they all perform similarly. Other studies suggest that GAC can be a more effective biofiltration media in some situations. The advantages of GAC appear to be that its irregular surface may provide a better attachment surface for bacteria, it may adsorb potentially inhibitory chemicals and thereby protect the biofilm, it may adsorb slowly biodegradable compounds that may then be degraded by the bacteria, and it can degrade oxidant residuals in the top few centimeters of the bed, thereby protecting the remaining biofilm from inadvertent exposure to oxidants such as chlorine or ozone. Because of these advantages, GAC may be able to establish a biofilm more rapidly, work better at colder temperatures, and be more robust following upsets or inadvertent oxidant exposure.

Results from studies comparing GAC and anthracite as biofilter media are shown on Fig. 11-21. Data shown on Fig. 11-21a were gathered under relatively warm temperature conditions of 10 to 15°C. The anthracite-sand filter performed as well as the GAC-sand filter for removal of oxalate, a common by-product of ozonation, regardless of EBCT. Similar performance in warm conditions was reported by Price et al. (1993) and Krasner et al. (1993). On the other hand, under cold temperature conditions as shown on Fig. 11-21b, the GAC-sand biofilter was still capable of removing a fraction of the oxalate (albeit with high EBCT values), while no removal was achieved with the anthracite-sand biofilter. The removal of total

**Figure 11-21**

Impact of media type and EBCT on the removal of oxalate with biofiltration (a): under warm temperature conditions (Adapted from Coffey et al., 1997) and (b) under cold temperature conditions (Adapted from Emelko et al., 1997).

**Figure 11-22**  
Removal of aldehydes with biological filtration at a full-scale water treatment plant (temperature = 12 to 24°C) (Data Courtesy of the Alameda County Water District, Fremont, California).

aldehydes (another common by-product of ozonation) with biofiltration in a full-scale water treatment plant in Fremont, California, is shown on Fig. 11-22. The 3-year operational data confirm that under relatively warm temperature conditions, anthracite-sand biofilters perform as well as GAC-sand biofilters.

#### BIOFILM MAINTENANCE AND BACKWASHING

A biofilm will establish itself in granular media as long as conditions (substrate, oxygen, temperature, etc.) are favorable. A key requirement is to prevent exposure to inhibitory substances; thus, the primary factor in operating a biofilter is to ensure that the filter influent has no chlorine or ozone residual.

Biofilters develop head loss similar to conventional filters, requiring backwashing on a regular basis. Numerous studies have indicated that biofilms adhere more strongly to filter media than nonbiological particles and that no major losses of biomass occur with proper backwashing procedures for particle removal. There are two types of concerns about backwashing of biological filters: (1) whether backwashing (especially with air scour) causes excessive detachment of the biomass off the filter media and (2) whether biofilters must be backwashed exclusively with nonchlorinated water to maintain their viability. Evaluations of these issues has concluded that rigorous backwashing does not adversely impact biofiltration performance (Miltner et al., 1995; Ahmad and Amirtharajah, 1995; Ahmad et al., 1998). While AOC removal was impaired immediately after backwashing with chlorinated water, its removal was back to normal levels

within a few hours of filter run. Amirtharajah (1993) concluded that air scour helped control the long-term buildup of head loss in a biofilter, which was confirmed by Teefy (2001) who noted that occasional backwashing with chlorinated water was necessary at a full-scale water treatment plant to prevent excessive biological growth, which otherwise results in shorter filter runs. The biofiltration performance shown on Fig. 11-22 was achieved with filters backwashed with chlorinated water approximately every third wash.

#### **FILTRATION PERFORMANCE**

Biological filters will generally achieve good turbidity removal, and many studies have observed no difference in turbidity removal between biological and prechlorinated filters. In other cases, differences in particle counts were observed. Bacterial counts in filter effluent may be higher with biofiltration; but postdisinfection will be provided in either case. The rate of head loss buildup may be higher in biologically active filters, leading to somewhat shorter filter runs if the length of the filter run is limited by the available head. Temperature is also an important factor with respect to biological activity and will vary through the year depending upon the climate. For example, biological activity is usually high in summer months but then drops in the winter months (Servais and Joret, 1999).

#### **DESIGN OF BIOFILTERS**

When used for both biological activity and particle removal, design of the filtration aspects of a biofilter is essentially identical to that presented earlier in this chapter for rapid filters. Contact time, expressed as empty bed contact time (EBCT), is a primary design variable for biofiltration. Removal of BOM generally increases as EBCT increases. Removal of ozone by-products can generally be accomplished with an EBCT of 2 to 4 min, and most biofilters in the United States have EBCT between 1 and 15 min. An appropriate value for the EBCT can be determined during pilot testing.

### **Slow Sand Filtration**

Slow sand filtration is substantially different from rapid filtration. Some of the most significant differences are that slow sand filters use sand media that does not need to be as uniform in size as in rapid filters, do not need coagulation pretreatment, and do not need backwashing. While these differences suggest that slow sand filters are simpler to build and operate than rapid filters, another key difference is that the filtration rate is 50 to 100 times lower, which means that slow sand filters require that much more land to treat the same amount of water. Other differences between rapid filtration and slow sand filtration are summarized in Table 11-11.

In slow sand filtration, the low filtration rate and the use of smaller, less uniform sand causes particles to be removed in the top few centimeters of the bed. The surface of the bed forms a mat of material, called a *schmutzdecke*. The *schmutzdecke* forms an additional filtration layer, physically straining smaller particles from the influent water. In addition, the *schmutzdecke*

**Table 11-11**Comparison between rapid and slow sand granular filtration design criteria<sup>a</sup>

Process Characteristic	Slow Sand Filtration	Rapid Filtration
Filtration rate	0.08–0.25 m/h (0.03–0.10 gpm/ft <sup>2</sup> )	5–15 m/h (2–6 gpm/ft <sup>2</sup> )
Media effective size	0.15–0.30 mm	0.50–1.2 mm
Media uniformity coefficient	<2.5	<1.4
Bed depth	0.9–1.5 m (3–5 ft)	0.6–1.8 m (2–6 ft)
Required head	0.9–1.8 m (3–6 ft)	1.8–3.0 m (6–10 ft)
Run length	1–6 months	1–4 days
Ripening period	Several days	15 min–2 h
Pretreatment	None required	Coagulation
Dominant filtration mechanism	Straining, biological activity	Depth filtration
Regeneration method	Scraping	Backwashing
Maximum raw-water turbidity	10 NTU	Unlimited with proper pretreatment

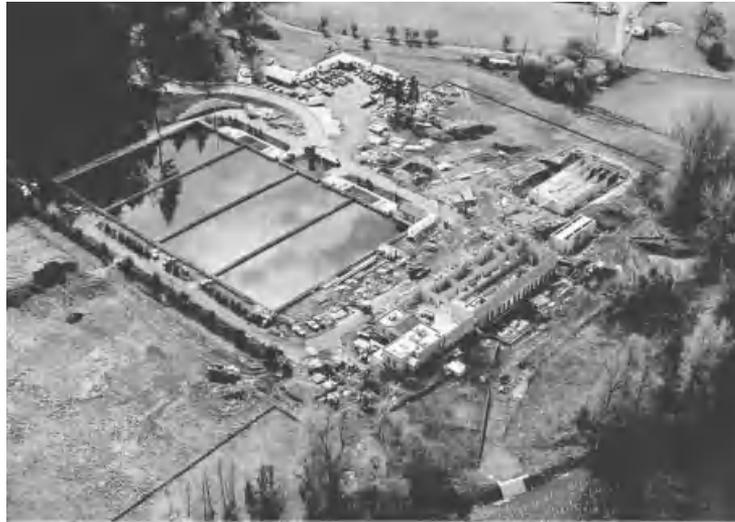

<sup>a</sup>Values represent typical ranges. Some filters are designed and operated outside of these ranges.

forms a complex biological community that degrades some organic matter. Because particles are physically strained at the surface of the filter bed, destabilization by coagulation pretreatment is not necessary.

A typical configuration for a slow sand filter is illustrated on Fig. 11-23. Filter effluent passes through a support layer of graded gravel about 0.3 to 0.6 m (1 to 2 ft) deep and is collected in an underdrain system constructed of perforated pipes or concrete blocks. The water level in the structure is several feet above the top of the media, with the maximum water level dictating the available head. The filtration rate is controlled by valves in either the influent or effluent piping.

#### OPERATING CYCLE FOR SLOW SAND FILTRATION

As with rapid filtration, slow sand filtration operates over a cycle with two stages, consisting of a filtration stage and a regeneration stage. Head loss builds slowly during a filter run that lasts weeks or months. Head loss builds slowly because of the low filtration rate and because the microorganisms degrade some of the accumulated particles. Slow sand filters typically never reach breakthrough and are always terminated when the head loss reaches the available head in the system, typically 0.9 to 1.8 m (3 to 6 ft). Instead of being backwashed when the available head is reached, the filter is drained and the top 1 to 2 cm (0.4 to 0.8 in.) of media is scraped off, hydraulically

**Figure 11-23**  
Typical slow sand filter.

cleaned, and stockpiled onsite. The filter is then placed back in service. The operation and scraping cycle can be repeated many times, often over a period of several years, before the sand must be replenished. When the sand reaches a minimum depth of 0.5 m (20 in.), the stockpiled sand is replaced in the filter to restore the original depth.

A filter with new media typically has a ripening period that can last several days, during which the *schmutzdecke* forms and the effluent quality improves. Filter-to-waste piping is provided to allow filtered water to be returned to the source during the ripening period. After several filter runs and scrapings, the microbial community can become established deeper in the bed and the ripening period can be shorter or nonexistent.

#### **ADVANTAGES AND USE OF SLOW SAND FILTRATION**

The primary advantage of slow sand filtration is that the filters are simple to operate and can run without constant supervision. Operators do not need to have knowledge of coagulation chemistry. Simple operational requirements are particularly attractive to small utilities that do not have the resources for full-time, highly trained treatment plant operators. The simplicity may make slow sand filtration appropriate in developing countries.

With no pretreatment, slow sand filters cannot adequately treat poor-quality surface waters. Slow sand filtration should be used only when source waters have turbidity less than 10 NTU, color less than 15 color units, and no colloidal clay (GLUMRB, 2007). While most slow sand filter plants treat water with less than 10 NTU of turbidity (Slezak and Sims, 1984), some research suggests that the upper limit should be 5 NTU (Cleasby et al., 1984).

For small facilities that have high-quality source water but want to avoid the use of coagulants, membrane filtration (see Chap. 12) or cartridge or bag filters should also be considered.

Slow sand filtration continues to be used successfully in Europe, including facilities supplying large communities such as London and Amsterdam (Joslin, 1997). However, it has been largely superseded by rapid filtration in the United States. A survey conducted in the early 1980s (Slezak and Sims, 1984) identified fewer than 50 operating slow sand filtration plants in the United States [for comparison, there are more than 50,000 community water systems in the United States (U.S. EPA, 2001)]. Most of the facilities listed in Slezak and Sims's (1984) survey were more than 50 years old and served populations of less than 10,000.

#### DESIGN OF SLOW SAND FILTERS

Slow sand filters can be housed in steel, fiberglass, or reinforced concrete structures. Details of slow sand filter design can be found in the literature, such as Hendricks et al. (1991), Visscher (1990), and Seelaus et al. (1986).

Greensand filtration combines oxidation and filtration in a single granular media filtration process. The filtration media is coated with a layer of manganese dioxide, which oxidizes soluble iron, manganese, hydrogen sulfide, and other reduced species. The underlying media can be sand, anthracite, or naturally occurring glauconite mineral. After oxidation, iron and manganese precipitate and can be removed by the filter. The manganese dioxide coating must periodically be regenerated by feeding an oxidant to the filter; typically, potassium permanganate is used. Continuous regeneration can be practiced by feeding potassium permanganate continuously.

The design of the filtration process using greensand media is essentially identical to rapid filtration. The media is typically specified with an effective size of about 0.3, uniformity coefficient  $< 1.6$ , and depth similar to rapid filtration. Filtration rates typically range from 7.5 to 12.5 m/h (3 to 5 gpm/ft<sup>2</sup>). Greensand filters can be designed as either gravity or pressure rapid filters. Additional information about the use of greensand filtration for iron and manganese removal is presented in Chap. 20.

### Greensand Filtration

Diatomaceous earth (DE) filtration, also known as precoat filtration, uses a thin cake (2 to 5 mm) of fine granular material as a filter medium. Particle removal occurs primarily at the surface of the cake, with straining as the predominant removal mechanism.

Diatomaceous earth (also known as Fuller's earth) is the microscopic remnants of the siliceous shells of diatoms, occurs in natural deposits, and is almost pure silica. DE used for filter media typically has a diameter between 4 and 30  $\mu\text{m}$  (Baumann, 1978). Smaller sizes produce higher

### Diatomaceous Earth Filtration

quality effluent but at the expense of more head loss. The properties and characteristics of precoat media are covered in *ANSI/AWWA B101-01 Standard for Precoat Filtering Media* (AWWA, 2001b).

The DE filtration cycle has three stages: precoat, filtration, and backwash (AWWA, 1988). In the first stage, a slurry of DE is fed into the filter vessel and deposited on the septum, which is a porous plate or screen designed to support the precoat material. After precoat is complete, raw water enters the filtration vessel and filtration occurs across the precoat layer. Additional DE (called body feed) is added to the influent water during filtration. The body feed reduces the rate at which head loss builds up by maintaining the porosity of the cake and extends the length of the filter run. Run lengths range from 10 min to 30 days (Baumann, 1957).

Backwash starts after the pressure drop reaches the limiting head, typically 2 to 3 bars (29 to 44 psi). During backwash, water is pumped through the septum in reverse and the filter cake and all accumulated solids slough off. In some instances, a surface wash or agitation system is used to break up an encrusted filter cake, particularly in high-pressure filters. After backwash is complete, the entire cycle begins again.

DE filtration is not used extensively in drinking water treatment (AWWA, 1988), but some small utilities have used it for compliance with the SWTR and subsequent surface water treatment rules. DE filters strain particles larger than about 1  $\mu\text{m}$ , so they can achieve high removal of *Giardia* and *Cryptosporidium* without coagulation. Under the SWTR and LT1ESWTR, precoat filters receive filtration credit for 2 log removal of *Giardia* and *Cryptosporidium* if the filtered water turbidity is equal to or less than 1 NTU (U.S. EPA, 1989, 2002). DE filters are less effective for particles smaller than 1  $\mu\text{m}$  and should only be used for high-quality source waters (turbidity of 10 NTU or less). Additional information on precoat filtration is available in the published literature (AWWA, 1988; Baumann, 1965).

### Bag and Cartridge Filtration

Bag and cartridge filtration are not granular filtration processes and therefore do not really belong in this chapter. They are, however, considered as alternatives for compliance for surface water treatment regulations and are discussed briefly here.

Bag and cartridge filters are filter elements installed inside a pressure vessel. Cartridge filters are typically a self-supporting filter element with either a pleated-fabric or string-wound construction. The flow is from the outside of the cartridge to the inside. Bag filters are a nonrigid, fabric filter with the flow from the inside of the bag to the outside. Although some cartridge filters are backwashable, both cartridge and bag filters are typically considered to be disposable media and are discarded when the head loss exceeds the available head. Thus, they are only suitable for small systems treating relatively high-quality water. Cartridge filter vessels are shown in Fig. 11-19.

## Problems and Discussion Topics

- 11-1 Samples of filter media was sifted through a stack of sieves and the weight retained on each sieve is recorded below. For a given sample (A, B, C, D, or E, to be selected by instructor), determine the effective size and uniformity coefficient for the media.

Sieve Designation	Sieve Opening, mm	Weight of Retained Media, g				
		A	B	C	D	E
8	2.36	0				4
10	2.00	35	0			11
12	1.70	178	11		0	60
14	1.40	216	315		4	227
16	1.18	242	242		16	343
18	1.00	51	116	0	33	216
20	0.85	12	55	23	75	40
25	0.71	5	26	217	285	16
30	0.60	3	14	325	270	3
35	0.50	0	2	151	121	1
40	0.425		0	71	21	0
45	0.355			49	8	
50	0.300			4	3	
Pan	—			20	4	

- 11-2 Explain why a low uniformity coefficient is important in rapid filtration.
- 11-3 Explain (a) the process of ripening, (b) how ripening affects recovery, or net water production, and (c) how to minimize the duration of ripening.
- 11-4 A filter is designed with the following specifications. The anthracite and sand have density of 1700 and 2650 kg/m<sup>3</sup>, respectively, and the design temperature is 10°C. For a given sample (A, B, C, D, or E; to be selected by instructor), calculate the clean-bed head loss.

Item	A	B	C	D	E
Bed type	Mono-media	Mono-media	Dual media	Dual media	Dual media
Filtration rate (m/h)	8	15	15	10	10
Anthracite specifications:					
Effective size (mm)		1.0	1.0	1.2	1.6
Depth (m)		1.8	1.5	1.4	1.2
Sand specifications:					
Effective size (mm)	0.55		0.5	0.55	0.55
Depth (m)	0.75		0.3	0.4	0.7

## 11 Granular Filtration

- 11-5 For the media specification given in Problem 7-4 (C, D, or E to be selected by instructor), determine if the two media layers are matched to each other.
- 11-6 A filter contains 0.55-mm sand that has a density of  $2650 \text{ kg/m}^3$ . Calculate the effective size of  $1550 \text{ kg/m}^3$  anthracite that would be matched to this sand.
- 11-7 In dual-media filter containing sand and anthracite, which material will be the top layer? Why?
- 11-8 Using the sieve analysis from Problem 11-1, determine the clean-bed head loss through a stratified filter bed by calculating the head loss contribution from each layer of media. Assume that the media stratifies into layers based on grain size, that the depth of each layer is proportional to the mass of media retained on each sieve pan, that the grain diameter of the media in each layer is equal to the arithmetic average of two adjacent sieve pans (i.e., the layer formed by the 178 g of media in sample A that passed through the 2.0-mm pan and was retained on the 1.70-mm pan has an average size of 1.85 mm), and that the total head loss is the sum of the head loss from each layer. In addition, assume that the sand that passed through the smallest pan has an average grain diameter of 0.1 mm. The total bed depth is 0.9 m, the filtration rate is 10 m/h, and the temperature is  $15^\circ\text{C}$ .
- Calculate the total clean-bed head loss using the entire sand sample in Problem 11-1, including the material smaller than the smallest sieve pan.
  - Calculate the total clean-bed head loss assuming that the top 5 percent of the filter bed has been scraped to remove fines.
  - Discuss the importance of scraping the surface of rapid-filter beds after media installation and the impact it has on clean-bed head loss.
- 11-9 Compare the clean-bed head loss at  $15^\circ\text{C}$  through a rapid filter with a filtration rate of 15 m/h to that through a slow sand filter with a filtration rate of 0.15 m/h for media with the following specifications: effective size 0.5 mm, density  $2650 \text{ kg/m}^3$ , depth 1 m, and porosity 0.42. What implications do these calculations have on the significance of clean-bed head loss in the design of rapid and slow sand filters?
- 11-10 Given a backwash flow rate of 45 m/h and temperature of  $20^\circ\text{C}$ , calculate the largest (a) sand particle (density =  $2650 \text{ kg/m}^3$ ) and (b) floc solid particle (density =  $1050 \text{ kg/m}^3$ ) that can be washed from a filter bed.
- 11-11 Calculate and plot the size of particles that will be washed from a filter as a function of backwash velocity ranging from 10 to

- 100 m/h at 20°C for (a) sand particles (density = 2650 kg/m<sup>3</sup>), (b) anthracite particles (density = 1650 kg/m<sup>3</sup>), and (c) floc solid particles (density = 1050 kg/m<sup>3</sup>). In addition, calculate the minimum fluidization velocities for 0.5-mm sand (porosity 0.40) and 1.0-mm anthracite (porosity 0.50) and indicate these velocities on your graph. What is an appropriate range for the backwash velocity for dual-media filters? Assuming the backwash troughs are placed high enough, will any media be lost with backwash velocities in this range?
- 11-12 A monomedia anthracite filter is designed with the following specifications: effective size 1.1 mm, uniformity coefficient 1.4, and density 1650 kg/m<sup>3</sup>.
- Calculate backwash rate to get a 25 percent expansion at the design summer temperature of 22°C.
  - Calculate the expansion that occurs at the backwash rate determined in part (a) at the minimum winter temperature of 3°C.
  - Discuss the implications of these results on backwash operations for plants that experience a large seasonal variation in water temperature.
- 11-13 Using the Yao filtration model, examine the effect of filtration rate on filter performance for particles with diameters of 0.1, 1.0, and 10 μm. Assume a monodisperse media of 0.5 mm diameter, porosity 0.42, particle density 1020 kg/m<sup>3</sup>, filtration rate 10 m/h, filter depth 1 m, temperature 20°C, and attachment efficiency 1.0. Plot the results as  $C/C_0$  as a function of filtration rate over a range from 1 to 25 m/h. Comment on the effect of filtration rate and particle size on filter performance.
- 11-14 Using the Tufenkji and Elimelech filtration model, examine the effect of water temperature on filter efficiency for particles with diameters of 0.1, 1.0, and 10 μm. Assume a monodisperse media of 0.5 mm diameter, porosity 0.42, particle density 1020 kg/m<sup>3</sup>, filtration rate 10 m/h, filter depth 1 m, and attachment efficiency 1.0. Plot the results as  $\log(C/C_0)$  as a function of temperature over a temperature range of 1 to 25°C. What implications do these calculations have on filtration in cold climates? Is temperature more important for filtration of certain particle sizes?
- 11-15 Using the Rajagopalan and Tien filtration model, calculate and plot the concentration profile of 4 μm particles (i.e., the size of *Cryptosporidium* oocysts), through monodisperse filter with 0.5-mm-diameter media under filtration conditions typical of rapid filtration ( $v = 10$  m/h) and slow sand filtration ( $v = 0.1$  m/h). Assume porosity 0.40, particle density 2650 kg/m<sup>3</sup>, filter depth

1 m, and temperature 20°C. Assume an attachment efficiency of 1.0 for the rapid filter and 0.05 for the slow sand filter. Explain why rapid and slow sand filtration should be modeled with different values for the attachment efficiency. Plot the results as  $C/C_0$  as a function of depth. Using these results, comment on the methods used to restore the filtration capacity of slow sand and rapid filters (i.e., scraping vs. backwashing).

11-16 The results of pilot filter experiments are summarized in the tables below. For each set of experiments, the independent variable was either the media effective size or the media depth, as given in the second column below. For a given set of experiments (A, B, C, or D, to be selected by instructor), determine equations for how the specific deposit at breakthrough ( $\sigma_B$ ) and the head loss rate constant ( $k_{HL}$ ) each depend on the independent variable. Also determine the optimal value of the independent variable and the corresponding filter run duration. For all problems, assume  $C_0 = 2.0$  mg/L and  $C_E = 0$  mg/L.

a. Design conditions:  $v_F = 15$  m/h, media = anthracite, depth = 1.75 m, max available head = 2.8 m.

A Filter	Media ES, mm	Time to Breakthrough, h	Initial Head Loss, m	Head Loss When Breakthrough Occurred, m
1	0.8	112	0.65	4.6
2	1.0	85	0.39	2.9
3	1.1	72	0.33	2.4
4	1.2	71	0.30	2.0
5	1.4	58	0.24	1.5

b. Design conditions:  $v_F = 15$  m/h, media = GAC, depth = 2.0 m, max available head = 3.0 m.

B Filter	Media ES, mm	Time to Breakthrough, h	Initial Head Loss, m	Head Loss When Breakthrough Occurred, m
1	0.83	54	0.65	6.1
2	1.05	43	0.40	4.3
3	1.25	38	0.33	2.9
4	1.54	32	0.22	2.0

c. Design conditions:  $v_F = 33.8$  m/h, media = anthracite, ES = 1.55 mm, max available head = 3 m (adapted from pilot results for the LADWP Aqueduct Filtration Plant).

C Filter	Media ES, m	Time to Breakthrough, h	Initial Head Loss, m	Head Loss When Breakthrough Occurred, m
1	0.6	4.0	0.16	1.0
2	1.0	6.7	0.30	1.7
3	1.8	11.9	0.50	3.2
4	2.0	13.4	0.58	3.6
5	2.2	14.5	0.65	4.1

- d. Design conditions:  $v_F = 25$  m/h, media = anthracite, ES = 1.50 mm, max available head = 3 m (adapted from pilot results for the Bull Run water supply)

D Filter	Media ES, m	Time to Breakthrough, h	Initial Head Loss, m	Head Loss When Breakthrough Occurred, m
1	2.0	41	0.43	1.8
2	2.3	49	0.51	2.0
3	2.5	55	0.51	2.5
4	3.0	65	0.63	2.9

- 11-17 For the filter design selected in Problem 11-16, what is the UFRV at the design condition? If the filters are designed to be backwashed at 40 m/h for 15 min, what are the UBWV and recovery, assuming there is no filter-to-waste period?
- 11-18 A filter has been designed to have a run length of 48 h while operating at a filtration rate of 12 m/h. The design backwash rate is 40 m/h, backwash duration is 15 min, and filter-to-waste duration is 10 min. The plant operator decides to clean the filters more thoroughly and backwashes at a rate of 55 m/h for 25 min. As a result, ripening takes longer and the filter-to-waste duration is 50 min. Calculate the UFRV, UBWV, UFWV, and recovery (a) as designed and (b) as operated. What is the percent increase in the volume of treated water lost as waste backwash water and filter-to-waste water?
- 11-19 Explain (a) the importance of flow control in proper filtration operation and (b) the main types of flow control systems.
- 11-20 Discuss (a) the impact of rapid variations in filtration rate on filter performance, (b) causes of rapid variations in filtration rate, and (c) design features and operational methods for preventing rapid variations in filtration rate.

- 11-21 Discuss factors that influence the selection of the number of filters in a treatment plant design.
- 11-22 Discuss the benefits and salient features of air scour.

## Terminology for Membrane Filtration

Term	Definition
Asymmetric membrane	Membrane whose morphology (structure) varies significantly across the thickness of the membrane.
Cross-flow filtration	Filtration technique in which the feed stream is pumped at high velocity parallel to the membrane surface to reduce the collection of retained species at the membrane surface.
Dalton	Unit for molecular weight, equal to one-twelfth of the mass of a carbon-12 atom. Also equal to the molar mass in units of grams per mole. Equivalent to atomic mass units (amu).
Dead-end filtration	Filtration technique in which the feed stream is directed toward and perpendicular to the membrane surface.
Fouling	Process resulting in loss of performance of a membrane due to the deposition of suspended or dissolved substances on its external surfaces, at its pore openings, or within its pores.
Homogeneous membrane	Membrane with consistent morphology and transport properties throughout its thickness.
Lumen	Bore, or cavity, in the center of a hollow fiber membrane.
Molecular weight cutoff	See <i>Retention rating</i> .
Packing density	Membrane area per unit volume in a membrane module.
Permeability	Specific flux of clean, deionized water through a new membrane.

Term	Definition
Permeate	Water and permeable components that pass through a membrane.
Retentate	Solution containing water and impermeable components retained on the feed side of a semipermeable membrane.
Retention rating	Designation for the size of materials retained by a membrane. The retention rating is called the pore size in micrometers for microfiltration (MF) membranes and the molecular weight cutoff (MWCO) in daltons for ultrafiltration (UF) membranes.
Semipermeable membrane	Membrane that is permeable to some components in a feed solution and impermeable to other components.
Specific flux	Flux divided by transmembrane pressure.
Straining	Process in which particles are retained because they are physically larger than the void spaces in the filter medium (often called sieving).
Transmembrane pressure	Differential pressure between the feed and permeate sides of a membrane.

Note: Additional membrane nomenclature is available in Koros et al. (1996) and ASTM (2001b).

Membrane processes are modern physicochemical separation techniques that use differences in permeability (of water constituents) as a separation mechanism. During membrane treatment, water is pumped against the surface of a membrane, resulting in the production of product and waste streams, as shown on Fig. 12-1. The membrane, typically a synthetic material less than 1 mm thick, is *semipermeable*—meaning that it is highly permeable to some components in the feed stream and less permeable (or impermeable) to others. During operation, permeable components pass through the membrane and impermeable components are retained on

**Figure 12-1**  
Schematic of separation process through semipermeable membrane.

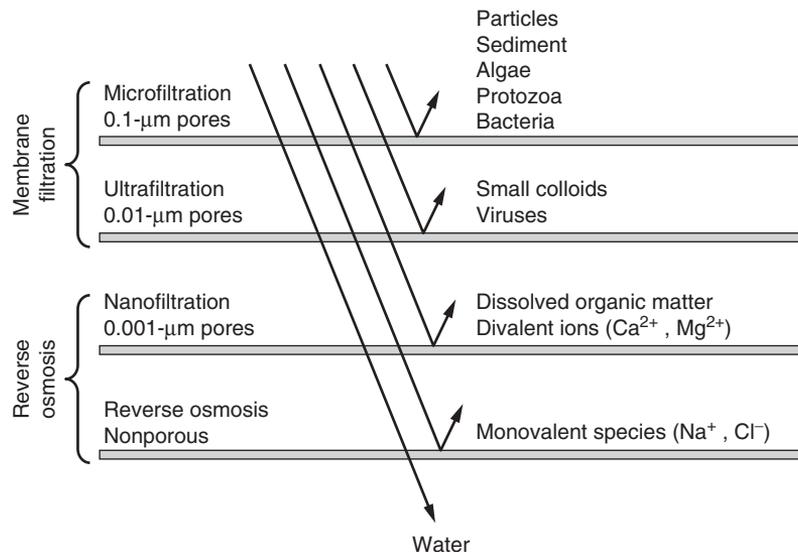

the feed side. As a result, the product stream is relatively free of impermeable constituents and the waste stream is concentrated in impermeable constituents.

## 12-1 Classification of Membrane Processes

Four types of pressure-driven membranes are currently used in municipal water treatment: microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO) membranes. The hierarchy of membrane processes is shown on Fig. 12-2. The distinction between the types of membranes is somewhat arbitrary and subject to differing interpretations, but the membranes are loosely identified by the types of materials rejected, operating pressures, and nominal pore dimensions (which are identified on an order-of-magnitude basis on Fig. 12-2). A “loose” NF membrane marketed by one manufacturer might be substantially similar to a “tight” UF membrane marketed by another manufacturer. As used in water treatment, these membranes can be classified into two distinct physicochemical processes: (1) membrane filtration and (2) reverse osmosis.

### Membrane Filtration

*Membrane filtration* is the focus of this chapter and encompasses the use of MF and UF membranes. Filtration can be broadly defined as a process that separates suspended particles (a dispersed solid phase) from a liquid phase by passage of the suspension through a porous medium (either membranes or granular media). In membrane filtration, the feed stream is a suspension,

**Figure 12-2**  
Hierarchy of pressure-driven membrane processes.

or two-phase system, in which the dispersed solid phase to be separated may include sediment, algae, bacteria, protozoa, viruses, or colloids. The primary goal of membrane filtration is to produce a product stream (water) from which the targeted solids have been completely removed, which is similar to the goal of granular filtration. While used for similar purposes, MF and UF membranes have important differences that will be described later in this chapter.

The other fundamental physicochemical membrane process is *reverse osmosis*. Reverse osmosis is the focus of Chap. 17 and encompasses the use of NF and RO membranes. *Osmosis* is the preferential diffusion of water through a semipermeable membrane in response to a concentration gradient. In reverse osmosis, the feed stream is a solution, or single-phase system, in which the constituents targeted for removal are truly dissolved solutes (ions such as sodium, chloride, calcium, or magnesium, and dissolved NOM). The primary goal of reverse osmosis is to reduce the concentration of these solutes in the product water. Reverse osmosis membranes are used to produce potable water from ocean or brackish water and to remove specific dissolved contaminants (e.g., pesticides, arsenic, nitrate, radionuclides). Nanofiltration membranes are used to soften hard waters (remove calcium and magnesium ions), freshen brackish waters, and reduce the concentration of NOM to control disinfection by-product (DBP) formation.

The differences between membrane filtration and reverse osmosis are substantial. The predominant removal mechanism in membrane filtration is straining, or size exclusion, so the process can theoretically achieve perfect exclusion of particles regardless of operational parameters such as influent concentration and pressure. Mass transfer in reverse osmosis, however, involves a diffusive mechanism so that separation efficiency is dependent on influent solute concentration, pressure, and water flux rate. Differences between membrane filtration and reverse osmosis are evident in the materials used for the membranes, the configuration of the membrane elements, the equipment used, the flow regimes, and the operating modes and procedures. Additional comparisons between membrane filtration and reverse osmosis are detailed in Table 12-1. It should be noted that membranes are used for many purposes in a wide variety of fields and industries, and the distinction between membrane types as used in water treatment may not be appropriate in other industries. For instance, UF membranes are used in food-processing and pharmaceutical industries for purifying, concentrating, and fractionating concentrated solutions of macromolecules such as proteins and polysaccharides; UF membrane use in those industries involves phenomena (such as concentration polarization) described in Chap. 17.

## Reverse Osmosis

## Differences between Membrane Processes

**Table 12-1**

Comparison between membrane filtration and reverse osmosis

Process Characteristic	Membrane Filtration	Reverse Osmosis
Objectives	Particle removal, microorganism removal	Seawater desalination, brackish water desalination, softening, NOM removal for DBP control, specific contaminant removal
Target contaminants	Particles	Dissolved solutes
Membranes types	Microfiltration, ultrafiltration	Nanofiltration, reverse osmosis
Typical source water	Fresh surface water (TDS < 1000 mg/L)	Ocean or seawater, brackish groundwater (TDS = 1000–20,000 mg/L), colored groundwater (TOC > 10 mg/L)
Membrane structure	Homogeneous or asymmetric	Asymmetric or thin-film composite
Most common membrane configuration	Hollow fiber	Spiral wound
Dominant exclusion mechanism	Straining	Differences in solubility or diffusivity
Removal efficiency of targeted impurities	Frequently 99.9999% or greater	Typically 50–99%, depending on objectives
Most common flow pattern	Dead end	Tangential
Operation includes backwash cycle	Yes	No
Influenced by osmotic pressure	No	Yes
Influenced by concentration polarization	No	Yes
Noteworthy regulatory issues	Challenge testing and integrity monitoring	Concentrate disposal
Typical transmembrane pressure	0.2–1 bar (3–15 psi)	5–85 bar (73–1200 psi)
Typical permeate flux	30–170 L/m <sup>2</sup> · h (18–100 gal/ft <sup>2</sup> · d)	1–50 L/m <sup>2</sup> · h (0.6–30 gal/ft <sup>2</sup> · d)
Typical recovery	>95%	50% (for seawater) to 90% (for colored groundwater)
Competing processes	Granular filtration	Carbon adsorption, ion exchange, precipitative softening, distillation

**Table 12-2**  
Non-pressure-driven membrane processes

Membrane Process	Driving Force
Dialysis	Concentration gradient
Electrodialysis	Electrical potential
Electrodialysis reversal	Electrical potential
Pervaporation	Pressure gradient
Forward osmosis	Osmosis
Membrane distillation	Vapor pressure
Thermosmosis	Temperature gradient

It should be noted that membrane filtration and reverse osmosis are both pressure-driven membrane processes. Driving forces other than pressure are used in other membrane processes, including some that are occasionally used in water treatment, such as electrodialysis. Other membrane processes (not covered in this text because of their limited applicability in water treatment) and their driving forces are identified in Table 12-2.

## 12-2 History of Membrane Filtration in Water Treatment

---

Microporous membranes were first patented in the 1920s (Belfort et al., 1994) and were limited primarily to laboratory use until the 1950s. They were used primarily for enumerating bacteria, removing microorganisms and particles from liquid and gas streams, fractionating and sizing macromolecules such as proteins, and diffusion studies. The U.S. Public Health Service (U.S. PHS) adopted membrane filtration as a method for identifying coliform bacteria in 1957.

In the 1950s, industrial users started applying membrane filtration to larger scale industrial use, with one common use being sterilization of liquid pharmaceuticals and intravenous solutions. Membrane filtration was used in food-processing industries for clarifying, concentrating, purifying, or sterilizing various products such as fruit juices, dairy products, vegetable oils, and alcoholic beverages. Membrane filtration also began to be used for industrial process and waste treatment—such as oily wastewater treatment, caustic acid, and brine recovery—and treatment or recovery of various other industrial waste streams.

The first interest in membrane filtration for potable water production began in the 1980s as utilities and regulators became increasingly concerned about microbiological contamination. Advances in industrial equipment design and operation, including the introduction of dead-end flow regimes, outside-in hollow-fiber flow configurations, and backwashing systems, made

**Application to  
Drinking Water  
Treatment**

the production of drinking water by membrane filtration an economically realistic possibility. Very small utilities, in particular, began to consider membrane filtration. Rapid granular filter equipment was expensive and required a level of operator attention and sophistication that was sometimes unaffordable for small communities, and membrane filtration offered an attractive, highly automated, operationally simple alternative. The first membrane filtration plant used for drinking water production in the United States was a 225-m<sup>3</sup>/d (0.06-mgd) plant at Keystone Resorts in Colorado in 1987 (U.S. EPA, 2001). Similar developments occurred in Europe, and a 250-m<sup>3</sup>/d (0.07-mgd) UF plant was installed in France in 1988 (Anselme et al., 1999).

The passage of the SWTR (U.S. EPA, 1989) in 1989 provided utilities with another reason to consider membrane filtration. Regulatory agencies were focusing greater attention on microorganisms in water supplies and lower turbidity levels were required. Membrane filtration offered the potential of higher quality treatment than granular filtration. Still, the use of membrane filtration grew slowly, and by 1993 there were only eight systems installed in the United States, all considerably smaller than 3800 m<sup>3</sup>/d (1 mgd) (U.S. EPA, 2001).

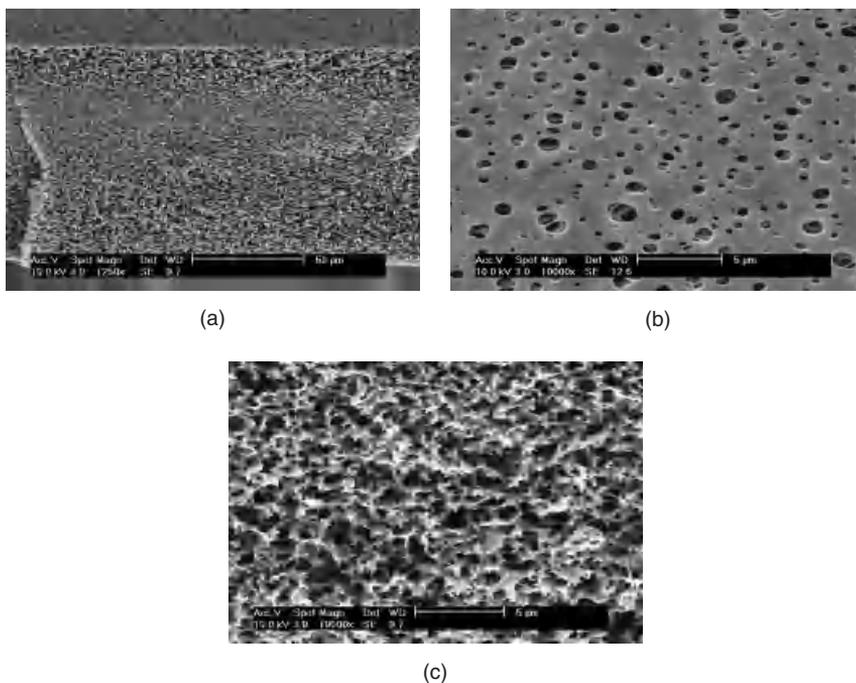

### **Effectiveness of Membrane Filtration for Removing Protozoa**

As noted in Chap. 1, an outbreak of cryptosporidiosis in Milwaukee, Wisconsin, in 1993 caused over 400,000 illnesses and 50 deaths (Craun et al., 1998; U.S. EPA, 1998). During the incident, *Cryptosporidium* oocysts had passed through the conventional water treatment plant, including the rapid granular filters. The outbreak underscored the fact that the effluent water quality from rapid granular filters is dependent on proper chemical conditioning of the feed water, which is ultimately dependent on operators' judgment, experience, and knowledge of water chemistry. In contrast, membrane filtration removes particles by straining so that complete removal of protozoa is virtually guaranteed as long as the membranes are intact.

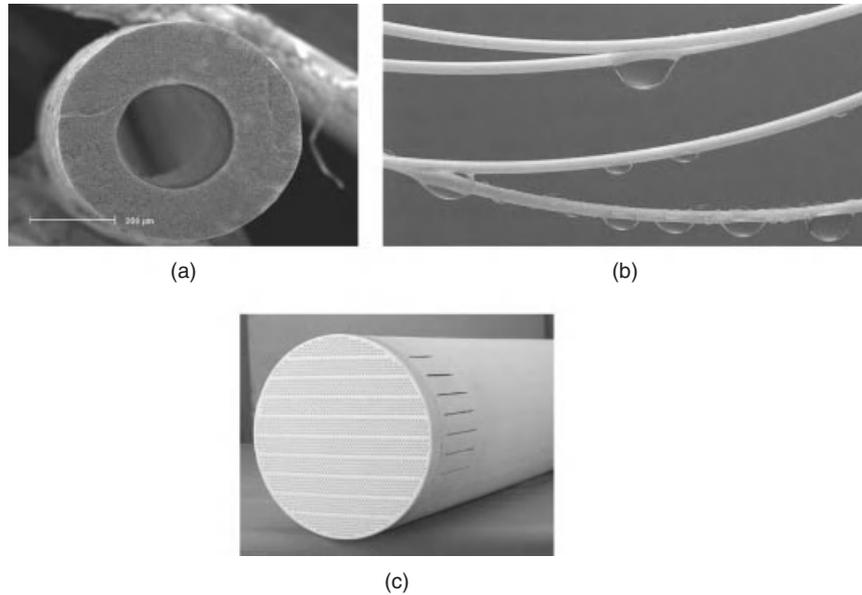

Afterward, the view that membranes provided superior filtration helped fuel a rapid increase in the installation of membrane filtration plants, with growth rates in installed capacity of 50 to 100 percent per year over the next several years. Costs of membrane filtration facilities dropped dramatically during this period as a result of advances in technology, mass production, and the entry of additional manufacturers into the market. A survey of equipment manufacturers revealed over 700 membrane filtration facilities in operation worldwide by the end of 2003. In North America, 213 plants [with capacity greater than 379 m<sup>3</sup>/d (0.1 mgd)] had a total installed capacity of 2.3 million m<sup>3</sup>/d (620 mgd) by the end of 2003 (Adham et al., 2005). Interest in membrane filtration has continued unabated since then. Membrane filtration is now considered a viable option for any surface water treatment facility of any size. The decision to use granular filtration or membrane filtration in any particular facility depends on site-specific circumstances.

## 12-3 Principal Features of Membrane Filtration Equipment and Operation

Membrane filtration occurs when water is forced through a thin wall of porous material. The filter medium is not woven or fibrous like cloth but is a continuous mass with tortuous interconnecting voids, as shown in the scanning electron microscope (SEM) images on Fig. 12-3. Nearly all membrane filtration systems installed in the United States use polymeric membranes. Polymeric membranes are almost always configured as hollow fibers, as shown on Figs. 12-4a and 12-4b. The fibers have an outside diameter ranging from about 0.65 to 2 mm and a wall thickness (i.e., membrane thickness) ranging from about 0.1 to 0.6 mm. Although the hollow fiber configuration is the most common used in water treatment, other configurations exist and are in widespread use in other industries. Membrane filtration is a rapidly evolving field, and other configurations might be used in the future. Ceramic membranes are used in some systems in Japan, and the first large ceramic membrane system in the United States was designed for Parker, Colorado, and is expected to be operational in 2012. Ceramic membranes have a tubular configuration with many parallel channels in a rigid monolithic element, as shown on Fig. 12-4c. The configuration has a strong effect on the *packing density*, or membrane area per unit of volume of equipment module, which can be

**Figure 12-3**  
Scanning electron microscope images of a 0.2- $\mu\text{m}$  polyethersulfone microfiltration membrane: (a) cross section of the entire membrane, (b) high magnification of the membrane surface, and (c) high magnification of the membrane internal structure.

**Figure 12-4**

(a) Scanning electron microscope image of end view of a hollow-fiber membrane (courtesy of US Filter Memcor Products), (b) water permeating hollow-fiber membranes (courtesy of Suez Environnement), and (c) end view of a ceramic tubular membrane (courtesy of NKG).

an important consideration in the cost effectiveness of membrane plants. Other membrane configurations are described in Table 12-3.

The water passing through the membrane is called permeate, and water remaining on the feed side is called retentate. As solids accumulate against the filter medium, the head across the membrane required to maintain constant flux increases. The difference in pressure between the feed and permeate is known as the transmembrane pressure. The transmembrane pressure is between 0.2 and 1 bar (3 and 15 psi) for most membrane filtration systems. Keeping pressure below 1 bar (15 psi) helps minimize membrane fouling.

Membrane filters operate over a cycle consisting of two stages, just like granular filters: (1) a filtration stage, during which particles accumulate, and (2) a backwash stage, during which the accumulated material is flushed from the system. During the backwash cycle, air and/or water is used to remove accumulated solids. Typical permeate flux, operating pressure, and duration of filter and backwash cycles, along with a comparison to rapid granular filtration, are presented in Table 12-4. Although the backwash removes accumulated solids, a gradual but continuous loss of performance is observed over a period of days or weeks, as shown on Fig. 12-5. The loss of performance, or fouling, is due to slow adsorption or clogging of material that cannot be removed during backwash. Fouling affects the cost effectiveness of membrane filtration and will be discussed in detail later in this chapter. Fouling is minimized by periodically adding chemicals to the backwash cycle, known as chemically enhanced backwash (CEB),

**Table 12-3**  
Membrane configurations

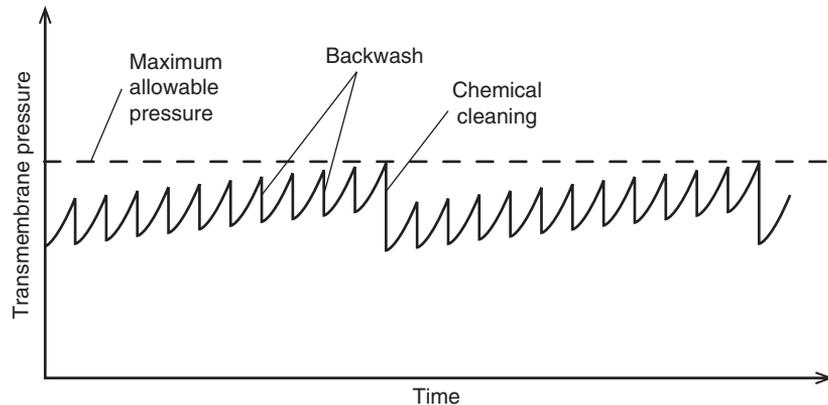

Configuration	Description
Hollow fiber	Membranes are cast as hollow tubes and filtration occurs as water passes through the wall of the fibers (see Fig. 12-4b). The module packing density (specific surface area) is 750–1700 m <sup>2</sup> /m <sup>3</sup> .
Tubular	Membranes are constructed as a monolithic structure with one or more channels through the structure (see Fig. 12-4c). Ceramic membranes are typically tubular membranes. These membranes can be operated at a high cross-flow velocity, which is ideal for applications where the particle concentration is high. The module packing density is up to 400–800 m <sup>2</sup> /m <sup>3</sup> .
Flat sheet	Membranes are cast as a sheet and used as a single layer or as a stack of sheets. Common in laboratory separations but not as common at an industrial scale. Packing density depends on spacing of the sheets.
Spiral wound	Flat-sheet membranes, stacked in layers separated by permeate and retentate spacers, then rolled around a central tube so that the permeate travels in a spiral flow path toward the central collection tube. Common in NF and RO membranes but not in wide use for membrane filtration due to clogging of flow paths with particulate matter and problems with backwashing effectively. See Chap. 17 for additional details on the construction of spiral-wound elements. The packing density is 700–1000 m <sup>2</sup> /m <sup>3</sup> .
Hollow fine fiber	Membranes cast as hollow tubes with an outside diameter of 0.085 mm (about the thickness of human hair). Hollow fine fibers are used only as RO membranes; see Chap. 17 for additional details. The packing density is 5600–7400 m <sup>2</sup> /m <sup>3</sup> .
Track etched	Flat-sheet membranes that are cast as a dense sheet of polymer material and exposed to a radioactive beam, which damages the material along “tracks,” or straight pathways through the material. The material is then immersed in an etching bath that dissolves the material along the pathways, widening the tracks to form pores of uniform cylindrical dimensions. The result is a flat-sheet membrane with a narrow, controllable, and extremely uniform pore size distribution, which is advantageous in laboratory separations. Track-etched membranes are not currently used in industrial-scale applications.

**Table 12-4**

Operating characteristics of membrane and rapid granular filters

Criteria	Membrane Filtration	Rapid Granular Filtration
Filtration rate (permeate flux)	0.03–0.17 m/h <sup>a</sup> (0.01–0.07 gpm/ft <sup>2</sup> )	5–15 m/h <sup>a</sup> (2–6 gpm/ft <sup>2</sup> )
Operating pressure	0.2–1 bar (7–34 ft)	0.18–0.3 bar (6–10 ft)
Filtration cycle duration	30–90 min	1–4 d
Backwash cycle duration	1–3 min	10–15 min
Ripening period	None	15–120 min
Recovery	>95 %	>95 %
Filtration mechanism	Straining	Depth filtration

<sup>a</sup>Conventional units for membrane permeate flux are L/m<sup>2</sup> · h and gal/ft<sup>2</sup> · d. The conversions to the units shown in this table are 1 L/m<sup>2</sup> · h = 10<sup>-3</sup> m/h and 1440 gal/ft<sup>2</sup> · d = 1 gpm/ft<sup>2</sup>.

**Figure 12-5**  
Transmembrane pressure development during membrane filtration.

and periodic chemical cleaning, known as the clean-in-place (CIP) cycle. CIP typically involves soaking the membranes for several hours in one or more warm solutions containing surfactants, acids, or bases. The cleaning frequency may range from a few days to several months, depending on the membrane material, operating conditions, and raw-water quality. The membranes degrade over a longer period of time, and replacement may be necessary after a period of 5 to 10 years.

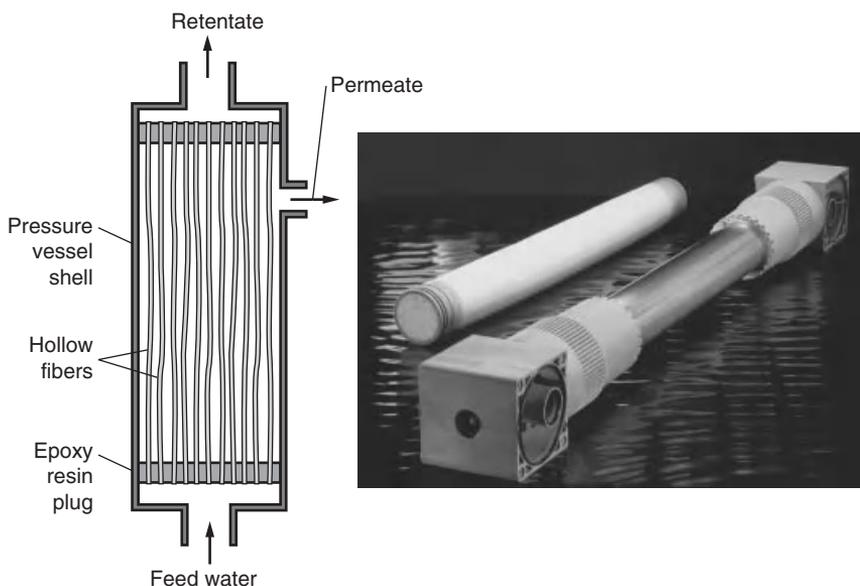

The increase in transmembrane pressure when filters are operated in a constant-flux, rising-pressure mode is shown on Fig. 12-5. Full-scale facilities are operated in this mode because of production capacity requirements. In contrast, laboratory studies are sometimes performed in a

constant-pressure, declining-flux mode to accommodate equipment capabilities and data analysis procedures.

As shown in Table 12-4, the flux through a membrane filter is typically about two orders of magnitude lower than the flux through a rapid granular filter; consequently, a membrane filtration plant needs 100 times the filter area of a rapid granular filtration plant to produce the same quantity of water. One characteristic of membrane filtration plants, however, is that they are frequently more compact than granular filtration plants. This apparent contradiction is possible because membrane plants are constructed by packing thousands of hollow fibers into modules; thus, 1 m<sup>2</sup> of floor space at a membrane plant may contain more than 100 m<sup>2</sup> of membrane area. Membrane modules are available in two basic configurations: pressure-vessel systems or submerged systems.

#### PRESSURE-VESSEL CONFIGURATION

Pressure-vessel modules are generally 100 to 300 mm (4 to 12 in.) in diameter, 0.9 to 5.5 m (3 to 18 ft) long, and arranged in racks or skids. Typical pressure-vessel membrane elements are shown on Fig. 12-6. A single module has thousands of fibers and typically contains between 40 and 80 m<sup>2</sup> (430 and 860 ft<sup>2</sup>) of filter area. The rack or skid is the basic production unit, and all modules within one rack are operated in parallel simultaneously (see Fig. 12-7). Racks can contain between 2 and 100 modules, depending on capacity requirements. Feed pumps typically deliver water

**Figure 12-6**

filtration facility using the  
pressure-vessel  
configuration.

to a common manifold that supplies each rack. Each module must be piped individually for feed and permeate water, so large racks involve a substantial number of piping connections. Transmembrane pressure is developed by a feed pump that increases the feed water pressure, while the permeate stays at near-atmospheric pressure. Pressure-vessel systems typically operate at transmembrane pressures between about 0.4 and 1 bar (6 and 15 psi).

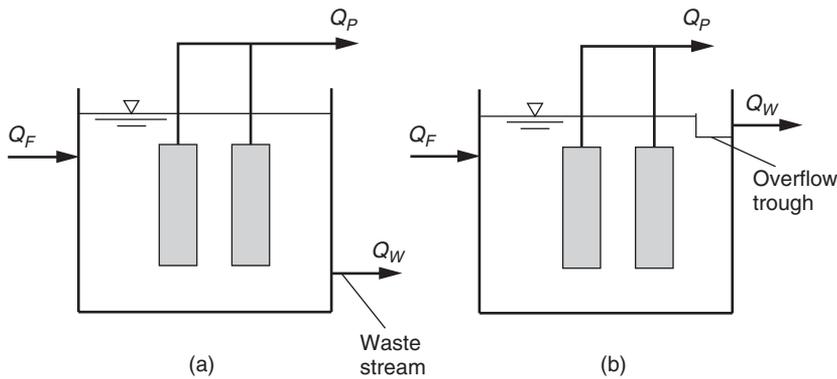

#### **SUBMERGED CONFIGURATION**

Submerged systems (also called immersed membranes) are modules of membranes suspended in basins containing feed water, as shown on Fig. 12-8. The basins are open to the atmosphere, so pressure on the influent side is limited to the static pressure provided by the water column. Transmembrane pressure is developed by a pump that develops suction on the permeate side of the membranes; thus submerged systems are sometimes called suction- or vacuum-based systems. Net positive suction head (NPSH) limitations on the permeate pump restrict submerged membranes to a maximum transmembrane pressure of about 0.5 bar (7.4 psi), and they typically operate at a transmembrane pressure of 0.2 to 0.4 bar (3 to 6 psi). Submerged systems are configured with multiple basins so that individual basins can be isolated for cleaning or maintenance without shutting down the entire plant. Each basin typically has its own permeate pump.

Because clean water is extracted from the feed basin through the membranes and solids are returned directly to the feed tank during the backwash

**Figure 12-8** Submerged configurations for membrane filtration: (a) schematic of a submerged membrane module and (b) photograph of a single module. (© 2011 General Electric Company. All rights reserved. Reprinted with permission.)

**Figure 12-9** Feed-and-bleed and semibatch modes of operation. In feed-and-bleed,  $Q_P$  and  $Q_W$  are both continuous, the sum of the two flows equals  $Q_F$ . In semibatch,  $Q_P$  is continuous and equal to  $Q_F$ ,  $Q_W$  only flows when solids are being wasted.

cycle, the solids concentration in the feed tank can be significantly higher than in the raw water. A high solids concentration can be advantageous when using treatment additives (i.e., coagulants or PAC) to remove dissolved contaminants but can have an adverse impact on the solids loading on the membrane during filtration. Two basic strategies are used to maintain the proper solids concentration in the feed tank, as shown on Fig. 12-9: (1) the feed-and-bleed strategy and (2) the semibatch strategy. In the feed-and-bleed strategy, a small waste stream is continuously drawn from the feed tank. The average solids concentration in the tank will be a function of the size of the waste stream:

$$C_w = \left( \frac{Q_f}{Q_w} \right) C_f \tag{12-1}$$

where  $C_f$  = solids concentration in influent, mg/L  
 $C_w$  = solids concentration in tank and waste stream, mg/L  
 $Q_f$  = influent flow rate, m<sup>3</sup>/h  
 $Q_w$  = waste flow rate, m<sup>3</sup>/h

Some guide books, such as the *Membrane Filtration Guidance Manual* (U.S. EPA, 2005), refer to the ratio  $C_w/C_f$ , and therefore the ratio  $Q_f/Q_w$ , as the volume concentration factor (VCF).

The semibatch strategy operates without a continuous waste stream, and the feed and permeate flows are at the same rate. As a result, solids accumulate in the feed tank during the filtration cycle. During the backwash cycle, the volume of water in the tank increases due to addition of the backwash flow (raw water continues to flow to the tank during the backwash cycle), and the excess water (and solids) exits the basin through an overflow trough or port.

In currently available equipment, submerged systems tend to accommodate larger modules than pressure-vessel systems. Furthermore, submerged systems have substantially fewer valves and piping connections. As larger membrane plants are designed and built, membrane manufacturers have tried to improve the economy of scale by developing larger modules to reduce the number of individual modules and piping connections necessary in large facilities, and these trends are expected to continue to lead to the development of larger modules.

### Flow Direction through Hollow Fibers

Filtration occurs as water passes through the wall of the hollow fiber. Some manufacturers have designed membrane systems to filter from outside to inside (the feed water is against the shell, or outside the fiber, and the permeate is in the lumen, or inside the fiber), and other manufacturers have designed systems to filter in the opposite direction (inside out). The advantages and disadvantages of each flow configuration are described in Table 12-5. Pressure vessels use either outside-in or inside-out membranes, while submerged systems use only outside-in membranes. The difference in flow that can be achieved with outside-in versus inside-out systems is demonstrated in Example 12-1.

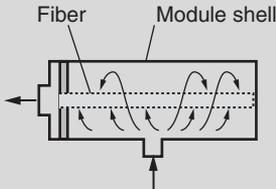

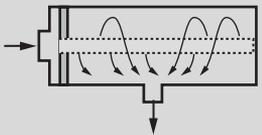

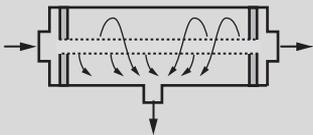

### Cross-Flow and Dead-End Flow Regimes

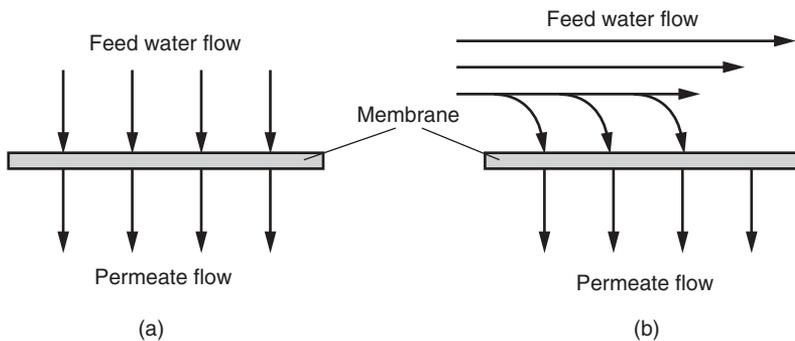

Permeate flux and fouling are affected by the flow regime of the feed water near the membrane surface. Two filtration strategies, cross-flow filtration and dead-end filtration, have been developed to influence this flow regime and are shown schematically on Fig. 12-10.

#### CROSS-FLOW FILTRATION

In cross-flow filtration, the feed water is pumped at a high rate through the lumen of inside-out membrane fibers. The cross-flow velocity, typically 0.5

**Table 12-5**  
Comparison of hollow-fiber membrane configurations

Configuration	Advantages	Disadvantages
<p>Outside in</p> 	<ul style="list-style-type: none"> <li><input type="checkbox"/> Can treat more water at same flux because outside of fiber has more surface area</li> <li><input type="checkbox"/> Less sensitive to presence of large solids in the feed water</li> </ul>	<ul style="list-style-type: none"> <li><input type="checkbox"/> Cannot be operated in cross-flow mode</li> </ul>
<p>Inside out (dead-end mode)</p> 	<ul style="list-style-type: none"> <li><input type="checkbox"/> Less expensive to operate than inside out in cross-flow mode</li> </ul>	<ul style="list-style-type: none"> <li><input type="checkbox"/> Large solids in feed water can clog lumen</li> <li><input type="checkbox"/> Can treat less water at same flux because inside of fiber has less surface area</li> </ul>
<p>Inside out (cross-flow mode)</p> 	<ul style="list-style-type: none"> <li><input type="checkbox"/> Can be operated at higher flux with high-turbidity feed water because cross-flow velocity flushes away solids and reduces impact of particles forming cake at membrane surface</li> </ul>	<ul style="list-style-type: none"> <li><input type="checkbox"/> Large solids in feed water can clog lumen</li> <li><input type="checkbox"/> Can treat less water at same flux because inside of fiber has less surface area</li> <li><input type="checkbox"/> Pumping costs associated with recirculating feed water through lumen can be expensive</li> </ul>

### Example 12-1 Comparison of outside-in and inside-out filtration

A Dow Filmtec SFX-2860 membrane module contains 5760 fibers. The fibers are 1.87 m long with an outside diameter of 1.3 mm and inside diameter of 0.7 mm. Calculate the water production from one module if the flux is  $75 \text{ L/m}^2 \cdot \text{h}$  and the flow direction is (1) outside in and (2) inside out. Compare the two answers.

#### Solution

1. Compute the product water flow for outside-in flow.
  - a. Determine the outside surface area per fiber:

$$\begin{aligned} a(\text{per fiber}) &= \pi dL = \pi(1.3 \text{ mm})(1.87 \text{ m})(10^{-3} \text{ m/mm}) \\ &= 7.64 \times 10^{-3} \text{ m}^2/\text{fiber} \end{aligned}$$

- b. Compute the product water flow:

$$\begin{aligned} Q &= Ja = (75 \text{ L/m}^2 \cdot \text{h})(7.64 \times 10^{-3} \text{ m}^2/\text{fiber})(5760 \text{ fibers}) \\ &= 3300 \text{ L/h} \end{aligned}$$

2. Compute the product water flow for inside-out flow.
  - a. Determine the inside surface area per fiber:

$$\begin{aligned} a(\text{per fiber}) &= \pi dL = \pi(0.7 \text{ mm})(1.87 \text{ m})(10^{-3} \text{ m/mm}) \\ &= 4.11 \times 10^{-3} \text{ m}^2/\text{fiber} \end{aligned}$$

- b. Compute the product water flow:

$$\begin{aligned} Q &= Ja = (75 \text{ L/m}^2 \cdot \text{h})(4.11 \times 10^{-3} \text{ m}^2/\text{fiber})(5760 \text{ fibers}) \\ &= 1780 \text{ L/h} \end{aligned}$$

3. Compare the outside-in and inside-out flow configurations:

$$\text{Ratio} = (3300/1780) \times 100\% = 186\%$$

#### Comment

Operating at the same flux, the outside-in system produces nearly double the product water flow (86 percent more) as the inside-out system. Based on the results presented in this example, membrane systems cannot be compared or specified on the basis of flux if the flow configuration is different (the total flow per module and cost per module would be more important indicators than flux).

to 1 m/s (1.6 to 3.3 ft/s), is parallel to the membrane surface and about four orders of magnitude greater than the superficial velocity of water toward the membrane surface. The velocity parallel to the membrane surface creates a shear force that reduces the development of a surface cake (Wiesner and Chellam, 1992). Because many solids are carried away with the retentate instead of accumulating on the membrane surface, the system can be operated at a higher flux or with longer intervals between backwashes. The retentate is recirculated to the feed water, so cross-flow filtration requires a substantial recirculation flow—the permeate flow is typically less than 25 percent of the feed flow. The recirculation requirements can be prohibitive in a large facility—a 50,000-m<sup>3</sup>/d (13.2-mgd) membrane filtration plant must recirculate 200,000 to 250,000 m<sup>3</sup>/d (53 to 66 mgd) to maintain sufficient cross-flow velocity.

The retentate can be returned directly to the feed line to the membrane modules or to a mixing basin upstream of the modules. In either case, the solids content of the feed water will increase due to the recirculation. Either the feed-and-bleed or the semibatch procedure can be used to control the solids content in the recycle line.

#### **DEAD-END FILTRATION**

Dead-end filtration operates without a cross-flow component to the feed stream. The bulk feed water flow is transverse (perpendicular) to and toward the membrane surface during dead-end filtration, so all solids accumulate on the membrane during the filtration cycle and are removed during the backwash cycle. The greater solids accumulation during the filter run may result in lower average flux values than those achieved with cross-flow filtration.

#### **PRACTICAL CONSIDERATIONS IN WATER TREATMENT**

The dead-end flow regime is most common in membrane filtration for water treatment, in contrast to many industrial applications of microfiltration and ultrafiltration. Many industrial feed streams have high solids concentrations (e.g., the solids concentration in many food-processing operations can be 1 to 30 percent), and cross-flow operation is critical for achieving reasonable flux and filter run length. Surface waters are fairly dilute (many membrane plants operate with feed water turbidity of 100 NTU or less, which corresponds to a solids concentration on the order of 0.01 percent) so the advantages of cross-flow filtration are less significant. In addition, the piping and pumping costs of recirculating a large fraction of the feed water become prohibitive as the facility size gets larger, and water treatment facilities are built with considerably higher capacity than most industrial applications. The electrical costs of cross-flow pumping can triple the operating costs (Glucina et al., 1998) over dead-end operation. Some cross-flow systems are designed to operate in a dead-end mode by

closing a valve in the retentate line when raw-water quality conditions permit (turbidity is low) and switch to a cross-flow mode only when necessary to maintain flux.

### **Comparison to Rapid Granular Filtration**

A comparison between membrane filtration and rapid granular filtration has been presented in Table 12-4. Membrane filtration has several advantages over granular filtration. Effective rapid filtration with granular media, as noted in Chap. 11, depends on properly destabilizing particles with a coagulant to facilitate the attachment process. The void spaces in a membrane filter are much smaller; particles are literally strained from the water so destabilization is not necessary. As a result, membrane filtration plants do not require coagulation, flocculation, and sedimentation facilities for effective particle removal. These differences can reduce requirements for chemical storage and handling and residual-handling facilities and allow membrane plants to be more compact and automated. Furthermore, the more compact installation can result in considerable cost savings in densely populated areas or other areas where land costs are high.

The most significant advantage, however, is that the filtered water turbidity from membrane filters is independent of the concentration of particulate matter in the feed. The effluent from rapid granular filters is not independent of influent quality. Changes in raw-water chemistry without changes in pretreatment (i.e., adjustment of the coagulant dose) can cause the rapid granular filtration process to fail. Rapid granular filtration is sensitive to fluctuations in raw-water quality and the experience of the plant operators.

## 12-4 Properties of Membrane Materials

---

An understanding of the mechanisms that control membrane filtration begins with an understanding of the filtration medium. Important material properties, membrane chemistry, and physical structure are discussed in this section. Although MF and UF membranes are used for similar purposes in water treatment, some of the properties are different.

### **Material Properties**

Membrane performance is affected strongly by the physical and chemical properties of the material. The ideal membrane material is one that can produce a high flux without clogging or fouling and is physically durable, chemically stable, nonbiodegradable, chemically resistant, and inexpensive. Important characteristics of membrane materials, methods of determination, and effects on membrane performance are described in Table 12-6.

One of the important characteristics in Table 12-6 with respect to membrane fouling is hydrophobicity. Hydrophilic materials, which like contact

**Table 12-6**Important properties of membrane materials<sup>a</sup>

<b>Property</b>	<b>Method of Determination</b>	<b>Impact on Membrane Performance</b>
Retention rating (pore size or molecular weight cut-off)	Bubble point, challenge tests	Controls the size of material retained by the membrane, making it one of the most significant parameters in membrane filtration. Also affects head loss.
Hydrophobicity	Contact angle	Reflects the interfacial tension between water and the membrane material. Hydrophobic materials “dislike” water; thus, constituents from the water accumulate at the liquid–solid interface to minimize the interfacial tension between the water and membrane. In general, hydrophobic materials will be more susceptible to fouling than hydrophilic materials.
Surface or pore charge	Streaming potential	Reflects the electrostatic charge at the membrane surface. Repulsive forces between negatively charged species in solution and negatively charged membrane surfaces can reduce fouling by minimizing contact between the membrane and fouling species. In UF, electrostatic repulsion can reduce the passage of like-charged solutes. Membranes fabricated of uncharged polymers typically acquire some negative charge while in operation.
Surface roughness	Atomic force microscopy	Affects membrane fouling; some studies have shown rough materials will foul more than smooth materials.
Porosity (surface and bulk)	Thickness/weight measurements	Affects the head loss through the membrane; higher porosity results in lower head loss.
Thickness	Thickness gauge, electron microscopy	Affects the head loss through the membrane; thinner membranes have lower head loss.
Surface chemistry	ATR/FTIR, SIMS, XPS	Affects fouling and cleaning by influencing chemical interactions between the membrane surfaces and constituents in the feed water.
Chemical and thermal stability	Exposure to chemicals and temperature extremes	Affects the longevity of the membrane; greater chemical and temperature tolerance allows more aggressive cleaning regimes with less degradation of the material.
Biological stability	Exposure to organisms	Affects the longevity of the membrane; low biological stability can result in the colonization and physical degradation of the membrane material by microorganisms.

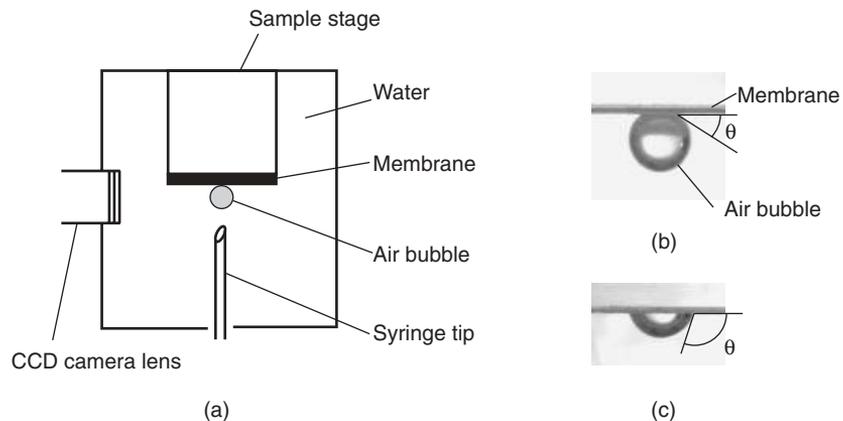

*(continues)*

Table 12-6 (Continued)

Property	Method of Determination	Impact on Membrane Performance
Chlorine/oxidant tolerance	Exposure to chlorine/oxidants	Affects the ability to disinfect the membrane equipment. Routine disinfection prevents microbial growth on the permeate side of membrane surfaces and prevents biological degradation of membrane materials (increasing the longevity of the membrane).
Mechanical durability	Mechanical tests	Affects the ability of the material to withstand surges due to operation of valves and pumps.
Internal physical structure, tortuosity	Electron microscopy	Affects the hydrodynamics of flow and particle capture. There are no standard procedures for quantifying the tortuosity or internal structure of membranes.
Cost	Material cost	Affects the cost of the membrane system.

<sup>a</sup>Abbreviations: ATR/FTIR = attenuated total reflectance/Fourier transform infrared spectrometry, SIMS = secondary ion mass spectrometry, XPS = X-ray photoelectron spectrometry.

with water, tend to have low fouling tendencies, whereas hydrophobic materials may foul extensively. Hydrophobicity is quantified by contact angle measurements, in which a droplet of water or bubble of air is placed against a membrane surface, and the angle between the surface and water or air is measured. Hydrophobic surfaces have a high contact angle (the water beads like on a freshly waxed car), whereas hydrophilic surfaces have a low contact angle (the water droplets spread out). Techniques for measuring contact angle are demonstrated on Fig. 12-11. Contact angle measurements vary widely because of differences in measurement techniques and variables such as surface roughness but typically range from about  $40^\circ$  to  $50^\circ$  for cellulose acetate to about  $110^\circ$  for polypropylene (Cheryan, 1998).

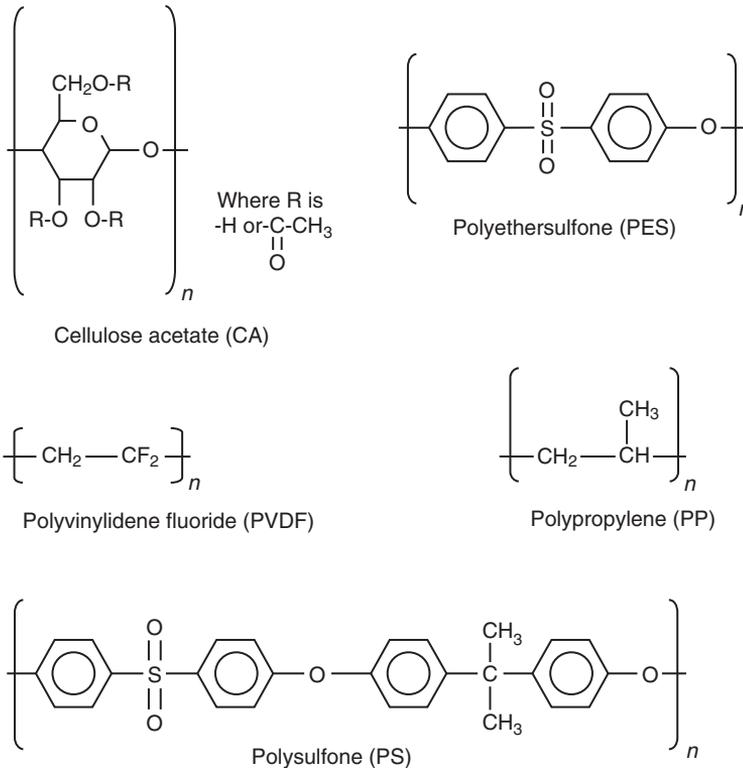

**Figure 12-11**  
Captive bubble contact angle measurements for determination of hydrophobicity: (a) contact angle measurement apparatus, (b) hydrophilic surface (low contact angle), and (c) hydrophobic surface (high contact angle).

Hydrophobicity is affected strongly by the chemical composition of the polymer comprising the material. Polymers that have ionized functional groups, polar groups (water is very polar), or oxygen-containing and hydroxyl groups (for hydrogen bonding) tend to be very hydrophilic. Unfortunately, chemical properties that improve hydrophilicity tend to reduce the chemical, mechanical, and thermal stability because water molecules act as plasticizers for hydrophilic materials (Anselme and Jacobs, 1996).

Lacking the existence of a perfect material, a variety of materials have been used. The two most common materials in early commercial membrane filtration systems were cellulose acetate (CA) and polypropylene (PP), but their use has been declining. The most common polymeric materials currently used in water treatment are polyvinylidene fluoride (PVDF), polysulfone (PS), and polyethersulfone (PES). Ceramic membrane may also be gaining in popularity. Some membrane manufacturers consider the composition of their membranes to be proprietary and do not release information on their material chemistry. The chemical structure of these polymers is shown on Fig. 12-12 and important properties are given in Table 12-7.

## Material Chemistry

**Figure 12-12**  
Chemical structure of common polymeric MF and UF membrane materials.

**Table 12-7**

Characteristics of common membrane materials

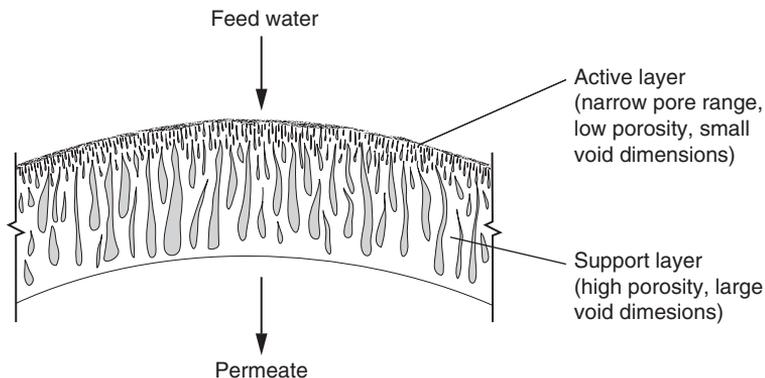

Membrane Material	Characteristics
Cellulose acetate (CA)	CA is the most hydrophilic of common industrial-grade membrane materials, which helps to minimize fouling and maintain high flux values. The material is easy to manufacture, inexpensive, and available in a wide range of pore sizes. Has been losing favor for membrane filters because of higher susceptibility to biological degradation, lack of tolerance to continuous exposure or high concentrations of free chlorine, gradual decline in the flux over its lifetime due to compaction, and lack of tolerance to aggressive cleaning chemicals or temperatures above 30°C.
Polysulfone (PS)/ polyethersulfone (PES)	PS and PES are moderately hydrophobic and have excellent chemical tolerance and biological resistance. They can withstand free chlorine contact to 200 mg/L for short periods of time for cleaning, pH values between 1 and 13, and temperatures to 75°C. Aggressive cleaning and disinfecting is possible.
Polyvinylidene fluoride (PVDF)	PVDF is moderately hydrophobic and has excellent durability, chemical tolerance, and biological resistance. It can withstand continuous free chlorine contact to any concentration, pH values between 2 and 10, and temperatures to 75°C. Aggressive cleaning and disinfecting is possible.
Polypropylene (PP)	PP is the most hydrophobic of common industrial-grade membrane materials. Only MF membranes are available in PP; the material is too hydrophobic to allow water to pass through the small pore spaces in UF membranes. It is durable, chemically and biologically resistant, and tolerant of moderately high temperatures and pH values between 1 and 13, which allows aggressive cleaning. It has been losing favor for membrane filters because it is not tolerant to chlorine, which hinders the ability to control biological growth.
Ceramic	Ceramic membranes are configured as rigid monolithic elements. The material is hydrophilic, rough, and can withstand high operating pressure and temperature. They have excellent chemical and pH tolerance. Aggressive cleaning and disinfecting is possible.

**Membrane  
Structure**

The structure, porosity, and transport properties of most MF membranes are relatively constant throughout their depth (this structure is called homogeneous). Theoretically, homogeneous membranes perform identically regardless of which direction filtration is proceeding. In contrast, UF membranes have an asymmetric (also called anisotropic or “skinned”) structure, which means that the morphology varies significantly across the depth of the membrane. A homogeneous membrane was shown on Fig. 12-4a, and the structure of an asymmetric membrane, consisting of an active layer and a support layer, is shown on Fig. 12-13. The active and support layers have separate functions.

Filtration occurs at the active layer in asymmetric membranes, which is a thin skin with low porosity and very small void spaces. The low porosity and small pores generate significant resistance to flow, which must be minimized by making the active layer as thin as possible. The active layer is so thin that it has no mechanical durability. Thus, the remainder of the membrane is a highly porous layer that provides support but produces very little hydraulic resistance. The support layer accounts for the majority of the membrane thickness. Asymmetric membranes allow the filtration and mechanical properties to be designed separately. Filtration through an asymmetric membrane is not the same in both directions. Filtration in the “wrong” direction would cause the voids in the support layer to become clogged and may cause the active layer to separate from the rest of the membrane. To prevent clogging, some commercial asymmetric membranes have active layers on both surfaces of the membrane with a support layer sandwiched between the two active layers.

Microfiltration and UF membranes have different porosities. The porosity of MF membranes varies widely, and values ranging from 30 to 90 percent have been reported. Theoretically, the porosity of homogeneous membranes should be constant throughout the depth of the membrane.

**Figure 12-13**  
Structure of an asymmetric UF  
membrane.

The porosity of the active layer of UF membranes is low and ranges from 0.5 to 10 percent, whereas the porosity in the support structure is considerably higher (50 to 90 percent).

## 12-5 Particle Capture in Membrane Filtration

---

For regulatory purposes in the United States, membrane filtration is defined as “a pressure or vacuum driven separation process in which particulate matter larger than 1  $\mu\text{m}$  is rejected by an engineered barrier primarily through a size exclusion mechanism and which has a measurable removal efficiency of a target organism that can be verified through the application of a direct integrity test” (U.S. EPA, 2006, p. 702). The principles by which membranes are rated, particles are captured, and performance is demonstrated is discussed in this section.

### Retention Rating

One of the most significant parameters in membrane filtration is the size of material retained. Microfiltration and UF membranes are currently rated with different systems, making them difficult to compare. The retention rating of MF membranes is based on the diameter of material that is retained by the membrane; for example, a 0.2- $\mu\text{m}$  MF membrane should hypothetically retain 100 percent of 0.2- $\mu\text{m}$ -diameter particles. The MF retention rating is frequently called the nominal pore diameter or pore size throughout the membrane industry, but those terms are misnomers. As was shown on Fig. 12-3, the “pores” in MF membranes are tortuous voids with a wide size distribution, not cylindrical holes of a particular diameter. It is generally accepted that the average void space dimension is somewhat larger than the membrane retention rating (Cheryan, 1998). The pore size value is a nominal rating, so some particles smaller than the pore size can be retained and some particles larger may be able to penetrate the membrane. The retention rating for MF membranes used in water treatment is typically between 0.1 and 1  $\mu\text{m}$ . Membranes with retention ratings in this range will completely retain bacteria and protozoan structures such as *Giardia lamblia* cysts and *Cryptosporidium parvum* oocysts. Because of their small size, viruses may not be completely retained by MF membranes.

Membrane manufacturers use two approaches for defining the retention rating of UF membranes. Some manufacturers use a pore size rating similar to MF membranes, with pore sizes of 0.01 to 0.04  $\mu\text{m}$  being common. For others, the retention rating for UF membranes is based on the molecular weight of material retained by the membrane and is called the molecular weight cutoff (MWCO) or nominal molecular weight limit (NMWL). The first applications of UF membranes were for fractionating macromolecules, so the original focus for classifying UF membranes was on molecular weight rather than size. Membrane filtration for water treatment, however, is principally concerned with retaining materials of a particular

size, such as viruses, which can be as small as 0.025  $\mu\text{m}$ . Unfortunately, the diameter of solids retained by a UF membrane is only loosely related to the MWCO value and depends on various physical and chemical properties (shape, electrostatic charge, etc.) of the solid. The standard procedure for determining the MWCO value of a UF membrane involves filtration of dextran solutions with varying average molecular weights (ASTM, 2001c). Dextran is a branched polysaccharide that might be expected to have substantially different physical and chemical properties from viruses or other particles. In addition, the MWCO of UF membranes is based on the molecular weight at 90 percent rejection. The difference between the rating of MF and UF membranes is shown on Fig. 12-14.

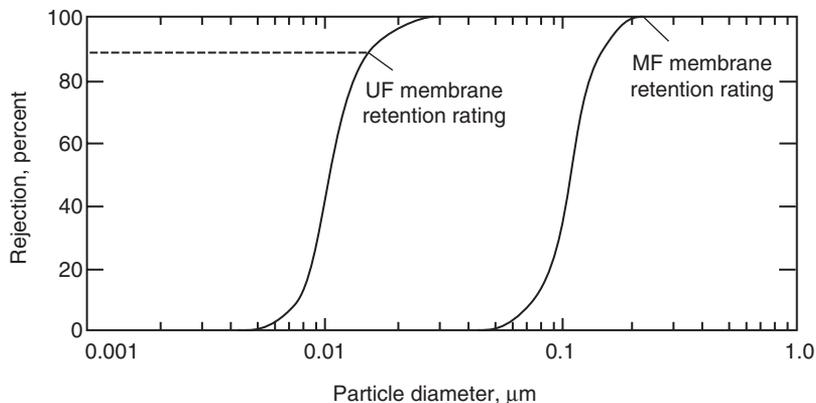

The hydrodynamic diameter of molecules can be roughly estimated from the molecular weight. For instance, data in Ioan et al. (2000) suggest the following empirical relationship between the hydrodynamic diameter and molecular weight of dextran:

$$d_H = 0.11 (\text{MW})^{0.46} \quad (12-2)$$

where  $d_H$  = hydrodynamic diameter of dextran molecule, nm  
 MW = molecular weight, g/mol

Researchers have attempted to use relationships such as Eq. 12-2 to estimate the pore size of UF membranes. In addition, analytical techniques such as electron microscopy, atomic force microscopy, thermoporometry, and biliquid permoporometry have been used to estimate the pore size of UF membranes (Kim et al., 1994).

The MWCO for UF membranes range from about 1000 daltons (Da) to about 500,000 Da. These MWCO values correspond to an ability to retain particles ranging from about 1 to 30 nm in diameter (Cheryan, 1998). Comparing these values to the size of viruses, it is clear that some UF membranes can completely retain viruses but others may not, depending

**Figure 12-14**  
 Determination of retention ratings for MF and UF membranes.

on the MWCO. Studies have shown, for instance, greater than 7-log removal of MS2 bacteriophage (a model virus) with a 100,000-Da UF membrane but less than 1-log removal with a 500,000-Da UF membrane (Jacangelo et al., 1995).

It should be noted that there is overlap between the size of pores of MF and UF membranes, and there are no standard specifications that classifies a particular product as one or the other. Often, the classification of a particular product as an MF or UF membrane depends on the marketing strategy of the manufacturer and whether the retention rating was measured as a pore size or MWCO. Furthermore, classification as an MF or UF membrane does not guarantee a particular level of removal efficiency for specific pathogen organisms. For that, challenge testing is required, as described later in this section.

### Rejection and Log Removal

The fraction of material removed from the permeate stream is called rejection:

$$R = 1 - \frac{C_p}{C_f} \quad (12-3)$$

where  $R$  = rejection, dimensionless

$C_p$  = permeate concentration, mol/L or mg/L

$C_f$  = feed water concentration, mol/L or mg/L

Rejection can be calculated for bulk measures of particulate matter (e.g., turbidity, particle counts) or individual components of interest (e.g., *Cryptosporidium* oocysts). In membrane filtration, the concentration of some components in the permeate can be several orders of magnitude lower than in the feed. Many significant figures must be retained to quantify rejection if Eq. 12-3 is used. In these cases, the log removal value (LRV) (see Sec. 4-5) is used:

$$\text{LRV} = \log(C_f) - \log(C_p) = \log\left(\frac{C_f}{C_p}\right) \quad (12-4)$$

A comparison of the calculation of rejection and log removal value is demonstrated in Example 12-2.

### Filtration Mechanisms

The primary mechanism for removing particles from solution in membrane filtration is straining, but removal is also affected by adsorption and cake formation. These removal mechanisms are depicted on Fig. 12-15.

#### STRAINING

Straining (also called sieving or steric exclusion) is the dominant filtration mechanism in membrane filtration. Nominally, particles larger than the retention rating of the membrane collect at the surface while water and

### Example 12-2 Calculation of rejection and log removal value

During testing of a prototype membrane filter, bacteriophage concentrations of  $10^7 \text{ mL}^{-1}$  and  $13 \text{ mL}^{-1}$  were measured in the influent and effluent, respectively. Calculate the rejection and log removal value.

#### Solution

1. Calculate rejection using Eq. 12-3:

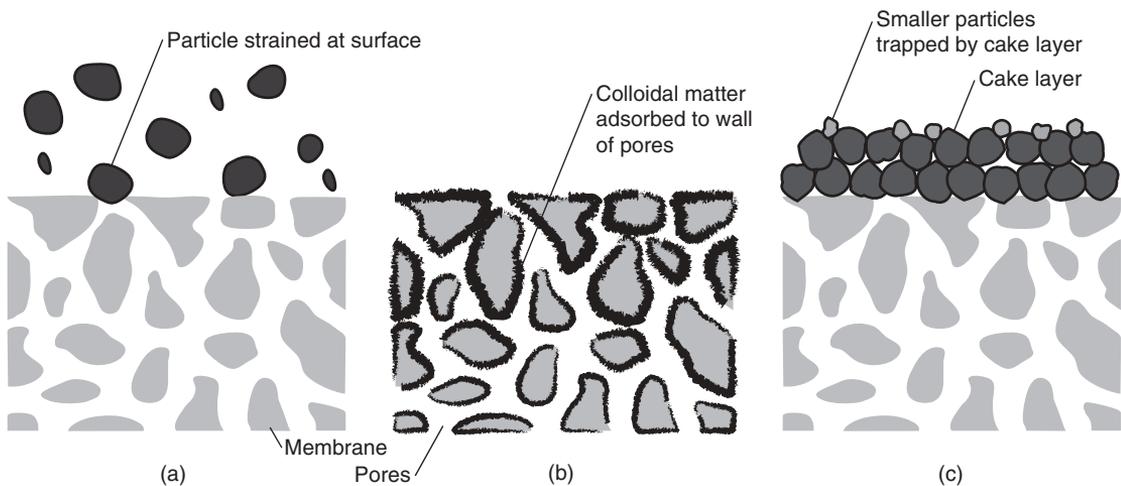

$$R = 1 - \frac{C_p}{C_f} = 1 - \frac{13 \text{ mL}^{-1}}{10^7 \text{ mL}^{-1}} = 0.9999987$$

2. Calculate log removal value using Eq. 12-4:

$$\text{LRV} = \log \left( \frac{C_f}{C_p} \right) = \log \left( \frac{10^7 \text{ mL}^{-1}}{13 \text{ mL}^{-1}} \right) = 5.89$$

#### Comment

Note that seven significant digits are necessary to express rejection adequately in arithmetic units, but only three significant digits are necessary to express log removal value for this example. Also note that  $\text{LRV} = 5$  corresponds to 99.999 percent and  $\text{LRV} = 6$  corresponds to 99.9999 percent rejection (i.e., the log removal value equals the “number of 9’s”).

**Figure 12-15**

Mechanisms for rejection in membrane filtration. (a) Straining occurs when particles are physically retained because they are larger than the pores. (b) Adsorption occurs when material small enough to enter pores adsorbs to the walls of the pores. (c) Cake filtration occurs when particles that are small enough to pass through the membrane are retained by a cake of larger material that collects at the membrane surface.

smaller particles pass through. This view, however, suggests that the relationship between particle size and retention rating is a step function, with  $R = 100\%$  for all particles larger than the retention rating and  $R = 0\%$  for all smaller particles. As shown on Fig. 12-14, particle removal is not a simple step function at the retention rating. This nonideal performance occurs when the particle size is close to the membrane retention rating and is caused by the variability of pore size dimensions, nonspherical shape of the particles, and other interactions such as electrostatic repulsion.

As is evident from Fig. 12-3c, the tortuous interconnecting voids in membrane filters have a distribution of sizes, including some larger than the retention rating. Thus, particles smaller than the retention rating may be trapped in smaller passageways, and larger particles may pass through the membrane in other areas. The existence of larger void spaces is particularly important when high rejection values are required.

A second source of nonideal rejection arises from particle dimensions. Particles in natural systems can have shape characteristics significantly different from the materials used to determine the retention rating. Rod-shaped bacteria and linear macromolecules may be very long in one dimension and considerably smaller in others and may not be adequately described by an average diameter. Rod-shaped bacteria near the retention rating of the membrane may or may not be rejected depending on orientation when they approach the membrane. Some small particles, particularly large proteins or other macromolecules, may be flexible, assuming a spherical shape when in solution but becoming more linear when forced through a membrane under pressure. Thus, particles that appear to be slightly larger than the retention rating may pass through the membrane.

Interactions between particles and the membrane can affect rejection when the particle size is close to the membrane retention rating. Typically, both particles and membrane surfaces are negatively charged. Electrostatic interactions may prevent the particles from entering the pores even if the physical size would permit passage. Ferry (1936) reported nonideal behavior even under near-ideal filtration conditions (filtration of a monodisperse dispersion through a track-etched membrane with uniform cylindrical pores).

#### **ADSORPTION**

Natural organic matter adsorbs to membrane surfaces (Jucker and Clark, 1994). Thus, soluble materials may be rejected even though their physical dimensions are orders of magnitude smaller than the membrane retention rating. Adsorption may be an important rejection mechanism during the early stages of filtration with a clean membrane. The adsorption capacity is quickly exhausted, however, and adsorption is not an effective mechanism in long-term operation of membrane filters. Nevertheless, adsorption has a profound impact on membrane operations. Adsorbed material can reduce the size of voids throughout the membrane, increasing the ability of the

membrane to retain smaller material by straining. In addition, adsorption has been implicated as a prime cause of membrane fouling by NOM.

#### CAKE FORMATION

During filtration, a clean membrane will quickly accumulate a cake of solids at the surface due to straining. This surface cake acts as a filtration medium, providing another mechanism for rejection. The surface cake is often called a “dynamic” membrane, because its filtering capability varies with time, growing in thickness during filtration but being partially or wholly removed during backwashing. Mathematical modeling of cake filtration is similar to granular filtration, and equations such as the Kozeny equation (see Chap. 11) are used to calculate the additional resistance to flow resulting from the formation of surface cakes.

The principal microorganisms of concern in water treatment are (1) protozoa and helminths, (2) bacteria, and (3) viruses. The removal of each of these is considered below.

### Removal of Microorganisms

#### REMOVAL OF PROTOZOA AND HELMINTHS

*Giardia lamblia* cysts and *C. parvum* oocysts, which are highly resistant to chemical disinfectants, are at least 10 times larger than the retention ratings of MF and UF membranes. Rejection of greater than 7 log has been observed for both MF and UF membranes (Jacangelo et al., 1991, 1995), as would be expected due to straining. Indeed, reported rejection values are limited only by the influent concentration of organisms. For instance, if  $10^6$  cysts/L are measured in the feed and the detection limit in the permeate is 1 cyst/L, the calculated log removal value is  $LRV \geq 6$ .

#### REMOVAL OF BACTERIA

Bacteria range in size from 0.1 to 100  $\mu\text{m}$  (Madigan et al., 1997). Being considerably larger than the retention rating, complete rejection via straining is expected for UF membranes. In addition, most species of bacteria should be rejected completely by MF membranes through straining. In many studies, bacteria are removed to below the detection limit; in some cases, rejection was higher than 8 log (U.S. EPA, 2001). In other studies, reported rejection was lower because of contamination and regrowth interferences. Some bacterial species are near the retention ratings of MF membranes. In these cases, lower rejection may be possible due to the factors mentioned earlier.

#### REMOVAL OF VIRUSES

The smallest viruses have a diameter of about 25 nm. At this size, viruses are considerably smaller than the retention rating of MF membranes and are similar to that of UF membranes. For MF membranes, straining, adsorption,

and cake filtration all contribute to rejection, and virus rejection can vary from  $LRV < 1$  to  $LRV > 4$ . Madaeni et al. (1995) studied poliovirus rejection by 0.2- $\mu\text{m}$  MF membranes and found complete rejection ( $LRV \geq 4.5$ ) during the first 15 min of filtration, but rejection quickly dropped to  $LRV = 1.31$  after 30 min of filtration and gradually rose to  $LRV = 1.71$  during the next 5 h. Adsorption appears to be significant in initial rejection, but the adsorption capacity was quickly exhausted. After 30 min, rejection may have been due to straining through small void spaces or continued adsorption. The gradual increase in rejection over time suggests that straining was increasing as the pores became more restricted with previously deposited virus particles. Jacangelo et al. (1995) also observed a gradual increase in virus rejection that correlated with a decrease in specific flux over a period of 45 days. Fouling caused a reduction in the pore diameter or formation of a surface cake that was able to increase virus rejection. Cake filtration also plays an important role in virus rejection by MF membranes. Preloading an MF membrane with kaolinite clay (Jacangelo et al., 1995) and increasing the turbidity of the feed water (Madaeni et al., 1995) result in higher rejection of viruses. Increased rejection of viruses with higher turbidity may also be due to attachment of the viruses to the particle prior to filtration.

Ultrafiltration membranes with low MWCO ratings may be able to achieve complete rejection of viruses, but UF membranes with higher MWCO ratings might not. It was noted earlier that the pore size of UF membranes may range from 1 to 30 nm depending on the MWCO. Jacangelo et al. (1995) found complete rejection ( $LRV > 7.2$ ) of MS2 bacteriophage, a model virus with a diameter of about 25 nm, with a 100,000-Da UF membrane but  $LRV < 1$  with a 500,000-Da UF membrane.

The overall implication for water treatment is that straining is only effective for particles significantly larger than the retention rating of the membrane. Cake filtration and adsorption may provide added rejection of smaller material, but are not considered effective removal mechanisms from a regulatory point of view. Thus, MF membranes should not be relied upon for complete removal of viruses (although some removal credit may be warranted), and poor selection of UF membranes may also provide insufficient removal for viruses. To validate the ability of MF and UF membranes to remove specific microorganisms, challenge testing is performed.

### Challenge Testing

Challenge testing is a process in which the ability of a membrane product to remove specific target organisms is determined in carefully controlled tests. Specific requirements in the Long Term 2 Enhanced Surface Water Treatment Rule (LT2ESWTR) (U.S. EPA, 2005) are focused on challenge testing for *Cryptosporidium* removal efficiency, but the general methods could be used for other microbial contaminants such as viruses, bacteria, or other protozoa. Challenge tests establish the maximum removal credit

allowed for a particular product. Once performance has been verified, site-specific testing by utilities is not required. The LT2ESWTR requires that the modules tested be similar in design, materials, and construction to full-scale modules, although the test modules do not necessarily need to be full size. The number of modules testing should be determined on a scientifically defensible basis to provide results that take manufacturing variability into account. Operating conditions representative of full-scale operation, such as maximum flux and recovery are necessary. The target microorganisms or particles should be measured directly and not inferred from a surrogate like turbidity. The concentration of particles in the feed water should be 6.5 log units higher than the detection limit in the permeate water to ensure that high removal efficiency can be demonstrated. Finally, nondestructive performance tests (NDPT) (such as bubble point or pressure decay tests, discussed later) should be performed at the same time, so that the NDPT can be performed on modules after manufacture and related to the results of the challenge testing.

## 12-6 Hydraulics of Flow through Membrane Filters

---

The flow of water through MF and UF membranes follows the fundamental law for flow through porous media known as Darcy's law:

$$v = k_p \frac{h_L}{L} \quad (12-5)$$

where  $v$  = superficial fluid velocity, m/s  
 $k_p$  = hydraulic permeability coefficient, m/s  
 $h_L$  = head loss across porous media, m  
 $L$  = thickness of porous media, m

The hydraulic permeability coefficient in Darcy's law is an empirical parameter that is used to describe the proportionality between head loss and fluid velocity and is dependent on media characteristics such as porosity and specific surface area. Although flow through membranes follows Darcy's law, the standard equation for membrane flow is written in a substantially different form. Flow is expressed in terms of volumetric flux  $J$  rather than superficial velocity, the driving force is expressed as transmembrane pressure  $\Delta P$  rather than head loss (which are related by  $\Delta P = \rho_w g h_L$ ), and media characteristics are expressed as a resistance coefficient (the inverse of a permeability coefficient). In addition, the membrane flow equation includes the fluid viscosity explicitly (Darcy's law buries it in the permeability coefficient) because viscosity has a significant impact on flux and is easy to determine (via temperature). Finally, the membrane flux equation

incorporates the membrane thickness into the resistance coefficient. The equation for membrane flux is

$$J = \frac{Q}{a} = \frac{\Delta P}{\mu \kappa_m} \quad (12-6)$$

where  $J$  = volumetric water flux through membrane,  $L/m^2 \cdot h$  or  $m/s$

$Q$  = flow rate,  $L/h$

$a$  = membrane area,  $m^2$

$\Delta P$  = differential pressure across membrane, bar

$\mu$  = dynamic viscosity of water,  $kg/m \cdot s$

$\kappa_m$  = membrane resistance coefficient,  $m^{-1}$

The membrane resistance coefficient can be calculated from laboratory experiments so that flux through a new membrane can be determined for other pressure or temperature conditions.

The linear relationship between flux and pressure in Eq. 12-6 suggests that the flux can be maximized by operating at the highest possible transmembrane pressure. While this relationship may be true for deionized water, high-pressure operation may not be preferable during filtration of natural waters. Fouling can be exacerbated by high-pressure operation (Cheryan, 1998), so a balance must be struck between flux and fouling. Fouling will be presented in detail later in this chapter.

Ideally, it would be desirable to calculate flux from measurable parameters that describe the internal structure of MF and UF membranes, such as porosity, nominal pore diameter, specific surface area, and membrane thickness, as is done for clean-bed head loss in granular filtration. These parameters, however, are difficult to measure, and the amorphous internal structure of MF and UF membranes (refer to Fig. 12-3c) cannot be described mathematically with any great accuracy. In addition, it will be shown later in this chapter that the volumetric flux through a full-scale membrane filter is influenced more by fouling than by the intrinsic clean-membrane resistance. As a result, currently no reliable models allow flux to be calculated from easily measurable fundamental parameters. To account for membrane fouling, Eq. 12-6 can be extended by adding additional resistance terms in the denominator, as will be presented later in the chapter. Calculation of the membrane resistance coefficient is demonstrated in Example 12-3.

### Temperature and Pressure Dependence

During operation, changes in permeate flux due to fouling are monitored to determine when cleaning is necessary. Because flux is dependent on pressure and water viscosity (see Eq. 12-6), determination of the extent of fouling is confounded by simultaneous changes in pressure and temperature (which changes viscosity). In temperate climates, water temperatures can vary by more than  $20^\circ C$  between summer and winter. Due to the

### Example 12-3 Calculation of membrane resistance coefficient

An MF membrane is tested in a laboratory by filtering clean, deionized water and the flux is found to be  $850 \text{ L/m}^2 \cdot \text{h}$  at  $20^\circ\text{C}$  and  $0.9 \text{ bar}$ . Calculate the membrane resistance coefficient.

#### Solution

Rearrange Eq. 12-6 to solve for the membrane resistance coefficient. The dynamic viscosity of water at  $20^\circ\text{C}$ , from Table C-1 in App. C, is  $1.00 \times 10^{-3} \text{ kg/m} \cdot \text{s}$ . Also recall that  $1 \text{ bar} = 100 \text{ kPa} = 10^5 \text{ N/m}^2 = 10^5 \text{ kg/s}^2 \cdot \text{m}$ .

$$\begin{aligned} \kappa_m &= \frac{\Delta P}{\mu J} = \frac{(0.9 \times 10^5 \text{ kg/s}^2 \cdot \text{m})(3600 \text{ s/h})(10^3 \text{ L/m}^3)}{(1.00 \times 10^{-3} \text{ kg/m} \cdot \text{s})(850 \text{ L/m}^2 \cdot \text{h})} \\ &= 3.81 \times 10^{11} \text{ m}^{-1} \end{aligned}$$

temperature dependence of water viscosity, the flux through a membrane can be 70 percent higher in the summer than in the winter. Temperature variations are usually accommodated by calculating the equivalent flux at a standard temperature:

$$J_s = J_m \left( \frac{\mu_m}{\mu_s} \right) \quad (12-7)$$

where  $J_m$  = flux at measured temperature,  $\text{L/m}^2 \cdot \text{h}$

$J_s$  = flux at standard temperature (typically  $20^\circ\text{C}$ ),  $\text{L/m}^2 \cdot \text{h}$

$\mu_m$  = dynamic viscosity of water at measured temperature,  $\text{kg/m} \cdot \text{s}$

$\mu_s$  = dynamic viscosity of water at standard temperature,  $\text{kg/m} \cdot \text{s}$

The dynamic viscosity can be obtained from tabular data or calculated from one of a variety of expressions that relate the viscosity of water to temperature. A relationship often used in membrane operations is (ASTM, 2001a)

$$J_s = J_m (1.03)^{T_s - T_m} \quad (12-8)$$

where  $T_m$  = measured temperature,  $^\circ\text{C}$

$T_s$  = standard temperature,  $^\circ\text{C}$

When using a standard temperature of  $20^\circ\text{C}$ , Eq. 12-8 is accurate to within 5 percent over a temperature range of 1 to  $28^\circ\text{C}$ , which covers most natural waters. At temperatures above  $28^\circ\text{C}$ , Eq. 12-8 becomes increasingly inaccurate and a more rigorous expression should be used.

The factor in Eq. 12-8 accounts only for the effect of water viscosity. Temperature may also have an effect on the membrane material, such as swelling of the material at higher temperature. Some manufacturers have developed temperature correction formulas that account for changes in both the water viscosity and material properties. Manufacturer or site-specific correction equations should be used, if available.

Flux is normalized for pressure by calculating specific flux, which is the flux at a standard temperature divided by the transmembrane pressure:

$$J_{sp} = \frac{J_s}{\Delta P} \quad (12-9)$$

where  $J_{sp}$  = specific flux at standard temperature,  $L/m^2 \cdot h \cdot bar$

The specific flux is called membrane permeability when clean water (reagent-grade water, typically deionized to a resistivity of  $>10 M\Omega \cdot cm$  and  $DOC < 0.2 mg/L$ ) is being filtered through a new, unused membrane. Membrane permeability is measured in laboratory experiments but rarely or never determined in full-scale installations because a large supply of deionized water is not available. Specific flux and membrane permeability are typically reported in units of  $L/m^2 \cdot h \cdot bar$  or  $gal/ft^2 \cdot d \cdot atm$ .

When flux has been normalized to account for temperature and pressure variations, the effect of fouling can be determined, as illustrated in Example 12-4.

## 12-7 Membrane Fouling

---

Fouling is widely perceived to be the most significant issue affecting the design and operation of membrane filtration facilities (AWWA, 1992, 1998, 2005a). The results of a laboratory experiment of natural water filtration through a membrane are shown on Fig. 12-16. In this experiment, the membrane lost about half of its flow capacity in just a few hours. The individual steep trend lines represent individual 30-min filter runs. Backwash after each filter run recovers most of the lost flux as solids are flushed from the membrane surface; however, not all of the flux is recovered and a longer-term decline in performance is also evident. Fouling can be more dramatic in laboratory tests conducted at constant pressure (as this experiment was), but the overall trends shown in Fig. 12-16 are routinely observed in full-scale operating membrane filtration facilities. Fouling is characterized by the mechanism (pore blockage, pore constriction, and cake formation), by whether it can be removed (i.e., reversible or irreversible), and by the material causing it (particles, biofouling, and natural organic matter). This section examines each of these views of membrane fouling, followed by an introduction of several ways to model fouling.

### Example 12-4 Calculation of specific flux

A membrane plant has a measured flux in March of  $80 \text{ L/m}^2 \cdot \text{h}$  at  $0.67 \text{ bar}$  and  $7^\circ\text{C}$ . Four months later, in July, the measured flux is  $85 \text{ L/m}^2 \cdot \text{h}$  at  $0.52 \text{ bar}$  and  $19^\circ\text{C}$ . Has a change in specific flux occurred? What is the change in percent? Has fouling occurred?

#### Solution

1. Calculate the specific flux in March.
  - a. Calculate the flux in March at a standard temperature of  $20^\circ\text{C}$  using Eq. 12-8:

$$\begin{aligned} J_s &= J_m(1.03)^{T_s - T_m} = (80 \text{ L/m}^2 \cdot \text{h})(1.03)^{20^\circ\text{C} - 7^\circ\text{C}} \\ &= 117 \text{ L/m}^2 \cdot \text{h} \end{aligned}$$

- b. Calculate the specific flux in March using Eq. 12-9:

$$J_{sp} = \frac{J_s}{\Delta P} = \frac{117 \text{ L/m}^2 \cdot \text{h}}{0.67 \text{ bar}} = 175 \text{ L/m}^2 \cdot \text{h} \cdot \text{bar}$$

2. Calculate the specific flux in July.
  - a. Calculate the flux in July at a standard temperature of  $20^\circ\text{C}$  using Eq. 12-8:

$$\begin{aligned} J_s &= J_m(1.03)^{T_s - T_m} = (85 \text{ L/m}^2 \cdot \text{h})(1.03)^{20^\circ\text{C} - 19^\circ\text{C}} \\ &= 87.6 \text{ L/m}^2 \cdot \text{h} \end{aligned}$$

- b. Calculate the specific flux in July using Eq. 12-9:

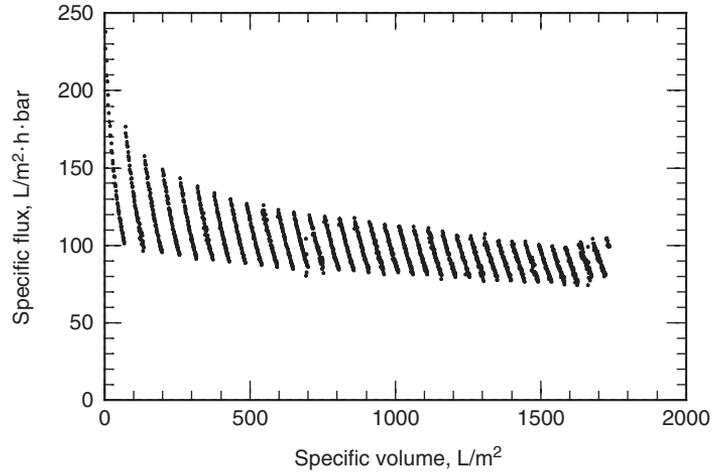

$$J_{sp} = \frac{J_s}{\Delta P} = \frac{87.6 \text{ L/m}^2 \cdot \text{h}}{0.52 \text{ bar}} = 168 \text{ L/m}^2 \cdot \text{h} \cdot \text{bar}$$

3. Calculate the percent loss of performance due to fouling:

$$\begin{aligned} &\frac{175 \text{ L/m}^2 \cdot \text{h} \cdot \text{bar} - 168 \text{ L/m}^2 \cdot \text{h} \cdot \text{bar}}{175 \text{ L/m}^2 \cdot \text{h} \cdot \text{bar}} \times 100 \\ &= 4\% \text{ loss of flux due to fouling} \end{aligned}$$

#### Comment

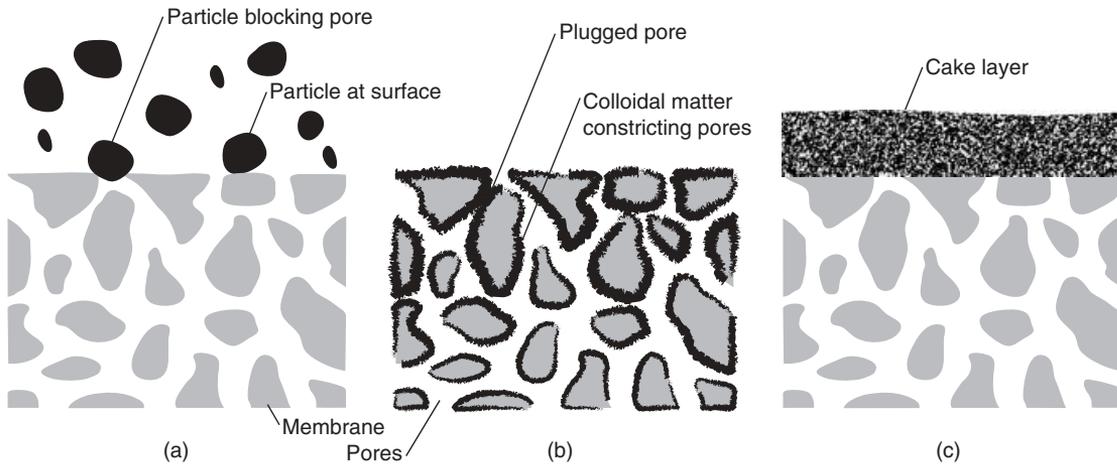

The specific flux at  $20^\circ\text{C}$  has declined from  $175$  to  $168 \text{ L/m}^2 \cdot \text{h} \cdot \text{bar}$ . Thus, although the plant is operating at a higher flux with a lower pressure in July than it was in March, there has been a 4 percent loss of performance due to fouling.

**Figure 12-16**  
Fouling of a membrane filter during filtration of natural water.

### Mechanisms of Fouling

Membrane fouling is traditionally visualized as occurring through three mechanisms—pore blocking, pore constriction, and cake formation—as shown on Fig. 12-17. The similarity between these mechanisms and the mechanisms for particle retention on Fig 12-15 should be evident. Pore blocking occurs when the entrance to a pore is completely sealed by a particle. For this mechanism, the membrane is viewed as a plate with orifices in it, and hydraulic resistance to flow is proportional to the net area of open pores. As a portion of the pore area is blocked at the surface, flow declines by a commensurate amount. While this mechanism may

**Figure 12-17**  
Mechanisms for fouling in membrane filtration: (a) Pore blocking, (b) pore constriction, and (c) cake layer formation.

be relevant on a track-etched membrane (see Table 12-3), it might have minimal significance in the fouling of commercial membranes for water treatment. As shown on Fig. 12-3, commercial membranes have a depth of tortuous interconnecting voids with a flow path much longer than the pore width. Since typical membrane thickness ranges from 0.1 to 0.6 mm and the pore width is 0.01 to 0.1  $\mu\text{m}$ , the pores are 1000 to 10,000 times longer than they are wide. Hydraulic resistance occurs throughout this depth, and the interconnectedness of the pores would allow flow to redistribute within the membrane matrix if a portion of the pores were plugged at the surface.

Pore constriction is the reduction of the void volume within a membrane due to adsorption of materials within the pores. Several essential elements must take place for pore constriction to occur. First, the materials must be smaller than the pore size of the membrane so they can penetrate into the membrane matrix instead of being sieved at the surface. Second, they must be transported to the pore walls either by diffusion or hydrodynamic conditions. Although the residence time through the membrane is short (less than 0.5 s), the characteristic diffusion time of a colloid to a pore wall is about 4 orders of magnitude shorter, so sufficient opportunity for diffusion exists (Howe, 2001). Third, materials must have an affinity for attaching to the pore walls, without which they would pass right through the membrane. Research has demonstrated that hydrophobic membranes foul more than hydrophilic ones, and hydrophobic materials in the feed water can cause greater fouling. Concepts of particle stability presented in Chap. 9 are also relevant here. Finally, the attached material must be sufficiently large to constrict the pore dimensions. Research has shown that high-MW and colloidal organics cause more fouling than low-MW dissolved materials. Low-MW dissolved materials would not have as large of an impact on pore dimensions as colloidal materials.

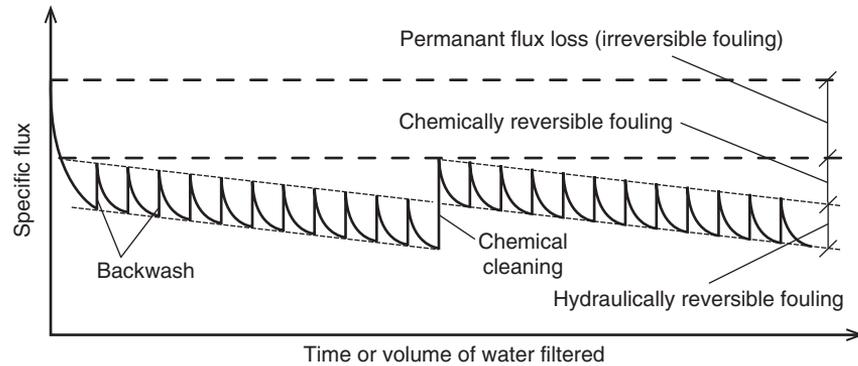

Particles that are too large to enter the pores collect on the membrane surface in a porous mat called a filter cake. Sediment larger than 0.2 mm is typically prefiltered with cartridge filters to protect the membrane, so the cake is initially composed of material between 0.2 mm and the membrane retention rating. The cake layer acts as a “dynamic” filter and can retain additional smaller material, but also generates hydraulic resistance to flow as it does so. The cake layer can prevent particles smaller than the retention rating from reaching the membrane, improving filtration effectiveness and possibly minimizing fouling from pore constriction.

Fouling can be characterized as irreversible or reversible. An idealized graph of specific flux over time is shown on Fig. 12-18. Full-scale facilities generally operate in a constant-flux mode; therefore, a decline in specific flux is caused by an increase in transmembrane pressure while flux remains constant. A decline in specific flux occurs during initial operation, and a portion of this flux loss cannot be recovered during backwashing and

## Reversibility of Fouling

**Figure 12-18**

Variation in specific flux during filtration of natural waters. The loss of specific flux from the initial clean membrane permeability, which cannot be recovered by backwashing or cleaning, is called irreversible fouling; that which can be recovered is called reversible fouling.

cleaning operations. Permanent flux loss is called irreversible fouling and depends on the source water quality as well as the type of membrane used. The specific flux declines further during each filter run (normally recorded as an increase in transmembrane pressure) but a significant portion can be recovered during backwashing. This loss of flux that can be recovered during backwashing is called hydraulically reversible fouling. Fouling due to cake formation is largely reversible during backwash. The longer-term, slower decline in specific flux over multiple filter runs is due to the slow adsorption and clogging of materials within the membrane matrix (pore constriction), which can be dissolved and removed during chemical cleaning. The loss of flux that can be recovered during cleaning is called chemically reversible fouling.

### Resistance-in-Series Model

As noted in the previous sections, several factors may contribute to resistance to flow. The resistance-in-series model applies a resistance value to each component of membrane fouling, assuming that each contributes to hydraulic resistance and that they act independently from one another. Typical forms of the resistance-in-series model are

$$J = \frac{\Delta P}{\mu (\kappa_m + \kappa_{ir} + \kappa_{hr} + \kappa_{cr})} \quad (12-10)$$

$$= \frac{\Delta P}{\mu (\kappa_m + \kappa_c + \kappa_p)} \quad (12-11)$$

where  $\kappa_m$  = membrane resistance coefficient,  $m^{-1}$   
 $\kappa_{ir}$  = irreversible fouling resistance coefficient,  $m^{-1}$   
 $\kappa_{hr}$  = hydraulically reversible fouling resistance coefficient,  $m^{-1}$   
 $\kappa_{cr}$  = chemically reversible fouling resistance coefficient,  $m^{-1}$   
 $\kappa_c$  = cake layer resistance coefficient,  $m^{-1}$   
 $\kappa_p$  = pore constriction resistance coefficient,  $m^{-1}$

The resistance-in-series equation can be applied to any number of individual resistances, which may be due to irreversible and reversible components, specific fouling materials (organic fouling resistance, biological fouling resistance, etc.), or fouling mechanisms (cake fouling resistance, pore constriction fouling resistance, etc.).

Individual resistance coefficients can be calculated by selecting operating conditions in which individual forms of fouling can be isolated. The procedure for calculating individual resistance coefficients is demonstrated in Example 12-5.

### Example 12-5 Calculation of resistance coefficients

The MF membrane in Example 12-3 is used under full-scale conditions in a water treatment facility, producing a flux of  $84 \text{ L/m}^2 \cdot \text{h}$  at 1.1 bar just before cleaning and  $106 \text{ L/m}^2 \cdot \text{h}$  at 0.52 bar immediately after cleaning, both at a standard temperature of  $20^\circ\text{C}$ . Calculate values for the membrane resistance coefficient, irreversible fouling resistance coefficient, and chemically reversible fouling resistance coefficient.

#### Solution

1. The membrane resistance coefficient was calculated in Example 12-3 (under conditions when  $\kappa_{ir} = 0$  and  $\kappa_{cr} = 0$ ) and found to be  $3.81 \times 10^{11} \text{ m}^{-1}$ .
2. Determine the irreversible fouling resistance coefficient.
  - a. The viscosity of water at  $20^\circ\text{C}$  from Table C-1 in App. C is  $1.00 \times 10^{-3} \text{ kg/m} \cdot \text{s}$ . Also recall that  $1 \text{ bar} = 100 \text{ kPa} = 10^5 \text{ N/m}^2 = 10^5 \text{ kg/s}^2 \cdot \text{m}$ .
  - b. The reversible component of fouling is removed by cleaning, so immediately after cleaning the chemically reversible fouling resistance coefficient is zero ( $\kappa_{cr} = 0$ ). The only factors that cause resistance to flow are the membrane resistance and the irreversible fouling resistance, so the resistance-in-series equation can be written

$$J = \frac{\Delta P}{\mu (\kappa_m + \kappa_{ir})} \quad (1)$$

- c. Rearrange Eq. 1 to solve for  $\kappa_{ir}$ :

$$\begin{aligned} \kappa_{ir} &= \frac{\Delta P}{\mu J} - \kappa_m = \frac{(0.52 \times 10^5 \text{ kg/s}^2 \cdot \text{m})(3600 \text{ s/h})(1 \times 10^3 \text{ L/m}^3)}{(1.00 \times 10^{-3} \text{ kg/m} \cdot \text{s})(106 \text{ L/m}^2 \cdot \text{h})} \\ &\quad - 3.81 \times 10^{11} \text{ m}^{-1} \\ &= 1.39 \times 10^{12} \text{ m}^{-1} \end{aligned}$$

3. Determine the chemically reversible fouling resistance coefficient.  
 a. Prior to cleaning, three components of resistance are present:

$$J = \frac{\Delta P}{\mu (\kappa_m + \kappa_{ir} + \kappa_{cr})}$$

- b. Rearrange the above equation to solve for  $\kappa_{cr}$ :

$$\begin{aligned} \kappa_{cr} &= \frac{\Delta P}{\mu J} - \kappa_m - \kappa_{ir} \\ &= \frac{(1.1 \times 10^5 \text{ kg/s}^2 \cdot \text{m}) (3600 \text{ s/h}) (1 \times 10^3 \text{ L/m}^3)}{(1.00 \times 10^{-3} \text{ kg/m} \cdot \text{s}) (84 \text{ L/m}^2 \cdot \text{h})} \\ &\quad - 3.81 \times 10^{11} \text{ m}^{-1} - 1.39 \times 10^{12} \text{ m}^{-1} \\ &= 2.94 \times 10^{12} \text{ m}^{-1} \end{aligned}$$

### Comment

In this example, the chemically reversible fouling resistance coefficient is the largest resistance and nearly an order of magnitude larger than the membrane resistance coefficient, which demonstrates the importance of fouling on overall membrane performance.

## Fouling by Particles

Large particles form a cake on the membrane surface. Fouling due to cake formation is often modeled using the resistance-in-series model. In laboratory studies using well-defined synthetic suspensions such as monodisperse spherical latex particles, the cake layer resistance coefficient in Eq. 12-11 can be calculated using the Kozeny equation for flow through a granular medium (see Chap. 11):

$$\kappa_C = \frac{36\kappa_K (1 - \varepsilon)^2 \delta_C}{\varepsilon^3 d_p^2} \quad (12-12)$$

where  $\kappa_C$  = cake layer resistance coefficient,  $\text{m}^{-1}$   
 $\kappa_K$  = Kozeny coefficient, unitless (typically 5)  
 $\varepsilon$  = cake porosity, dimensionless  
 $\delta_C$  = thickness of cake layer, m  
 $d_p$  = diameter of retained particles, m

In dead-end filtration, the thickness of the cake layer as a function of time can be calculated from the mass flux of particles toward the membrane

surface, assuming that the backward migration of particles due to diffusion can be neglected:

$$\delta_C(t) = \frac{CV}{\rho_P a(1 - \varepsilon)} \quad (12-13)$$

where  $\delta_C(t)$  = thickness of cake layer at time  $t$ , m

$C$  = concentration of particles, mg/L

$V$  = volume of feed water filtered, m<sup>3</sup>

$\rho_P$  = density of particles, kg/m<sup>3</sup>

$a$  = membrane area, m<sup>2</sup>

In natural systems, the cake layer is an amorphous mat of polydisperse solids, so the cake layer resistance cannot be related easily to parameters such as particle diameter, porosity, and cake thickness. In this case, the cake resistance coefficient can be defined in terms of a specific cake resistance, or resistance per unit of mass loading. The mass loading is the mass of dry solids retained by the membrane per unit of membrane area. Because the influent solids concentration, volume filtered, and membrane area can be readily measured, the cake resistance as a function of time (via volume filtered) can be determined:

$$\kappa_C = \alpha_C \frac{CV}{a} \quad (12-14)$$

where  $\alpha_C$  = specific cake resistance, m/g

During cross-flow filtration, cake layer formation is more complex because additional phenomena contribute to the transport of particles away from the membrane surface. The convective flow of particles toward the membrane is opposed by at least three mechanisms (Kim and DiGiano, 2009; Cheryan, 1998). First, the flow of water parallel to the membrane surface causes surface shear forces that drag particles downstream and minimize the formation of the cake. Second, the cross-flow velocity decreases the thickness of the concentration boundary layer, which increases the concentration gradient and enhances diffusion of particles away from the membrane surface. Finally, a velocity gradient exists close to the membrane surface such that particles in this velocity field are exposed to a higher velocity on the side opposite the membrane.

The differential velocity between the near and far sides of particles leads to inertial lift that draws them away from the membrane surface. The random movement of particles in this velocity field also enhances their migration toward streamlines moving at a higher velocity, a phenomenon that has been called shear-enhanced diffusion (Zydney and Colton, 1986). Shear-enhanced diffusion coefficients can be more than two orders of magnitude greater than Brownian diffusion coefficients (Belfort et al., 1994). Additional phenomena, such as electrostatic interactions (McDonogh et al.,

1988; Welsch et al., 1995), boundary layer separation (Treybal, 1980), gravitational forces, or van der Waals attractions (Wiesner and Chellam, 1992), may contribute to the movement of particles toward or away from the membrane surface.

A substantial number of models have been developed to predict the flux of membranes during cross-flow filtration of particle suspensions (Kim and DiGiano, 2009; Bacchin et al., 1995; Cheryan, 1998; Field et al., 1995; Koltuniewicz, 1992; Lee and Clark, 1997; Wiesner and Chellam, 1992). The trajectory of particles is evaluated in these models by considering all forces on individual particles. An important prediction of many of these models is that under certain conditions the net forces pushing particles away from the membrane are greater than the convective forces drawing particles to the membrane surface. As a result, no particle deposition and no fouling should occur. Wiesner et al. (1989) suggested that particles above a certain size should not deposit on the membrane, and others (Field et al., 1995) extended this to define the concept of a “critical flux,” the flux at which no particles deposit on the membrane surface and no fouling occurs. In addition, many of the models suggest that particles between about 0.1 and 1  $\mu\text{m}$  in diameter exhibit the least backmigration from the membrane surface and will cause the greatest fouling during cross-flow filtration.

### **Biofouling**

Biofouling is the loss of system performance due to the formation of a biofilm (Ridgway and Fleming, 1996). During filtration, microorganisms are transported to the membrane surface, where they can attach with sufficient force as to prevent removal during backwashing. Once attached, they can excrete extracellular material that causes additional fouling. Biofouling is particularly relevant in membrane filtration systems operated in wastewater applications, such as membrane bioreactors. In water treatment, biofouling is addressed by the use of chemical disinfectants such as chlorine in the feed water, backwash water, or both. The recent trend by manufacturers to use membrane materials with good chlorine resistance has helped reduce the importance of biofouling.

### **Natural Organic Matter Fouling**

Fouling by particles can be managed by proper backwashing (as long as the particles are significantly larger than the membrane pores) and biofouling can be managed with proper disinfection. The most problematic and least controllable membrane fouling is due to the adsorption of natural organic matter (NOM) to the membrane surface. Fouling by NOM (or the dissolved fraction, DOM) has been confirmed with laboratory experiments with solutions of commercially available dissolved organic matter. The ability of DOM to adsorb to membranes has been demonstrated with traditional adsorption isotherms (Crozes et al., 1993; Jucker and Clark, 1994). Filtration of commercially available humic, fulvic, and tannic acid

solutions has been shown to lead to rapid membrane fouling (Crozes et al., 1993; Lahoussine-Turcaud et al., 1990; Yuan and Zydney, 1999, 2000). Surface cake formation and pore constriction have both been proposed as mechanisms for fouling (Combe et al., 1999; Kim et al., 1992; Yuan and Zydney, 1999; Yuan et al., 2002). The relationship between DOM adsorption and flux has not been successfully described mathematically, and there are currently no models that can predict the extent of DOM fouling as a function of water quality measurements. Fouling depends on characteristics of the DOM, the membrane material, and the solution properties, although the size and stability of the DOM appear to be the most important factors. The effects of several important factors on DOM fouling are identified in Table 12-8.

Some studies have found that removing a large fraction of DOM (up to 85 percent) by carbon adsorption (Lainé et al., 1990; Carroll et al., 2000; Lin et al., 2000) can have little or no reduction of fouling or, alternatively, removing a small fraction of DOM (less than 10 percent) by prefiltration through a 3-kD membrane (Howe, 2001) can completely eliminate fouling. Collectively, this research suggests that only a fraction of DOM causes the majority of fouling in membrane filtration, and this and other research suggests that the high-MW and colloidal fractions are the necessary components because they have the necessary dimensions to constrict membrane pores. Chemical properties and particle stability are also important (Huang et al., 2008a; Huang and O'Melia, 2008) because fouling will not occur unless the colloids have an affinity for attachment to the membrane pore walls.

Significant fouling by a small amount of DOM is possible when the relationship between transmembrane pressure and pore diameter under laminar flow conditions is considered. Poiseuille's law for laminar flow (see Eq. 11-10 in Chap. 11) indicates that pressure drop varies as the inverse fourth power of diameter under constant flow conditions (i.e., transmembrane pressure could double following a mere 16 percent decrease in pore diameter).

Strategies to minimize fouling by NOM, such as coagulation pretreatment, are discussed in Sec. 12-8.

Models that simulate fouling mechanisms have been developed for filtration under specific laboratory operating conditions and have come to be known as the blocking laws. The analytical solution for each fouling mechanism is shown in Table 12-9. The equations predict a different rate of flux decline for each type of fouling.

Hermia (1982) demonstrated that the equations in Table 12-9 can be written in a consistent format. By multiplying flux by membrane area and integrating with respect to time, the total volume of permeate produced can be determined. Rearranging the equations with time as the dependent

### **Blocking Filtration Laws for Membrane Fouling**

**Table 12-8**

Factors contributing to membrane fouling by dissolved organic matter (DOM)

Factor	Observed Effects
Hydrophobicity	Hydrophobic membranes adsorb more DOM and therefore foul more rapidly than hydrophilic membranes (Matthiasson, 1983; L��n�� et al., 1989; Cheryan, 1998). Hydrophobic fractions of DOM and hydrophobic sources of DOM are expected to cause greater fouling, which has been observed in some research (Crozes et al., 1993; Yuan and Zydney, 1999; Sch��fer et al., 2000). However, researchers have also reported that hydrophilic fractions of DOM may be implicated in greater fouling (Amy and Cho, 1999; Carroll et al., 2000; Lin et al., 2000).
Electrostatic charge	Most DOM is negatively charged, and many MF and UF membranes acquire a slight negative charge during operation. Conditions that increase electrostatic repulsion might reduce fouling. The magnitude of the negative charge on membrane (Causserand et al., 1994; Nystr��m et al., 1994; Combe et al., 1999) and the negative charge on DOC both tend to increase at higher pH. As expected, low-pH conditions increase the adsorption of DOM to membranes (Jucker and Clark, 1994; Combe et al., 1999) and the fouling due to DOM adsorption (Kulovaara et al., 1999).
Size/molecular weight	Size may be an essential factor in determining which components of DOM cause fouling. Several studies suggest that high-MW and colloidal materials cause greater fouling (Lin et al., 1999, 2000; Yuan and Zydney, 1999, 2000; Habarou et al., 2001; Howe and Clark, 2002). Fouling by this colloidal fraction is consistent with the ability of larger material to constrict pores more efficiently than dissolved materials.
Colloidal stability	Since colloids must be smaller than the pore size to enter the membrane matrix, an additional mechanism must explain their attachment to the pore walls. A model developed by Huang et al. (2008a) and supported by experimental results indicated that colloids with low particle–membrane stability and high particle–particle stability caused the greatest fouling.
Ionic strength	High ionic strength reduces electrostatic repulsion (and particle stability) by compressing the double layer, and irreversible fouling has been shown to increase at high ionic strength (e.g., seawater) (Kulovaara et al., 1999).
Calcium concentration	Calcium ions may act as a positively charged bridge between DOM and membrane surfaces. Calcium has been shown to neutralize the negative charge on DOM and increase the adsorption of NOM on membranes (Jucker and Clark, 1994) and contribute to greater flux decline (Sch��fer et al., 2000).

Flux Equation	Equation Number	Filtration Coefficient, k	Filtration Exponent, n	Major Features and Assumptions
<b>Intermediate Blocking Filtration Law (Pore Sealing with Superposition)</b>				
$J_t = \frac{J_0}{\left(1 + 1.5 \frac{C_0 t}{\rho_P d_P a}\right)}$	(12-18)	$\frac{1.5C}{\rho_P d_P a}$	1	<input type="checkbox"/> Models blockage of the entrance to pores by particles retained at the membrane surface. <input type="checkbox"/> Extension of the complete blocking filtration law. <input type="checkbox"/> Relaxes the “monolayer” assumption in the complete blocking filtration law by allowing particles to land on previously retained particles or on the membrane surface by evaluating the probability that a particle will block a pore.
<b>Cake Filtration Law</b>				
$J_t = \frac{J_0}{\left(1 + 2 \frac{\alpha_C C_0 t}{\kappa_M}\right)^{0.5}}$	(12-19)	$\frac{\alpha_C C}{\kappa_M J_0 a^2}$	0	<input type="checkbox"/> Models the formation of a cake on the surface of a membrane using the resistance-in-series model. <input type="checkbox"/> The retained particles have no impact on the membrane itself, i.e., no pore blocking or pore constriction.

variable and taking the first and second derivatives with respect to volume, all four filtration laws can be written in the form

$$\frac{d^2t}{dV^2} = k \left( \frac{dt}{dV} \right)^n \quad (12-15)$$

where  $t$  = time, s

$V$  = volume, L

$k$  = blocking law filtration coefficient, units vary depending on  $n$

$n$  = blocking law filtration exponent, unitless

The parameters  $k$  and  $n$  are defined for each filtration law in Table 12-9. The form of the filtration laws shown in Eq. 12-15 can be used to analyze experimental data to determine which law most closely approximates the data. Permeate volume is measured at constant time intervals and tabulated in a spreadsheet. Using the spreadsheet, the derivatives  $d^2t/dV^2$  and  $dt/dV$  can be determined. The slope of the line is the coefficient  $n$  from Table 12-9.

Many researchers have fit laboratory flux data to these equations in an attempt to isolate which mechanism causes fouling under specific conditions. Despite their use in research studies, however, the equations have failed to have much predictive value to relate bench studies to full-scale applications for several reasons. First, membranes are modeled as perfectly flat and uniformly porous with vertical cylindrical pores, which does not match the membranes used in commercial applications. Second, filtration is modeled as being under constant-pressure, declining flux conditions, compared to the constant-flux, rising pressure situation normally used during water treatment. Third, the original models envision flux as declining due to a single mechanism and the shape of the flux decline curve reveals the fouling mechanism, whereas in full-scale operation several fouling mechanisms probably occur simultaneously. Finally, the original model equations have few or no parameters related to membrane properties so it is not possible to analyze, for instance, the impact of pore size on which mechanism might be most important for fouling by a particular size particle. More sophisticated models have been developed recently to address some of these limitations (Ho and Zydney, 2000; Chellam and Xu, 2006; Cogan and Chellam, 2009), but current models do not yet have predictive value for full-scale applications.

The filtration blocking laws apply only to constant-pressure, dead-end filtration. Models for flux decline have been developed for other operating conditions with varying levels of complexity (Belfort et al., 1994; Chang and Benjamin, 2003; Fane and Fell, 1987; Yuan et al., 2002; Kim and DiGiano, 2009). Theory regarding fouling of MF and UF membranes is evolving, and the current technical literature should be consulted if an in-depth understanding of flux modeling is required.

### Membrane Fouling Index

In the absence of fundamental models that can predict full-scale performance, it is useful to have empirical models that can compare fouling under different conditions, such as with different source waters, different membrane products, or at different scales. A fouling index can be derived using the resistance-in-series model with two resistance terms: one for clean membrane resistance and another for fouling resistance:

$$J = \frac{\Delta P}{\mu (\kappa_m + \kappa_f)} \quad (12-20)$$

where  $\kappa_f$  = resistance due to all forms of fouling,  $m^{-1}$

With the basic assumption that fouling resistance is directly proportional to the mass of foulants that have been transported to the membrane surface with the feed water, the fouling resistance can be related to the amount of water filtered per unit of membrane area, that is,

$$\kappa_f = kV_{sp} \quad (12-21)$$

where  $k$  = rate of increase in resistance,  $m^{-2}$

$V_{sp}$  = specific throughput, volume of water filtered per membrane area,  $m^3/m^2$

After conversion to flux at a standard temperature using Eq. 12-8 and substituting Eq. 12-21, Eq. 12-20 can be written in terms of specific flux:

$$J_{sp} = \frac{J_s}{\Delta P} = \frac{1}{\mu (\kappa_m + kV_{sp})} \quad (12-22)$$

For a new membrane,  $V_{sp} = 0$  so  $\kappa_f = 0$ , so

$$J_{sp0} = \frac{1}{\mu \kappa_m} \quad (12-23)$$

Membrane filtration performance is typically evaluated by comparing the flux over time to the initial flux through the membrane when it was new. Clean membrane permeability can vary from one membrane sample to another due to slight variations in membrane pore dimensions, thickness, or porosity because of manufacturing variability. Normalizing against new membrane performance eliminates membrane sample variability when comparing experiments. Dividing by clean membrane specific flux yields

$$J'_{sp} = \frac{J_{sp}}{J_{sp0}} = \frac{1/[\mu (\kappa_m + kV_{sp})]}{1/(\mu \kappa_m)} = \frac{\kappa_m}{\kappa_m + kV_{sp}} \quad (12-24)$$

A fouling index can be defined as the slope of the line when the inverse of  $J'_{sp}$  is plotted as a function of the specific throughput:

$$\frac{1}{J'_{sp}} = 1 + (\text{MFI}) V_{sp} \quad (12-25)$$

where  $\text{MFI} = k/\kappa_m =$  membrane fouling index,  $\text{m}^{-1}$

The MFI is an empirical fouling index that can be used to compare the rate of fouling between experiments or between bench and pilot-scale results. The MFI is valid for any form of fouling as long as the fouling resistance is directly proportional to the specific throughput. The use of specific flux allows filter runs at either constant pressure or constant flux to be compared, because  $J_{sp}$  declines as membranes foul regardless of whether filtration occurs at constant pressure ( $J$  declines at constant  $\Delta P$ ) or constant flux ( $\Delta P$  increases at constant  $J$ ). Specific throughput allows runs of different duration or systems with different membrane area (i.e., different scale) to be compared. Huang et al. (2008b) demonstrated that Eq. 12-25 could be derived as an approximation for standard blocking, intermediate blocking, or cake filtration mechanisms under either constant-flux or constant-pressure filtration scenarios. The MFI has been used to compare fouling between different membrane products and source waters, and studies have shown reasonably good agreement between MFI values using bench-scale and pilot-scale data with the same membrane and source water (Huang et al., 2008b, 2009b).

The MFI can be calculated using either a linear regression of flux data or as the slope of the line between two points, depending on the data available. Calculation of the MFI using both methods is demonstrated in Example 12-6.

Early bench-scale studies to explore membrane filtration and understand fouling were often done with flat-sheet membranes in a constant-pressure operating mode over a single filter run. A typical flat-sheet membrane experimental setup of this type is shown on Fig. 12-19a. While the research

### Evaluating Fouling with Bench-Scale Studies

(a)

(b)

**Figure 12-19**  
Equipment for bench-scale testing of membrane filtration: (a) flat-sheet membrane cell configuration and (b) backwashable hollow-fiber configuration.

### Example 12-6 Calculation of the membrane fouling index

A laboratory membrane experiment using a backwashable single-fiber membrane module was carried out to collect the data in Fig. 12-16. The membrane had a total area of  $23.0 \text{ cm}^2$  and the initial permeability of the new membrane was  $225.0 \text{ L/m}^2 \cdot \text{h} \cdot \text{bar}$ . The test was run at a constant pressure of  $1.023 \text{ bar}$  and temperature of  $22^\circ\text{C}$ . The membrane was backwashed every 30 min. Time and volume filtered were recorded at 2-min intervals and the data from filter run 6 is shown in the first two columns of Table 1 below. The flux at the beginning of each of the first 10 filter runs is also shown in Table 2 below. Calculate the fouling index during filter run 6 and the hydraulically irreversible fouling index (fouling that corresponds to the flux that could not be recovered by backwashing).

#### Solution

1. Divide the volume filtered by the membrane area to determine the specific throughput. Results are in column (3) in Table 1. For the second row,

$$V_{\text{sp}} = \frac{(743.92 \text{ mL}) (10^4 \text{ cm}^2/\text{m}^2)}{(23.0 \text{ cm}^2) (10^3 \text{ mL/L})} = 323.4 \text{ L/m}^2$$

2. Calculate the volume filtered in each time increment by subtracting the previous volume. Results are in column (4) in Table 1. For the second row,

$$\Delta V = 743.92 \text{ mL} - 732.63 \text{ mL} = 11.29 \text{ mL}$$

3. Divide the volume filtered in each increment by membrane area and time to determine flux. Then correct for temperature and pressure using Eqs. 12-8 and 12-9 to determine specific flux. Results are in column (5) in Table 1. For the second row,

$$J_m = \frac{(11.29 \text{ mL}) (10^4 \text{ cm}^2/\text{m}^2) (60 \text{ min/h})}{(23.0 \text{ cm}^2) (2 \text{ min}) (10^3 \text{ mL/L})} = 147.3 \text{ L/m}^2 \cdot \text{h}$$

$$J_{\text{sp}} = \frac{J_m (1.03)^{T_s - T_m}}{\Delta P} = \frac{147.3 \text{ L/m}^2 \cdot \text{h} (1.03)^{20 - 22}}{1.023 \text{ bar}}$$

$$= 135.7 \text{ L/m}^2 \cdot \text{h} \cdot \text{bar}$$

4. Divide the specific flux ( $J_{\text{sp}}$ ) by the initial specific flux ( $J_{\text{sp}0}$ ). Results are in column (6) in Table 1. For the second row,

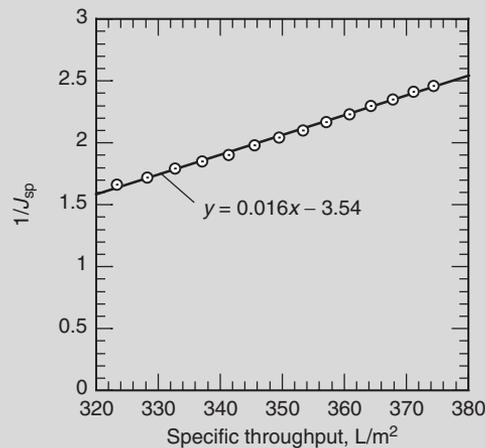

$$J'_{\text{sp}} = \frac{135.7}{225.0} = 0.60$$

5. Invert the normalized flux from column 6. Results are in column (7) in Table 1.

**Example 12-6 Table 1**

Filtration Time, min	Volume Filtered, mL	Specific throughput, L/m <sup>2</sup>	Delta volume, mL	Specific flux, L/m <sup>2</sup> · h	Normalized specific flux, $J'_{sp}$	Inverse normalized specific flux, $1/J'_{sp}$
0	732.63	—	—	—	—	—
2	743.92	323.4	11.29	135.7	0.60	1.66
4	754.79	328.2	10.87	130.6	0.58	1.72
6	765.26	332.7	10.47	125.8	0.56	1.79
8	775.40	337.1	10.14	121.9	0.54	1.85
10	785.17	341.4	9.77	118.4	0.53	1.90
12	794.63	345.5	9.46	113.7	0.51	1.98
14	803.79	349.5	9.16	110.1	0.49	2.04
16	812.70	353.3	8.91	107.1	0.48	2.10
18	821.34	357.1	8.64	103.8	0.46	2.17
20	829.73	360.8	8.39	100.8	0.45	2.23
22	837.88	364.3	8.15	97.9	0.44	2.30
24	845.85	367.8	7.97	95.8	0.43	2.35
26	853.62	371.1	7.77	93.4	0.42	2.41
28	861.22	374.4	7.60	91.3	0.41	2.46

6. Plot the inverse of the normalized specific flux ( $1/J'_{sp}$ ) as a function of the specific throughput ( $V_{sp}$ ), as shown in the following figure:

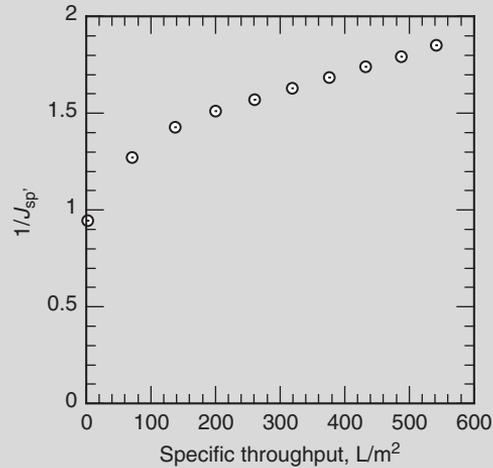

The slope of the line is the membrane fouling index for filter run 6,  $MFI_6 = 0.016 \text{ m}^2/\text{L} = 16 \text{ m}^{-1}$ . Note that the intercept of the graph is not 1.0 as is suggested by Eq. 12-25. This result is because backwashes remove foulants and reset membrane performance to a higher flux, whereas the specific volume progresses continuously. For an initial filter run (i.e., before any backwashes or cleanings), the intercept is very close to 1.0.

7. Determine the hydraulically irreversible membrane fouling index ( $MFI_{hi}$ ). The  $MFI_{hi}$  represents the flux that cannot be recovered by backwashing and can be evaluated by considering the net reduction in flux at the beginning of each filter run (immediately after backwashing). Data from the first 10 filter runs of the experiment shown in Fig. 12-16 is shown in Table 2 below. Column (1) is the filter run number, Column (2) is the specific throughput at the beginning of each filter run, and Column (3) is the average specific flux over the first 30 of each filter run.

**Example 12-6 Table 2**

(1)	(2)	(3)	(4)	(5)
Filter Run	Specific throughput, $\text{L}/\text{m}^2$	Specific flux, $\text{L}/\text{m}^2 \cdot \text{h}$	Normalized specific flux, $J'_{sp}$	Inverse normalized specific flux, $1/J'_{sp}$
1	2.2	238.0	1.06	0.95
2	71.3	176.9	0.79	1.27
3	137.6	157.7	0.70	1.43
4	200.0	149.0	0.66	1.51
5	260.5	143.3	0.64	1.57
6	319.0	138.0	0.61	1.63
7	376.4	133.6	0.59	1.68
8	432.6	129.3	0.57	1.74
9	487.9	125.5	0.56	1.79
10	542.4	121.6	0.54	1.85

8. A graph of the inverse of the normalized flux ( $1/J'_{sp}$ ) as a function of the specific throughput is shown in the following figure:

The graph indicates more rapid fouling during the first two filter runs (i.e., the first two runs are not linear with the rest of the data), and a linear regression through all of the data would not reflect the longer-term fouling index. The long-term hydraulically irreversible membrane fouling index can be calculated as a straight line between runs 3 and 10:

$$\begin{aligned} \text{MFI}_{\text{hi}} &= \frac{(1/J'_{\text{sp}})_{10} - (1/J'_{\text{sp}})_3}{(V_{\text{sp}})_{10} - (V_{\text{sp}})_3} = \frac{1.850 - 1.427}{542.4 \text{ L/m}^2 - 137.6 \text{ L/m}^2} \\ &= 0.00104 \text{ m}^2/\text{L} \\ \text{MFI}_{\text{hi}} &= (0.00104 \text{ m}^2/\text{L})(10^3 \text{ L/m}^3) = 1.04 \text{ m}^{-1} \end{aligned}$$

has helped improved the industry's understanding of membrane filtration, researchers have gradually realized that performance with this system did not effectively simulate full-scale commercial membrane filtration systems. New membranes tend to experience an initial period of irreversible fouling that might mask longer-term fouling trends. Constant-pressure filtration through a flat-sheet membrane can cause very high initial flux that leads to rapid fouling in the first moments of operation. Studies have shown different fouling with constant-pressure operation than with constant-flux operation (Tarabara et al., 2002). Commercial membrane manufacturers often have proprietary chemical formulations or fabrication methods to optimize performance, and use of a laboratory-grade flat-sheet membrane may not adequately represent the commercial product, even if nominally

of the same material. Studies have demonstrated that rates of fouling of hollow-fiber and flat-sheet membranes are not the same even when made of the same material and filtering the same water (Howe et al., 2007).

To rectify these limitations, researchers have developed small-scale hollow-fiber modules (often with only one or two fibers) that can be used at bench scale but more effectively simulate pilot- or full-scale systems (Chang and Benjamin, 1996; Kim and DiGiano, 2006; Huang et al., 2009b). A typical hollow-fiber experimental system is shown on Fig. 12-19b. The hollow-fiber membranes are exactly the same product as used in commercial membrane modules. The bench-scale modules can be operated in either inside-out or outside-in flow configurations to match full-scale operation and can be backwashed to allow operation over multiple filter runs. Constant flux operation can be simulated, although pumps must be selected carefully because low-flow positive-displacement pumps often used in laboratories may produce pulsations that are not characteristic of centrifugal pumps used in pilot- or full-scale applications. While the hydraulics of small-scale systems are not identical to commercial modules, they are more representative of larger systems than earlier flat-sheet bench-scale systems were. The membrane fouling index presented in the previous section offers the potential to relate bench-scale membrane performance to pilot- or full-scale performance, although more experimental validation of this approach is needed.

## 12-8 Process Design

---

Membrane filtration design concepts are changing rapidly, so the application of this technology presents unique challenges for the design engineer. Design based on previous projects or “tried-and-true” rules of thumb may fail to capitalize on recent technological advancements. On the other hand, undue reliance on manufacturers’ claims about unproven technologies may lead to failure. A critical role for the design engineer is to stay abreast of technical advancements and provide appropriate guidance to facility owners. An understanding of the fundamentals of membrane materials, modules, fouling, and performance is necessary to evaluate new technologies with the objective of allowing the design to capitalize on valuable technological advancements while avoiding unproven alternatives that have an unreasonable chance of failure. Detailed guidance and design manuals for membrane filtration systems have recently been published by EPA and AWWA (U.S. EPA, 2005; AWWA, 2005b, 2008).

The primary tasks for the design engineer during preliminary design of a membrane filtration installation include:

1. Set performance criteria, such as retention criteria, plant capacity, and recovery, based on raw-water resources, finished-water quality goals, and projected water demand.

2. Evaluate the need for supplementary unit processes such as pretreatment or disinfection in the overall treatment facility, based on raw and finished-water quality and the capabilities of membrane filtration.
3. Evaluate process alternatives, including new developments and technological advancements. Frequently, this evaluation will include pilot studies and evaluation of the construction and O&M costs of the appropriate alternatives.
4. Establish process design criteria and develop specifications for major system components. Pilot studies contribute to the basis of design.
5. Predesign ancillary and support facilities, such as transfer piping, pumping facilities, chemical storage facilities, laboratory space, buildings, and electrical systems. Evaluate hydraulic-grade line and waste washwater disposal options.

Important performance criteria include retention capabilities, capacity requirements, and recovery. Performance criteria also provide a basis for determining whether membrane filtration must be coupled with other treatment technologies.

## Performance Criteria

### RETENTION CAPABILITIES

As noted in Sec. 12-5, MF membranes achieve excellent rejection of most microorganisms but are not a complete barrier to viruses. Some UF products do provide excellent virus rejection, suggesting that there might be an advantage to specifying UF membrane systems exclusively. However, viruses are readily inactivated by free chlorine, and most regulatory agencies, if not all, will require primary disinfection as part of a multibarrier approach to water treatment. Thus, while some UF membranes may provide a more robust treatment train with respect to virus removal, as a practical matter there is generally no regulatory or cost advantage to selecting UF membranes over MF membranes when specifying acceptable membrane technologies.

Because membrane filtration is still a relatively new water treatment process, the regulatory system in the United States does not have uniform criteria for the rejection capabilities of membrane filters. Criteria are applied at the state level and vary between states. In the United States, most states with guidelines for membrane filtration grant between 2 and 4 log rejection credits for *Giardia* and *Cryptosporidium* and between 0 and 4 log rejection credits for viruses. Numerous states grant the same log rejection credit regardless of whether the system is marketed as an MF or UF system (Herschell, 2007). The *Cryptosporidium* challenge testing requirements in the LT2ESWTR (U.S. EPA, 2005) are becoming the de facto standard for specifying rejection requirements for membrane systems.

Effluent turbidity is an important performance criterion in the design of granular filtration facilities. For membrane filtration design, turbidity

provides little guidance because all properly operating membrane filters will reduce turbidity to very low levels.

#### PLANT CAPACITY AND RECOVERY

Plant capacity is governed by the anticipated water demand at the end of the design life. Summer and winter demand must be considered separately because of the effect of temperature on permeate flux. In most locales, summer water demand is higher than winter demand, which fortunately corresponds to the seasonal variation in water temperatures. For each season, required plant size should be determined for the peak-day demand and minimum water temperature, which are worst-case conditions.

Recovery is the ratio of net water production to gross water production over a filter run:

$$r = \frac{Q_p}{Q_f} = \frac{V_f - V_{bw}}{V_f} \quad (12-26)$$

where  $r$  = recovery

$Q_p$  = permeate flow rate, m<sup>3</sup>/d

$Q_f$  = feed flow rate, m<sup>3</sup>/d

$V_f$  = volume of water fed to membrane over filter run, m<sup>3</sup>

$V_{bw}$  = volume of water used during backwash, m<sup>3</sup>

The calculation for recovery is identical to that for granular filters, except that common terminology in granular filtration (UFRV and UBWW) currently is not used in membrane filtration. Recovery in membrane filtration is typically 95 to 98 percent, which is comparable to rapid granular filters. If waste washwater is recovered, processed, and recycled to the feed stream, even higher recovery (greater than 99 percent) can be achieved.

#### Integration with Other Treatment Processes

Application of membrane filtration for water treatment started with small facilities with straightforward treatment requirements, so the membranes were a stand-alone process with no significant pretreatment or integration with other processes (except postmembrane disinfection). Now membrane filtration is an alternative to granular filtration regardless of source water quality. Integration of membrane filters as part of a larger process train is now the norm (Adham et al., 2005). Membrane filtration is used as pretreatment for other processes, such as granular activated carbon (GAC) adsorption or reverse osmosis. Processes that precede membrane filtration include coagulation and flocculation, sedimentation, granular filtration, adsorption, oxidation, and softening. A substantial amount of technical literature about pretreatment for membrane filtration is available, including reviews by Farahbakhsh et al. (2004) and Huang et al. (2009a).

Pretreatment is employed for two major reasons. First, additional processes can remove contaminants that are not removed by membrane

filtration alone, such as dissolved constituents. For example, coagulation is used for removal of arsenic; GAC is used for removal of taste, odor, and synthetic organic chemicals; oxidants are used for the removal of iron and manganese; and lime is used for the removal of hardness. Other technologies are being explored for other treatment objectives.

Second, pretreatment can enhance membrane performance by reducing the solids loading on the membrane process or by reducing membrane fouling. High turbidity sources may require excessive backwashing unless coagulation, flocculation, and sedimentation are used to remove a significant fraction of the solids, a strategy identical to conventional treatment using granular filtration. Processes can also remove membrane foulants, allowing the membrane system to operate at higher flux or with decreased backwashing and cleaning requirements. If the flux enhancement is significant, the cost of pretreatment may be offset by decreased membrane system costs.

Regardless of the reason for applying pretreatment, the impact on the membrane process must be considered. While some pretreatment can substantially improve membrane performance, other pretreatment can foul or even damage the membranes. Bench or pilot testing is recommended to evaluate the impact of chemicals on membranes. The two most common pretreatment strategies, coagulation and adsorption, are considered in more detail in the following sections.

#### **COAGULATION PRETREATMENT**

Coagulation and flocculation, sometimes with settling, is the most common pretreatment for membrane filtration. Coagulation can remove 15 to 50 percent of the NOM in natural waters and may be appropriate for utilities that need some NOM removal to meet DBP regulations. Coagulation with settling allows membrane filtration to be applied to source waters with higher and more variable turbidity.

Coagulation frequently reduces membrane fouling, and many studies and full-scale facilities have reported higher flux or reduced cleaning requirements when coagulation is used (Huang et al., 2009a). As noted earlier, high-MW and colloidal constituents may be a primary factor in fouling by NOM, and coagulation is effective at removing the higher-MW and more hydrophobic components of NOM. In some cases, however, coagulation has made fouling worse (Adham et al., 2006; Schäfer et al., 2001; Shorney et al., 2001; Shrive et al., 1999). The effect of coagulation on membrane fouling is site specific and is due to specific interactions between coagulants, feed water components, and membrane materials. One factor in the differences between the studies reported above is the coagulant dose: When the dose is sufficient to remove a significant fraction of the NOM, membrane performance may be improved due to the reduction of fouling (Howe and Clark, 2006). Until further research clearly identifies the interactions between coagulants, foulants, and membranes,

pilot studies are necessary to assess the effect of coagulation on membrane performance.

Experience with polymeric coagulant aids is mixed. Some studies have reported improved membrane performance when coagulant aids were used during coagulation, but others have reported that the polymers irreversibly fouled the membranes. Some manufacturers discourage the use of cationic polymers as pretreatment to their membrane filter systems.

#### **POWDERED ACTIVATED CARBON–MEMBRANE REACTORS**

Powdered activated carbon has been applied in the raw water of conventional treatment facilities for the removal of taste and odors as well as a variety of synthetic organic compounds. In conventional facilities PAC use can be complicated by competition from other treatment chemicals, limited contact time due to settling of the PAC in sedimentation basins, or breakthrough of the PAC through the filters and into the distribution system. The coupling of PAC treatment with membrane filtration provides a unique process without these disadvantages. Additional details of adsorption by PAC are provided in Chap. 15.

In the typical PAC–membrane reactor, PAC is added to the feed water upstream of the membranes. By using pressure-vessel membranes in a cross-flow mode or by using submerged membranes, the PAC is recycled to the feed water, increasing contact time and maximizing carbon utilization. Powdered activated carbon is considerably larger than the membrane pores, so passage of PAC into the distribution system is avoided. A recirculating or submerged membrane filtration system provides an ideal reactor for PAC adsorption, and this process is in use at full-scale water treatment plants (Anselme et al., 1999; Petry et al., 2001).

Powdered activated carbon adsorption is affected by the operating mode. The PAC can be added and withdrawn continuously during filtration in a feed-and-bleed configuration or the PAC can be added to an upstream reactor and allowed to accumulate over a filtration cycle. Each operating mode provides a different contact time distribution between the PAC and the contaminants. Campos et al. (2000a,b) determined that dosing carbon at the beginning (i.e., pulse input) of the filtration run rather than continuously resulted in lower average concentrations of contaminants.

While PAC is generally effective at removing synthetic organics, its ability to improve membrane performance is less evident. Although some studies have concluded that PAC can improve membrane performance, others have shown only minor improvement or worse performance. The primary reason PAC is less effective than coagulation at improving membrane performance is that activated carbon tends to remove the lower-MW components of NOM. The high-MW components of NOM that are implicated in membrane fouling tend to be excluded from the small pores of activated carbon.

Currently, membrane filtration systems are available as modular systems from several manufacturers. Current vendors of membrane filtration equipment are listed in AWWA (2005b). Other suppliers are expected to enter the market as the technology evolves, including suppliers experienced in the reverse osmosis (see Chap. 17) market. Systems are often offered as a package containing all necessary filtration and ancillary equipment. Integral parts of membrane filtration facilities are the pretreatment processes, backwashing facilities, and cleaning facilities. These components are discussed in the following sections.

#### **PRETREATMENT**

When processes for nonparticulate treatment goals are not present, the pretreatment requirements for membrane filtration are minimal. Pretreatment is necessary to protect the filter fibers from damage or clogging of the lumen (in the case of inside-out membranes). Microscreening or prefiltration to remove coarse sediment larger in diameter than 0.1 to 0.5 mm, depending on the manufacturer, is required. Prefiltration is accomplished with self-cleaning screens, cartridge filters, or bag filters.

Because the primary removal mechanism is straining, chemical conditioning to destabilize particles is not required, although coagulation is now often applied as pretreatment for other reasons. The lack of a requirement for particle destabilization can be an advantage over granular filtration because the elimination of coagulation and flocculation facilities reduces chemical handling and storage facilities and residual management requirements.

#### **BACKWASHING**

The objective of backwashing is to remove the surface cake that develops during the filtration cycle. Backwashing occurs automatically at timed intervals ranging from 30 to 90 min. The increase in transmembrane pressure during the filtration cycle is typically 0.01 to 0.07 bar (0.2 to 1 psi). Most systems also initiate the backwash cycle early if the increase in transmembrane pressure during the filter run exceeds a preset limit. The backwash cycle lasts 1 to 3 min, and the sequence is run entirely by the control system. All modules in a rack are backwashed simultaneously. Backwashing of MF membranes involves forcing either air or permeate water through the fiber wall in the reverse direction at a pressure higher than the normal filtration pressure. Ultrafiltration membranes are backwashed with permeate water because the air pressure required to force water from the small pores in UF membranes can be excessive. In some pressure-vessel systems, the backwash flow is supplemented by a high-velocity flush in the feed channels to assist with removing the surface cake, and the wastewater is piped to a washwater handling facility. The backwash water in submerged systems flows directly into the feed tank.

Many membrane systems periodically add chemicals to backwash water to improve the backwash process, a sequence called chemically enhanced backwash (CEB). CEB chemicals can include hypochlorite or other cleaning chemicals. Chemically enhanced backwash reduces the rate of membrane fouling and can decrease the required frequency for the more extensive clean-in-place (CIP) cycle, which is discussed below.

Many membrane systems use a single backwash system to service multiple racks. The system is sized to backwash a single rack at a time, so backwashing of multiple racks must be staggered. The automated backwash sequence is a complex operation that involves the sequencing of numerous valves, which may take several minutes. The design engineer must consider the time requirements to complete one backwash cycle and ensure that there is sufficient time for all units to be washed within the allowable time between backwashes, including a factor of safety. If sufficient time is not available, more than one backwash system may be necessary.

#### **CLEANING**

Despite frequent backwashing, membrane filters gradually lose filtration capacity due to clogging or adsorption of material that cannot be removed during the backwash cycle. When the transmembrane pressure increases to a preset maximum limit or when a preset time interval has elapsed, the membranes are chemically cleaned. Chemical cleaning frequency ranges from a few days to several months depending on the membrane system characteristics and source water quality. The cleaning procedure typically takes several hours and involves circulating cleaning solutions that have been heated to 30 to 40°C. Cleaning solutions are proprietary mixtures provided by membrane manufacturers but are often high-pH solutions containing detergents or surfactants, which are effective for removing organic foulants. Low-pH solutions such as citric acid can be used for removing inorganic foulants. For some membrane materials (e.g., cellulose acetate), the pH of the cleaning solution is limited by the pH compatibility of the material. The membranes in both pressure-vessel and submerged systems are typically cleaned without removing the membranes from the modules, so the process is typically called the clean-in-place cycle.

#### **POSTTREATMENT**

The membrane filtration process has no inherent posttreatment requirements. Fluoridation or pH adjustment may be added after membrane filtration to fulfill other treatment objectives. Although membrane filtration is capable of completely removing microorganisms, disinfection is normally practiced after filtration as part of the multibarrier concept and to provide a disinfectant residual in the distribution system. Most state regulatory agencies have specific regulations for chemical disinfection following filtration.

Membrane integrity monitoring involves procedures to verify that membrane filters are meeting treatment objectives. Integrity monitoring is important because of the physical characteristics of the filtration barrier. In a granular filtration plant, water is cleaned gradually as it flows through a series of processes, ending with a thick bed of filter media; clean water and dirty water are separated in both time and space. In a membrane filtration plant, water is cleaned nearly instantaneously as it flows through a thin membrane; clean water and dirty water are separated by a distance less than 1 mm and time less than 1 s. In addition, broken fibers or leaking O-ring connectors may compromise the filtration system. The regulatory framework for integrity monitoring is provided as part of the LT2ESWTR (U.S. EPA, 2006).

Integrity monitoring for membrane filtration has both direct and indirect components. As defined in the LT2ESWTR, the direct integrity test is a physical test that is sensitive enough to detect a 3- $\mu\text{m}$  breach in the membrane system, is conducted at least one per day, and can verify the log removal value awarded to the membrane process. Continuous indirect integrity monitoring is the measurement of a water quality parameter that is indicative of particle removal, such as turbidity or particle counts.

#### **INDIRECT INTEGRITY MONITORING**

Indirect integrity monitoring is the continuous (at least every 15 min) monitoring of a suitable effluent water quality parameter, such as turbidity or particle levels. Indirect integrity monitoring is not as sensitive as direct integrity testing, but it has the advantages that it can be applied continuously and uses commercially available equipment that can be used with any membrane system (whereas most direct integrity testing equipment is proprietary to the specific membrane system manufacturer). Therefore, it is complementary to direct integrity testing in an overall integrity verification program.

Membrane filter effluent may be monitored for turbidity or particle concentrations. Particle counters, in which particles are classified according to size, are in common use in water treatment facilities (see Chap. 2). Particle monitors are a less expensive alternative to particle counters and provide only a relative measurement of total particulate matter in water. Particle counting is generally more sensitive than turbidity monitoring.

The sensitivity of effluent monitors is dependent on the filtration area being monitored. A study performed by Adham et al. (1995) showed that turbidity monitoring was able to detect a single pinhole in 5 m<sup>2</sup> of membrane area, whereas a particle monitor and a batch particle counter were able to detect similar breaches in 12 and 720 m<sup>2</sup> of membrane area, respectively. However, individual membrane modules may have 40 to 80 m<sup>2</sup> of membrane area and racks may contain 2 to 100 modules. The limitation of turbidity for integrity monitoring, which drives the need for direct integrity testing, is illustrated in Example 12-7.

### Example 12-7 Indirect integrity monitoring with turbidity

A membrane filtration plant treating a feed water with  $10^6$  microorganisms/L and turbidity of 10 NTU reduces both to below detection limits. For this example, assume the detection limits are 1 org/L for microorganisms and 0.03 NTU for turbidity. Using this information, calculate (1) the log rejection value for microorganisms under normal operation and (2) the effluent turbidity and microorganism concentration and the rejection of microorganisms assuming the membrane develops a hole that allows 0.01 percent of the water to pass through untreated.

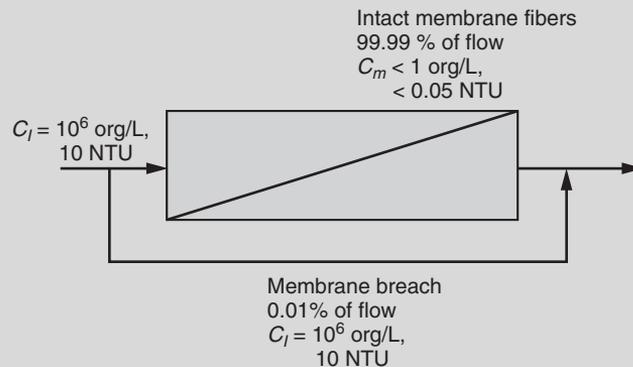

#### Solution

1. Calculate the log rejection value under normal operation. Use the detection limit for the effluent concentration and Eq. 12-4:

$$\text{LRV} = \log \left( \frac{C_f}{C_p} \right) = \log \left( \frac{10^6 \text{ org/L}}{1 \text{ org/L}} \right) = 6.0 \text{ for microorganisms}$$

Because the effluent concentration is below the detection limit, the log rejection is greater than calculated, that is,  $\text{LRV} \geq 6.0$  for microorganisms.

2. Calculate log rejection under compromised operation.
  - a. Draw a mass balance diagram for membrane breach:

- b. Write the mass balance equation for microorganisms and solve:

$$\begin{aligned} C_e &= \frac{Q_m C_m + Q_b C_b}{Q_e} = \frac{(1 \text{ org/L})(0.9999) + (10^6 \text{ org/L})(0.0001)}{1} \\ &= 101 \text{ org/L} \end{aligned}$$

- c. Write the mass balance equation for turbidity and solve:

$$C_e = \frac{Q_m C_m + Q_b C_b}{Q_e} = \frac{(0.03 \text{ NTU})(0.9999) + (10 \text{ NTU})(0.0001)}{1}$$

$$= 0.031 \text{ NTU}$$

- d. Calculate the log rejection value under compromised operation using Eq. 12-4:

$$\text{LRV} = \log\left(\frac{C_p}{C_f}\right) = \log\left(\frac{10^6 \text{ org/L}}{101 \text{ org/L}}\right) = 4.0 \text{ for microorganisms}$$

### Comment

As demonstrated in this example, effluent turbidity with a 0.01 percent breach would not be distinguishable from the turbidity with an intact membrane (turbidity = 0.031 NTU versus 0.03 NTU). For microorganisms, however,  $C_E = 101 \text{ org/L}$  and  $\text{LRV} = 4.0$  compared to  $C_E < 1 \text{ org/L}$  and  $\text{LRV} > 6.0$  with no breach—a dramatic reduction in rejection capabilities. In other words, a small breach has a substantial effect on microorganism log rejection value but is undetectable by turbidity measurements.

Most membrane filtration systems produce effluent water turbidity between 0.03 and 0.07 NTU, which is near the limit of detection. Indirect integrity monitoring involves establishing a control limit, typically between 0.10 and 0.15 NTU. Readings greater than the control limit for more than 15 min may indicate an integrity problem and would trigger the need to perform a direct integrity test.

### DIRECT INTEGRITY TESTS

Direct integrity tests can be either pressure-based or marker-based tests. Pressure-based tests involve applying pressurizing one side of the membrane with air and monitoring the change in air pressure, flow of air, or volume of displaced water, based on the concept that passage of air through a hole in the membrane is much faster than the diffusion of air through the water-filled pores in the membrane. Marker-based tests involve spiking the influent with particles or molecular markers and measuring the concentration of the marker in the effluent, which is similar to the challenge test that manufacturers have performed to get systems approved for use under the LT2ESWTR. Pressure-based integrity tests are most common for commercial membrane filtration systems, and the equipment, instrumentation, and procedures for conducting the test are built into the skid and implemented automatically.

The general principle of pressure-based integrity testing is to isolate a group of modules being tested (typically, one rack), drain the water from one side of the membrane, and pressurize the system with air. In the pressure-hold test, the rate of decay in the pressure is monitored. In a membrane with no breaches, air will diffuse through the water in the membrane pores, and pressure will decay slowly. Air can flow more rapidly through pinholes. The pressure required must be high enough to detect a 3- $\mu\text{m}$  breach but below the bubble point of the membrane material. This pressure range depends on membrane properties and the procedure to determine the appropriate pressure is defined in the *Membrane Filtration Guidance Manual* (U.S. EPA, 2005). The *Guidance Manual* also describes procedures necessary to calculate the sensitivity of the test, which is related to the log removal value that the system would achieve if a portion of the water was flowing through a hole in the membrane untreated and the rest of the water was flowing through membrane pores and achieving complete removal of microorganisms. Acceptable rates of pressure decay vary with the system being monitored according to calculations in the *Membrane Filtration Guidance Manual*. Decay rates of 0.007 to 0.03 bar/min (0.1 to 0.5 psi/min) are typical limits (U.S. EPA, 2001).

Pressure-hold tests have been reported to be capable of detecting one broken fiber in a module containing 20,000 fibers. Entire racks of membranes can be monitored simultaneously, but these tests are sensitive to the size of the system being monitored because the air diffusion through the pore water may exceed the airflow through a breach if the filter area being monitored is too large. Breakage of several fibers in a large pressure-vessel rack, containing 90 modules with 20,000 fibers each, cannot be detected with pressure-hold tests (Landsness, 2001).

The pressure-hold test is the most common method and most manufacturers include all necessary equipment as part of the skid. Less common variations of this test involve measuring the rate of airflow through the membrane at constant pressure or measuring the volume of water displaced by the flowing air.

Current direct integrity testing methods require that the plant be taken out of service, thus reducing the available time for water production. The required frequency of pressure-hold test requirements in state regulations vary from once every 4 h to weekly (Allgeier, 2001).

#### **SONIC TESTING**

Sonic testing is a method of identifying leaks in individual pressure vessels. The test involves manually placing an acoustic sensor against a module and listening for changes in the sounds emanating from within the module. During a pressure-hold test, air bubbling through a damaged fiber will make enough noise to be detected by the sensor. The sonic test is highly sensitive when performed by a skilled operator but is subject to background equipment noise. A single broken fiber in a module containing 20,000

fibers can be detected (Landsness, 2001). The sonic test is typically used in conjunction with other integrity monitoring techniques. Effluent monitoring or pressure-hold tests are typically used to identify possible problems in a group of modules, and sonic testing can then be used to confirm the presence of a damaged fiber and identify the individual module containing the breach.

#### REPAIR OF MODULES

Modules can be repaired by isolating damaged fibers in a process called pinning. The module is typically removed from the rack and placed in a special test casing. The module can be pressurized with air while the ends of the fibers are exposed and covered with water. In this setting, bubbles will emit from the end of the broken fiber, so that the damaged fiber can be identified. A pin is glued into the end of the fiber, effectively taking the individual fiber out of service. The repaired module can then be placed back in service.

Typical operating criteria for membrane filtration facilities are given in Table 12-10. As demonstrated previously, steady-state membrane performance is controlled not by intrinsic membrane properties but by the fouled state of the membrane after it has been in contact with natural water. Fouling depends on interactions between the source water and membrane material, but current understanding of fouling is not sufficient for predicting basic design criteria from measurable water quality parameters and membrane properties. Thus, pilot testing is typically part of the process evaluation procedure. AWWA's *Manual M53* (AWWA, 2005b) describes pilot testing efforts for two different water supplies where the same two membrane products were tested. For one water supply, one membrane performed well and the other fouled rapidly; for the other water supply, the results were exactly reversed. Such information is critical for selecting the most appropriate membrane product and operating conditions for a particular water supply. In addition, nearly all states require pilot testing as part of the permitting process (Herschell, 2007).

### Design Criteria Development Based on Pilot Testing

#### PILOT TESTING

When done properly, pilot testing can be used to demonstrate the effectiveness of innovative technologies or to provide a basis for comparing alternative systems. Pilot testing should incorporate all pretreatment processes that are being considered for the full-scale facility. For most MF and UF membrane studies the following parameters should be studied:

1. Feed and permeate water quality, including pH, turbidity, particle counts, TOC or DOC,  $UV_{254}$  absorbance, and other parameters relevant to the specific site
2. Feed water temperature

3. Feed water and permeate flow rates
4. Transmembrane pressure
5. Backwash requirements (frequency, duration, flow rate, pressure)
6. Cleaning requirements (frequency, duration, chemical dosages, procedures)
7. Other constituents of concern in specific applications, such as NOM

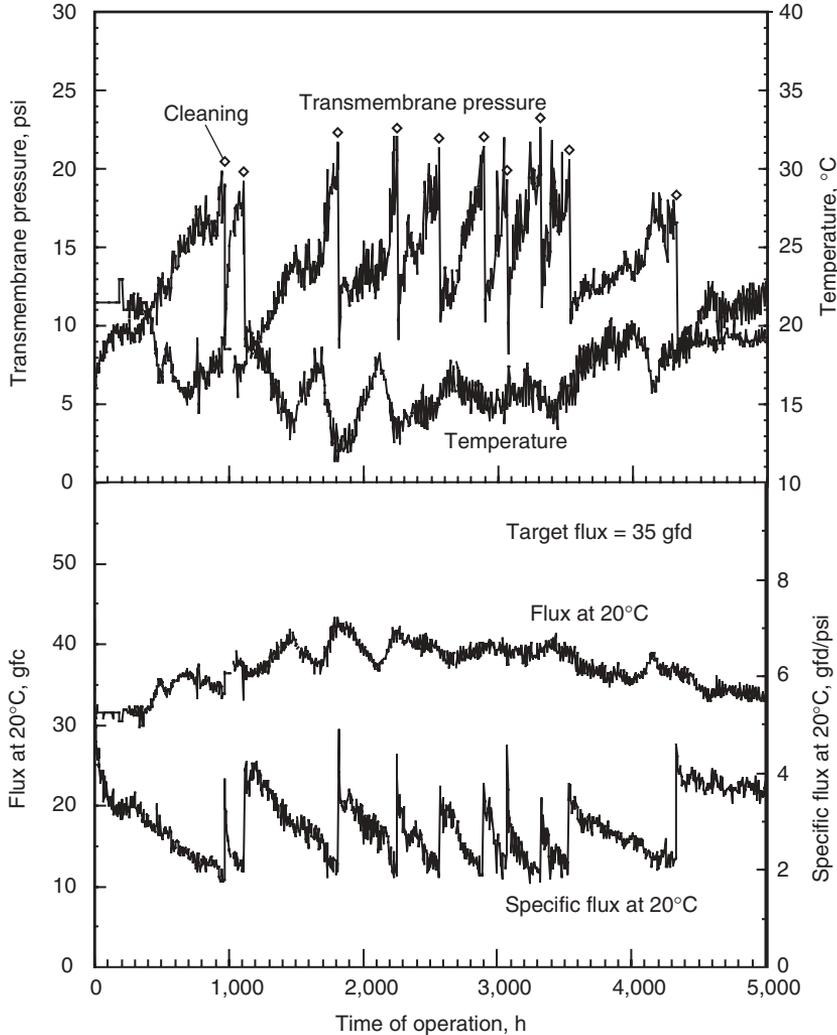

#### PILOT TESTING PERIOD

Pilot testing should be performed over an extended time, ranging from several months to a year, depending on seasonal variations in water quality and temperature. For instance, spring runoff or lake turnover may lead to water quality conditions that cause considerably greater fouling than other times of the year. When complete, pilot testing will provide data on each of the design criteria shown in Table 12-10, with the exception of membrane life. For comparisons between alternatives to be meaningful, data for permeate flux, pressure, and temperature must be combined

**Table 12-10**

Typical operating characteristics of membrane filtration facilities

Parameter	Units	Range of Typical Values
Permeate flux		
Pressurized systems	L/m <sup>2</sup> · h gal/ft <sup>2</sup> · d	30–170 18–100
Submerged systems	L/m <sup>2</sup> · h gal/ft <sup>2</sup> · d	25–75 15–45
Normal transmembrane pressure		
Pressurized systems	bar psi	0.4–1 6–15
Submerged systems	bar psi	0.2–0.4 3–6
Maximum transmembrane pressure		
Pressurized systems	bar psi	2 30
Submerged systems	bar psi	0.5 7.4
Recovery	%	>95
Filter run duration	min	30–90
Backwash duration	min	1–3
Time between chemical cleaning	d	5–180
Duration of chemical cleaning	h	1–6
Membrane life	yr	5–10

**Figure 12-20**  
Variation in flux, pressure, temperature, and specific flux during pilot testing.

to determine specific flux at a standard temperature. Variations in flux, pressure, temperature, and specific flux from a 7-month pilot study are shown on Fig. 12-20. The effect of chemical cleaning (manifested as lower pressure or higher specific flux) can be observed on Fig. 12-20.

#### OPERATING PARAMETERS

A basic operating parameter that should be varied during pilot testing is permeate flux. Pilot facilities and full-scale facilities normally operate with constant-flux, rising-pressure conditions. Flux and recovery determine the filtration area required to provide the required capacity, which is a

significant factor in determining the capital cost of a facility. Often, pilot testing demonstrates the existence of a critical limit to permeate flux, below which long-term operation is successful and above which pressure rise, backwash frequency, and cleaning frequency are unacceptable. Backwash and cleaning strategies should also be evaluated during the pilot study.

#### **PILOT PLANT UNITS**

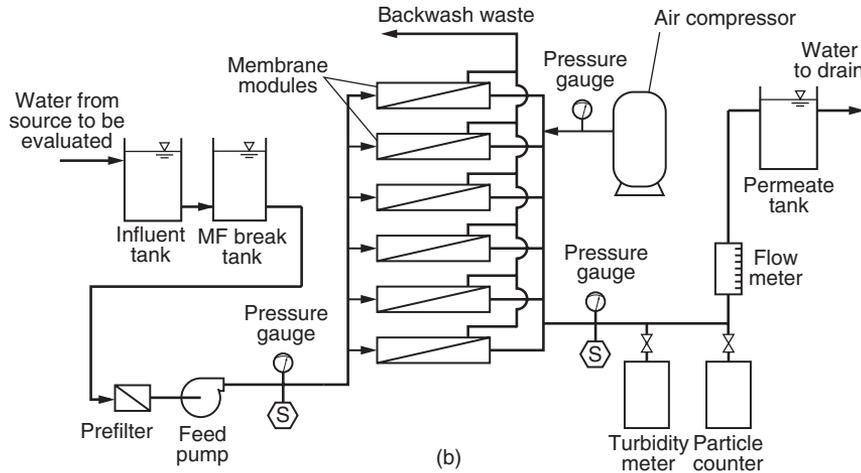

Most membrane manufacturers provide self-contained pilot plant units for use in evaluating performance. A typical skid-mounted membrane filtration pilot plant is shown on Fig. 12-21. Manufacturer-provided pilot plants typically contain all necessary equipment for their membrane system, including membrane modules, a feed tank, a feed pump, a backwash system with either an air compressor or liquid feed backwash pump, a clean-in-place system, permeate storage tank, all piping, valves, and instrumentation, and a programmable logic controller (PLC). The membrane modules are standard full-size modules identical to what would be provided on a full-scale system; the only difference is that a pilot unit typically will contain only 1 to 6 modules whereas a full-scale system may have 50 to 100 modules. Since the modules are identical and are tested with operating conditions that are identical to full-scale operation, the performance and fouling of the membranes can be expected to be very similar to that which would occur at full scale. Pilot plants may be designed with more instrumentation and operational flexibility than full-scale units to allow a range of testing conditions. Manufacturers typically supply specifications for pilot plant systems so they can be operated properly.

#### **PILOT TESTING EXPECTATIONS**

Pilot testing establishes the minimum performance requirements that can be accomplished by specific systems. For instance, the flux observed in pilot testing should be achievable in a full-scale facility by the same manufacturer, and the pilot testing can be used to set the minimum performance requirements for each manufacturer that will submit a bid for the project. Pilot testing provides a basis for comparing the effectiveness of alternative systems or new technologies. Individual design parameters, however, should not be compared directly when evaluating alternative systems. For instance, it would be inappropriate to use pilot testing to establish a minimum flux value as a requirement for all systems. A system operating at a low flux may be more cost effective if it operates at a lower pressure with less frequent backwash and clean sequences and has a lower cost per unit of filter area. Physical dimensions, capacity, and filtration area of individual modules, permeate flux, operating pressure, and backwashing and cleaning requirements, taken individually, generally are not a basis for comparing systems. Many parameters are interrelated and can only be compared on the basis of total system performance and cost.

plant.

#### SYSTEM DESIGN FROM PILOT DATA

The data generated during pilot testing can be used to design the full-scale facility. Membrane systems are routinely taken off-line for backwashing, integrity testing, and cleaning, which reduces the time available for permeate production. The percent of time that permeate is produced, or online production factor (AWWA, 2005b), is expressed as

$$\eta = \frac{1440 - t_{bw} - t_{dit} - t_{cip}}{1440} \quad (12-27)$$

where  $\eta$  = online production factor  
 $t_{bw}$  = time per day for backwashing, min  
 $t_{dit}$  = time per day for direct integrity testing, min  
 $t_{cip}$  = time for cleaning, prorated per day, min

The water produced during each filter run can be determined from the flux, membrane area, and run duration:

$$V_f = J a t_f \quad (12-28)$$

where  $V_f$  = volume of water filtered per filter run, L  
 $t_f$  = duration of filter run (excluding backwash time), min

The water consumed during backwashing should be recorded during the pilot testing. With that information and the volume of water filtered from Eq. 12-28, the recovery and the required feed flow rate can be calculated with Eq. 12-26. The amount of time that the system is not producing permeate and the quantity of water that must be used for backwashing both increase the required total membrane area:

$$a_t = \frac{Q_p}{J \eta r} = \frac{Q_f}{J \eta} \quad (12-29)$$

where  $a_t$  = total membrane area, m<sup>2</sup>  
 $r$  = recovery, unitless

Once the total membrane area is determined, the number of racks and modules per rack can be determined by relating the total required membrane area to the capabilities of the system. An example of the sizing of a full-scale membrane system from pilot data is demonstrated in Example 12-8.

### Residual-Handling Requirements

Residual handling from membrane filters is similar in many respects to residual handling from granular filters. However, the reduced or eliminated use of coagulants reduces the generation of sludge and simplifies sludge disposal in some cases. Some utilities discharge the waste washwater to the wastewater collection system and allow the sludge to be handled at the wastewater treatment plant rather than have separate sludge-handling facilities at the water treatment plant. Waste washwater can be clarified and returned to the plant influent or the source water, depending on regulatory constraints. The sludge can be thickened and dewatered similar to sludge from granular filters, and when coagulants are not used, the sludge is generally easier to thicken and dewater. Residual management is discussed further in Chap. 21.

### Example 12-8 Determining system size from pilot data

A treatment plant is to be designed to produce 75,700 m<sup>3</sup>/d (20 mgd) of treated water at 20°C. Pilot testing demonstrates that it can operate effectively at a flux of 65 L/m<sup>2</sup> · h at 20°C with a 2-min backwash cycle every 45 min and cleaning once per month. The membrane modules have 50 m<sup>2</sup> of membrane area. The pilot unit contained 3 membrane modules and the full-scale racks can contain up to 100 modules. Backwashes for the pilot unit consumed 300 L of treated water. Cleaning takes 4 h. Regulations require direct integrity testing, which takes 10 min, once per day.

Determine the following: (a) the online production factor, (b) system recovery, (c) feed flow rate, (d) total membrane area, (e) number of racks, and (f) number of modules per rack.

#### Solution

1. Determine the fraction of time the system is producing permeate.

$$t_{\text{bw}} = (2 \text{ min}) \left( \frac{1440 \text{ min/d}}{45 \text{ min}} \right) = 64 \text{ min/d}$$

$$t_{\text{dit}} = 10 \text{ min/d}$$

$$t_{\text{cip}} = \frac{(4 \text{ h})(60 \text{ min/h})}{30 \text{ d}} = 8 \text{ min/d}$$

$$\eta = \frac{1440 - t_{\text{bw}} - t_{\text{dit}} - t_{\text{cip}}}{1440} = \frac{1440 - 64 - 10 - 8 \text{ min/d}}{1440 \text{ min/d}} = 0.943$$

2. Determine the system recovery. The system recovery is the same for one element as for all elements and can be calculated using Eq. 12-26. For one element that filters for 43 min per cycle (2 min out of every cycle is backwash),

$$V_f = Jat_f = \frac{(65 \text{ L/m}^2 \cdot \text{h})(50.0 \text{ m}^2)(43 \text{ min})}{60 \text{ min/h}} = 2330 \text{ L}$$

$$V_{\text{bw}} = \frac{300 \text{ L}}{3 \text{ modules}} = 100 \text{ L}$$

$$r = \frac{V_f - V_{\text{bw}}}{V_f} = \frac{2330 \text{ L} - 100 \text{ L}}{2330 \text{ L}} = 0.957$$

3. Calculate required feed flow:

$$Q_f = \frac{Q_p}{r} = \frac{75,700 \text{ m}^3/\text{d}}{0.957} = 79,100 \text{ m}^3/\text{d}$$

4. Calculate the total membrane area required:

$$a = \frac{Q_f}{J_{\eta}} = \frac{(79,100 \text{ m}^3/\text{d})(10^3 \text{ L/m}^3)}{(65 \text{ L/m}^2 \cdot \text{h})(24 \text{ h/d})(0.943)} = 53,800 \text{ m}^2$$

5. Calculate the total number of modules required:

$$N_{\text{MOD}} = \frac{53,800 \text{ m}^2}{50 \text{ m}^2} = 1076$$

6. Determine the number of racks and modules/rack. Since the racks can accommodate up to 100 modules, at least 11 racks will be required. Dividing the required modules evenly among racks is preferred. In addition, leaving space in the racks is recommended as an inexpensive way to provide flexibility to reduce flux or increase capacity by adding additional modules in the future. Twelve racks are chosen in this example.

$$N_{\text{Racks}} = 12$$

$$N_{\text{MOD/Rack}} = \frac{1076}{12} = 90$$

The system will have 12 racks that each have 90 modules.

## Problems and Discussion Topics

- 12-1 Discuss the differences between MF and UF membranes. What impact do these differences have on their use in water treatment?
- 12-2 Discuss the similarities, differences, advantages, and disadvantages between membrane filtration and rapid granular filtration. This is an essay question.
- 12-3 How effective do you think membrane filtration is for each of the following treatment issues? Explain your reasoning.
- Arsenic
  - Anthrax spores
  - Hardness
  - Taste and odor
- 12-4 Calculate rejection and log removal value for the following filtration process (to be selected by instructor). Use the number of significant figures necessary to correctly illustrate the removal being obtained.

	A	B	C	D	E
Influent concentration (#/mL)	$10^6$	$6.85 \times 10^5$	$7.1 \times 10^5$	$1.65 \times 10^7$	$2.8 \times 10^6$
Effluent concentration (#/mL)	10	136	0.16	65	96

- 12-5 An inside-out hollow-fiber membrane system is operated with a cross-flow configuration. Each module contains 10,200 fibers that have an inside diameter of 0.9 mm and a length of 1.75 m. Calculate the following for one module:
- Feed flow necessary to achieve a cross-flow velocity of 1 m/s at the entrance to the module.
  - Permeate flow rate if the system maintains an average permeate flux of  $80 \text{ L/m}^2 \cdot \text{h}$ .
  - Cross-flow velocity at the exit to the module.
  - Ratio of the cross-flow velocity at the entrance of the module to the flow velocity toward the membrane surface. Given the magnitude of this ratio, what effect would you expect cross-flow velocity to have on fouling in cross-flow versus dead-end filtration?
  - Ratio of permeate flow rate to feed flow rate (known as the single-pass recovery). What impact does this ratio have on operational costs in cross-flow versus dead-end filtration?
- 12-6 Hollow-fiber membranes with a membrane area of  $23.3 \text{ cm}^2$  were tested in a laboratory and found to have the clean-water flow shown in the table below, at the given temperature and pressure.

	A	B	C	D	E
Flow (mL/min)	4.47	4.22	2.87	6.05	1.22
Temperature ( $^{\circ}\text{C}$ )	16	22	23	25	22
Pressure (bar)	0.67	0.80	0.71	1.25	0.21

- For the data set selected by your professor,
- Calculate the specific flux at  $20^{\circ}\text{C}$ .
  - Calculate the membrane resistance coefficient.
  - Does membrane resistance coefficient depend on the pressure and temperature used for the tests? Why or why not?
- 12-7 The  $0.2 \mu\text{m}$  polyethersulfone microfiltration membrane shown on Fig. 12-3 was tested in the laboratory and found to have a clean-water flux of  $6500 \text{ L/m}^2 \cdot \text{h}$  at  $23^{\circ}\text{C}$  and 0.69 bar. Assume that the flow through a microfiltration membrane can be modeled using the Kozeny equation for flow through porous media (Eq. 11-11 in Chap. 11).

- a. Calculate the specific surface area of the membrane assuming a porosity of 0.6, thickness of 0.10 mm, and Kozeny coefficient of 5.0.
  - b. What would the theoretical grain diameter be if the membrane were composed of spherical granular media with the same specific surface area (see Eq. 11-6)?
  - c. How does the theoretical grain diameter compare to the retention rating for the membrane? Using concepts of particle retention through granular media from Chap. 11, what does this comparison suggest about the mechanisms for particle removal in microfiltration?
  - d. Using the theoretical grain diameter as the characteristic dimension, calculate the Reynolds number for flow through a microfiltration membrane. Is the flow laminar or turbulent?
- 12-8 A membrane plant is operated at a volumetric flux of  $75 \text{ L/m}^2 \cdot \text{h}$  at  $17^\circ\text{C}$  and 0.85 bar. Calculate the specific flux at  $20^\circ\text{C}$ .
- 12-9 Feed water pressure and temperature and permeate flux at a membrane filtration plant are reported on two dates below. For the plant selected by your instructor, calculate the specific flux on each date, and indicate whether fouling has occurred between the first and second dates.

	A	B	C	D	E
Day 1					
Flux ( $\text{L/m}^2 \cdot \text{h}$ )	72	26	31	86	112
Temperature ( $^\circ\text{C}$ )	21	17	17	22	19
Pressure (bar)	0.62	0.24	0.24	0.72	0.66
Day 2					
Flux ( $\text{L/m}^2 \cdot \text{h}$ )	56	26	27	90	120
Temperature ( $^\circ\text{C}$ )	4	15	10	25	11
Pressure (bar)	0.80	0.29	0.26	0.77	1.05

- 12-10 A new membrane plant is being designed. Pilot testing indicates that the membrane will be able to operate at a specific flux of  $120 \text{ L/m}^2 \cdot \text{h} \cdot \text{bar}$  at  $20^\circ\text{C}$ . The full-scale plant will operate at 0.8 bar, online production factor of 95 percent, and recovery of 97 percent. Water demand projections predict a summer peak-day demand of  $90,000 \text{ m}^3/\text{d}$  and a winter peak-day demand of  $60,000 \text{ m}^3/\text{d}$ . Historical records indicate that the source water has a minimum temperature of  $3^\circ\text{C}$  in winter and  $18^\circ\text{C}$  in summer.
- a. Which season will govern the size (membrane area) of the plant?
  - b. What is the required membrane area?

- 12-11 An ultrafiltration membrane with a membrane resistance coefficient of  $2.7 \times 10^{12} \text{ m}^{-1}$  is used to filter a 150-mg/L suspension of 0.5- $\mu\text{m}$  latex particles in a laboratory unstirred dead-end filtration cell. The experiment is operated at a constant flux of  $120 \text{ L/m}^2 \cdot \text{h}$  and temperature of  $20^\circ\text{C}$ , and the membrane has an area of  $28.2 \text{ cm}^2$ . Assume that fouling is due to cake formation, the particle density is  $1050 \text{ kg/m}^3$ , the cake porosity is 0.38, and the Kozeny coefficient is 5. Neglecting the backmigration of particles due to diffusion, calculate and plot the transmembrane pressure and specific flux over the first 90 min of the filter run.
- 12-12 Show how the cake layer resistance coefficient (Eq. 12-12) can be derived from the Kozeny equation (Eq. 11-11 in Chap. 11) when the membrane feed water is a suspension of monodisperse, well-characterized particles.
- 12-13 A membrane plant containing  $1200 \text{ m}^2$  of membrane area operates at a constant permeate flux of  $45 \text{ L/m}^2 \cdot \text{h}$  at a temperature of  $15^\circ\text{C}$  and pressure of 0.25 bar immediately after backwash. The feed water contains 12 mg/L of suspended solids. After 40 min of operation, the pressure rises to 0.30 bar.
- Assuming that pressure rise between backwashes is due to formation of a cake layer, calculate the specific cake resistance.
  - If permeate flux is increased to  $50 \text{ L/m}^2 \cdot \text{h}$ , calculate the pressure immediately after backwash and the pressure after 40 min of operation.
- 12-14 Calculate the membrane fouling index for the following data, for the data set specified by your instructor.
- Experimental flat-sheet laboratory filter, membrane area =  $30 \text{ cm}^2$ , initial flux =  $3560 \text{ L/m}^2 \cdot \text{h} \cdot \text{bar}$ , test pressure = 0.69 bar, test temperature =  $23.9^\circ\text{C}$ .

Time, min	Permeate Volume, mL	Time, min	Permeate Volume, mL
0	0	6	458.3
1	108.8	7	506.8
2	199.8	8	552.1
3	277.4	9	594.1
4	345.0	10	634.1
5	404.2	11	670.8

- Full-scale plant operating at constant permeate flow of 15,000  $\text{m}^3/\text{day}$ , temperature =  $20^\circ\text{C}$ , 5800  $\text{m}^2$  of membrane area, pressure each day as shown below. Use day 0 as the initial flux.

Time, Day	Transmemb. Pressure, Bar	Time, Day	Transmemb. Pressure, Bar	Time, Day	Transmemb. Pressure, Bar
0	0.704				
2	0.712	12	0.747	22	0.786
4	0.721	14	0.754	24	0.794
6	0.726	16	0.765	26	0.801
8	0.735	18	0.770	28	0.812
10	0.740	20	0.777	30	0.812

- c. Data from a 30-min filter run in the middle of a day of laboratory testing of coagulated feed water, membrane area =  $23 \text{ cm}^2$ , initial flux =  $238 \text{ L/m}^2 \cdot \text{h} \cdot \text{bar}$ , test pressure = 2.07 bar, test temperature =  $21.5^\circ\text{C}$ .

Time, min	Permeate Volume, mL	Time, min	Permeate Volume, mL	Time, min	Permeate Volume, mL
0	2276.64				
2	2292.62	12	2370.17	22	2444.76
4	2308.41	14	2385.31	24	2459.35
6	2324.05	16	2400.33	26	2473.88

10	2354.92	20	2430.04		

- 12-15 A membrane filtration plant is to be designed using results from a pilot study. Treatment plant requirements and pilot results are given in the table below. For the selected system (to be specified by the instructor), determine (a) the online production factor, (b) system recovery, (c) feed flow rate, (d) total membrane area, (e) number of skids, and (f) number of modules per skid. The pilot system contained two membrane elements that had  $45 \text{ m}^2$  of membrane area each. In the full-scale plant, integrity testing will be required by regulations once per day and will take 15 min. Chemical cleaning (CIP) will take 4 h.

	A	B	C	D	E
Design capacity ( $\text{m}^3/\text{d}$ )	56,000	115,000	38,000	76,000	227,000
Memb. area in full-scale modules ( $\text{m}^2$ )	45	55	45	45	80
Max. modules in skid	80	90	80	80	100

	A	B	C	D	E
Pilot results					
Flux (L/m <sup>2</sup> · h)	80	125	40	80	110
