## Terminology for Disinfection

<b>Term</b>	<b>Definition</b>
Absorbance	Amount of light of a specified wavelength absorbed by the constituents in water.
Biodosimetry	Determination of the dose of a disinfectant to inactivate a specific biological test organism.
Breakpoint chlorination	Process in which chlorine is added to react with all oxidizable substances in water so that if additional chlorine is added it will remain as free chlorine (see below, $\text{HOCl} + \text{OCl}^-$ ).
Combined chlorine residual	Concentration of chlorine species resulting from the reaction of chlorine and ammonia, specifically the sum of monochloramine ( $\text{NH}_2\text{Cl}$ ), dichloramine ( $\text{NHCl}_2$ ), and trichloramine ( $\text{NCl}_3$ ), expressed as mg/L as $\text{Cl}_2$ .
<i>Ct</i>	Product of chlorine residual expressed in mg/L and contact time expressed in min. The term <i>Ct</i> is used to assess the effectiveness of the disinfection process for regulatory purposes.
Disinfection	Partial destruction and inactivation of disease-causing organisms from exposure to chemical agents (e.g., chlorine) or physical processes (e.g., UV irradiation).

<b>Term</b>	<b>Definition</b>
Decay rate	Rate at which the concentration of a disinfectant decreases over time.
Disinfection by-products (DBPs)	Undesirable products of reactions between disinfectants and other species in the feed water. DBPs of concern are those that are carcinogenic or have other negative health effects.
Dose–response curve	Relationship between the degree of microorganism inactivation and the dose of a disinfectant.
Free chlorine residual	Sum of the hypochlorous acid (HOCl) and hypochlorite ion (OCl <sup>-</sup> ) in solution, expressed as mg/L as Cl <sub>2</sub> .
Inactivation	Rendering microorganisms incapable of reproducing and thus limiting their ability to cause disease.
Pathogens	Microorganisms capable of causing disease.
Photoreactivation and dark repair	Methods used by microorganisms to repair the damage caused by exposure to UV irradiation.
Reactivation	Process by which organisms repair the damage caused by exposure to a disinfectant.
Sterilization	Total destruction of disease-causing and other organisms.
Transmittance	Ability of water to transmit light. Transmittance is related to absorbance.
Total chlorine residual	Sum of the concentrations of free and combined chlorine.
UV light	Portion of the electromagnetic spectrum between 100 and 400 nm.

The threat of microbiological contaminants in drinking water is eliminated by three complementary strategies: (1) preventing their access to the water source, (2) employing water treatment to reduce their concentration in the water, and (3) maximizing the integrity of the distribution system for finished water. Early in the history of public drinking water systems, the emphasis was almost entirely on gaining access to a protected source. In recent years, greater emphasis has been directed toward providing effective water treatment to reduce microbiological contaminants. Today, there is increasing emphasis on employing both source protection and treatment to ensure that safe water is produced and on improving distribution system integrity to ensure that contamination does not occur during transport from the treatment plant to the consumer's tap.

In the water treatment process, *reducing* microbiological contaminants is accomplished by two basic strategies, *removing* them from the water or *inactivating* them. Inactivated microorganisms, although still present in the water, are no longer able to cause disease in the consumer. Processes that

use inactivation as their strategy are traditionally referred to as disinfection, the focus of this chapter.

In water works practice, the term *disinfection* is used to refer to two activities: (1) primary disinfection—the inactivation of microorganisms in the water—and (2) secondary disinfection—maintaining a disinfectant residual in the treated-water distribution system. The characteristics that make a disinfectant the best choice for each of these purposes are not the same.

Primary disinfection is discussed in this chapter, along with the role disinfection plays in protecting the public, the strengths and weaknesses of inactivation versus removal, the kinetics of the disinfection process, and some specific details about the design of disinfection facilities. Disinfection by-products are discussed in Chap. 19.

## 13-1 Historical Perspective

---

Beginning a decade before the work of Dr. John Snow (1849 and 1853, see Chap. 3) and continuing for five decades after, two principal means were employed to control waterborne disease: (1) using water supplies not exposed to fecal contamination and (2) filtration through sand. At first, slow sand filtration was the dominant water treatment process; however, it was not always effective. The first efforts in rapid sand filtration were even less effective. Eventually George W. Fuller (1897) demonstrated that it is essential that complete coagulation precede the filtration step. Even with proper coagulation, however, filtration alone was not consistently successful in reducing the microorganisms to safe levels (Johnson, 1911; Whipple, 1906).

In 1881, not long before Fuller did his work on coagulation and filtration, Koch, the German scientist who demonstrated the role bacteria play in waterborne disease, also demonstrated that chlorine could inactivate pathogenic bacteria. The first continuous use of chlorination for disinfection of drinking water occurred in Middelkerke, Belgium, in 1902. The first continuous application to drinking water in the United States was at the Boonton Reservoir for the water works of Jersey City, New Jersey, in late 1908. In these first applications, disinfection was accomplished by feeding solid calcium hypochlorite. Soon after, liquid chlorine gas became available, making large-scale continuous chlorination more feasible. The first water treatment facility to use liquid chlorine gas on a permanent basis was in Philadelphia in 1913. Most of these early installations were used to address serious contamination or to avoid filtration, but in the three decades following the installation in Philadelphia, the practice of chlorination was expanded rapidly to include most surface water supplies, even those that were filtered. By 1941, 85 percent of the drinking water supplies in the United States were chlorinated (U.S. PHS, 1943). Also, by the 1940s, disinfection with chlorine had become a world water treatment standard and, even today, many water supplies are treated with chlorination alone.

The presence of a free chlorine residual in water at the tap was generally taken as a guarantee of microbiological safety by health officials and the public. Disinfection thus became established as the most important water treatment process. A more detailed discussion of the use of chlorine can be found in Baker (1948) and White (1999).

From the beginning, the use of chlorine has been contentious with many of its opponents arguing for the use of protected supplies in place of disinfection (Drown, 1893/1894). Equally important, a significant portion of the population has always had an aversion to the use of chlorine, complaining about its impact on the water's aesthetic qualities and wishing to avoid exposure to a chemical with such toxic properties, even at low concentrations. Largely for this second reason, ozone became the preferred primary disinfectant in much of mainland Europe in the late 1960s and 1970s.

In the mid-1970s, events took place that stimulated a reevaluation of disinfection practice. In Holland and the United States, researchers demonstrated that free chlorine reacts with natural organic matter (NOM) in water to produce chlorinated organics, specifically the trihalomethanes (THMs) (Bellar and Lichtenberg, 1974; Rook, 1974). Not long thereafter, limits were set on the allowable THM concentrations in potable water (U.S. EPA, 1979; WHO, 1994). Since then, more by-products have been identified resulting from chlorination and the use of other disinfectants (Bull et al., 1990). Limits have also been established for many of these by-products (U.S. EPA, 1998). It is likely that chemical by-products are formed any time an oxidant is employed in water treatment and that some of these by-products will be regulated in the future (Trussell, 1992, 1993).

During the last two decades of the twentieth century, events occurred that have also resulted in the questioning of the effectiveness of chlorination in controlling waterborne disease. In the 1980s, the protozoa *Giardia lamblia* was identified as an important waterborne pathogen. Because *G. lamblia* is more resistant to chlorine than other targets of disinfection, more stringent standards for reduction of pathogens were established (U.S. EPA, 1989). More recently, another protozoa, *Cryptosporidium parvum*, has also been identified as an important source of waterborne disease and is even more resistant to chlorine than *G. lamblia*. In fact, chlorination is ineffective for *C. parvum*.

The discovery of chlorination by-products and chlorine-resistant organisms is causing a reevaluation of the use of chlorine as the primary disinfectant and a reevaluation of the role of inactivation itself in the control of pathogens. For example, because methods are not available to determine if *C. parvum* oocysts found in water supplies will cause disease if ingested by a consumer, the Drinking Water Inspectorate in the United Kingdom recognizes only *removal*, not *inactivation*, as a viable strategy for addressing the control of this pathogen (U.K. Department of the Environment, 1999a,b).

New treatment processes have also come to the fore that show promise for the removal or inactivation of chlorine-resistant organisms and others as well. Membrane filtration processes, developed originally in the mid-1950s and later employed for sterilizing laboratory solutions, juices, and eventually brewed beverages, have now reached a stage in their development where they are commercially viable at large scale. Membranes are capable of removing pathogens much more effectively than traditional physical treatment processes such as coagulation and granular media filtration. In fact, the removals that have been demonstrated using membranes are on the same order of magnitude of inactivation of bacteria customarily achieved by chlorine (Jacangelo et al., 1989). Disinfection with UV light is also effective for inactivating *Giardia* (Stolarik et al., 2001) and *Cryptosporidium* (Craik et al., 2001). While chlorine remains the dominant drinking water disinfectant and disinfection (inactivation) remains the cornerstone of water treatment, this situation may change in the future.

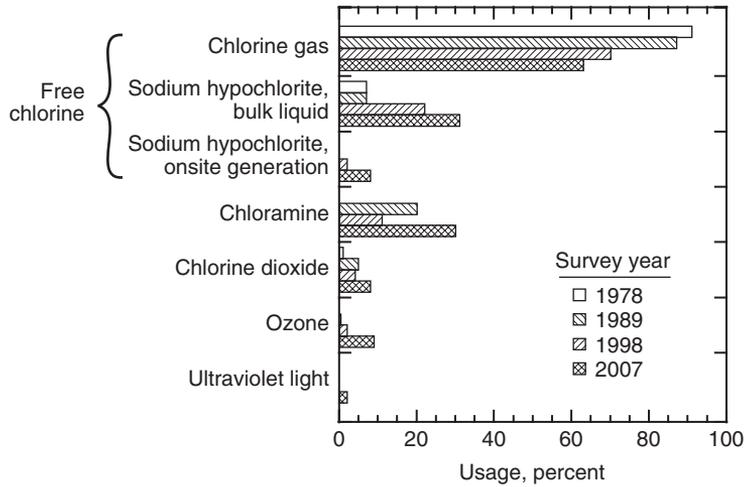

## 13-2 Methods of Disinfection Commonly Used in Water Treatment

---

Five disinfection agents are commonly used in drinking water treatment today: (1) free chlorine, (2) combined chlorine (chlorine combined with ammonia, also known as chloramines), (3) chlorine dioxide, (4) ozone, and (5) UV light. The first four are chemical oxidants, whereas UV light involves the use of electromagnetic radiation. Of the five, by far the most common in the United States is free chlorine. As shown on Fig. 13-1, surveys of disinfectant use by the American Water Works Association Disinfection Systems Committee in 1978, 1989, 1998, and 2007 found that nearly all water utilities in the United States use free chlorine, although the method of application has been changing over time (AWWA, 2008). In 1978, 91 percent of utilities used chlorine gas to apply free chlorine to the water and 7 percent used sodium hypochlorite (i.e., bleach). By 2007, however, only 63 percent of utilities were using chlorine gas and nearly 40 percent were using either bulk liquid or onsite generation of sodium hypochlorite. The transition from chlorine gas to hypochlorite is primarily because of safety and security reasons because chlorine gas is highly toxic.

As shown on Fig. 13-1, the number of utilities using chloramines for disinfection has increased to 30 percent by 2007. Its use, however, is often limited to residual maintenance, and typically a different disinfectant is used for primary disinfection when chloramine is used.

Ozone is the strongest of the four oxidants and its use has increased from less than 1 percent of utilities in 1989 to 9 percent in 2007. The increasing use is in part because of its stronger disinfecting properties and in part because it controls taste and odor compounds, specifically geosmin

**Figure 13-1**  
Disinfectant use in municipal drinking water treatment in the United States. (Adapted from AWWA 2008.)

and methyl isoborneol. UV light is not frequently used for disinfecting in drinking water applications, with only 2 percent of utilities reporting to use it in 2007. Its use may increase in the future, however, because of its lack of by-product generation and its effectiveness against protozoa. Information on each of these common disinfectants is summarized in Table 13-1.

Historically, chlorine was added to the raw water at a treatment plant and disinfection occurred during contact over the residence time of the entire plant. This practice has become obsolete and disinfection is now best applied as a separate unit process. The chemical disinfectants are most often applied in baffled, serpentine contact chambers or long pipelines when these are available. Both types of contactors can be designed to be highly efficient, closely approaching ideal plug flow. Additionally, ozone can be introduced in over–under baffled contactors. Over–under baffled contactors, however, have bigger problems with short circuiting, so pipeline and serpentine basin contactors have become more common for ozone disinfection. Design of contactors for chemical disinfectants is discussed in Sec. 13-8 in this chapter.

Ultraviolet light disinfection is often applied in proprietary reactors. Short circuiting is a special concern for UV reactors, particularly the proprietary reactors because their contact times are so short. Proprietary pressure vessels are particularly common where medium-pressure UV lamps are used because the high intensity of the UV lamps enables the delivery of a high UV dosage in a small space. Standards to address these issues exist in Europe (DVGW, 1997) and are being developed in the United States (NWRI, 2003; U.S. EPA, 2006).

**Table 13-1**  
 Characteristics of five most common disinfectants

Issue	Disinfectant				
	Free Chlorine	Combined Chlorine	Chlorine Dioxide	Ozone	Ultraviolet Light
Effectiveness in disinfection					
Bacteria	Excellent	Good	Excellent	Excellent	Good
Viruses	Excellent	Fair	Excellent	Excellent	Fair
Protozoa	Fair to poor	Poor	Good	Good	Excellent
Endospores	Good to poor	Poor	Fair	Excellent	Fair
Regulatory limit on residuals	4 mg/L	4 mg/L	0.8 mg/L	—	—
Formation of chemical by-products					
Regulated by-products	Forms 4 THMs <sup>a</sup> and 5 HAAs <sup>b</sup>	Traces of THMs and HAAs	Chlorite	Bromate	None
By-products that may be regulated in future	Several	Cyanogen halides, NDMA <sup>c</sup>	Chlorate	Biodegradable organic carbon	None known
Typical application					

Dose, mg/L (kg/ML)	1–6	2–6	0.2–1.5	1–5	20–100 mJ/cm <sup>2</sup>
Dose, lb/MG	8–50	17–50	2–13	8–42	—
Chemical source	Delivered: as liquid gas in tank cars, 1 tonne and 68-kg (150-lb) cylinders, or as liquid bleach. Onsite generation from salt and water using electrolysis. Calcium hypochlorite powder is used for very small applications.	Same sources for chlorine. Ammonia is delivered as aqua ammonia solution, liquid gas in cylinders, or solid ammonium sulfate. Chlorine and ammonia are mixed in treatment process.	ClO <sub>2</sub> is manufactured with an onsite generator from chlorine and chlorite. Same sources for chlorine. Chlorite as powder or stabilized liquid solution.	Manufactured onsite using a corona discharge in dry air or pure oxygen. Oxygen is usually delivered as a liquid. Oxygen can also be manufactured onsite.	Uses low-pressure or low-pressure, high-intensity UV (254-nm) or medium-pressure UV (several wavelengths) lamps in the contactor itself.

<sup>a</sup>THMs = trihalomethanes.

<sup>b</sup>HAA5 = haloacetic acids.

<sup>c</sup>NDMA = N: nitrosodimethylamine.

### 13-3 Disinfection Kinetics

---

For chemical disinfectants, the specific mechanisms of microorganism inactivation are not well understood. Inactivation depends on the properties of each microorganism, the disinfectant, and the water. As will be shown later, the reaction rates that have been observed can vary by as much as six orders of magnitude from one organism to the next, even for one disinfectant. Even for disinfection reactions where the reaction mechanism is well understood, for example, UV light, reaction rates vary by one and one-half orders of magnitude.

Nevertheless, there is one simple kinetic model that is widely used, and there is enough commonality in the behavior of all these reactions to allow the development of some phenomenological laws that are useful in modeling all of these reactions. As these disinfection processes are physiochemical processes, they are also subject to the rules of analysis discussed in Chaps. 6 and 7. In the following discussion, the form of disinfection data resulting from laboratory experiments is examined by considering the shape of classical disinfection kinetic plots. Following this discussion, useful phenomenological kinetic models are discussed along with the merits of each.

#### Classical Disinfection Kinetics— Chick–Watson

Near the beginning of the twentieth century, Dr. Harriet Chick, a research assistant at the Lister Institute of Preventive Medicine in Chelsea, England, proposed that disinfection could be modeled as a first-order reaction with respect to the concentration of the organisms. Chick demonstrated her concept by plotting the concentration of viable organisms versus time on a semilog graph for disinfection data for a broad variety of disinfectants and organisms (Chick, 1908). Chick worked with disinfectants such as phenol, mercuric chloride, and silver nitrate and organisms such as *Salmonella typhi*, *Salmonella paratyphi*, *Escherichia coli*, *Staphylococcus aureus*, *Yersinia pestis*, and *Bacillus anthracis*. Over the subsequent years “Chick’s law” has been shown to be broadly applicable to disinfection data. Chick’s law takes the form

$$r = -k_c N \quad (13-1)$$

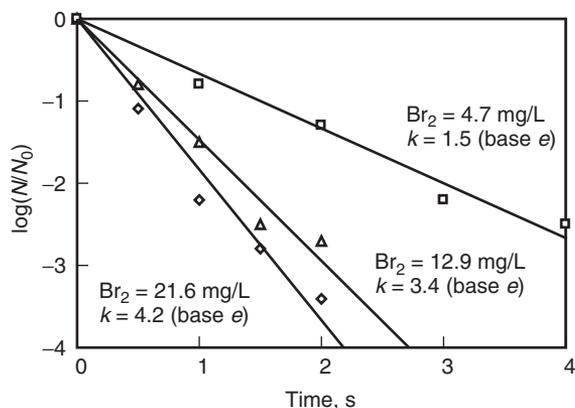

where  $r$  = reaction rate for the decrease in viable organisms with time,  
org/L·min

$k_c$  = Chick’s law rate constant, min<sup>-1</sup>

$N$  = concentration of organisms, org/L

Application of Chick’s concept met with immediate success, and that success has continued through the years and across all the disciplines interested in disinfection.

While Chick’s law has broad applicability, one important effect not addressed in the model is the effect of the concentration of the disinfectant. Frequently, different concentrations of disinfectant will lead to different

**Figure 13-2**  
Inactivation of poliovirus type I with three concentrations of bromine in a batch reactor. (Adapted from Floyd et al., 1978.)

rates in the decrease in viable organisms, as illustrated on Fig. 13-2. Note that there is a different slope for each concentration of bromine and, using Eq. 13-1, the reaction has a different rate constant for each concentration. Thus, while Chick's first-order concept is consistent with the data, a better means for accounting for disinfectant concentration is necessary.

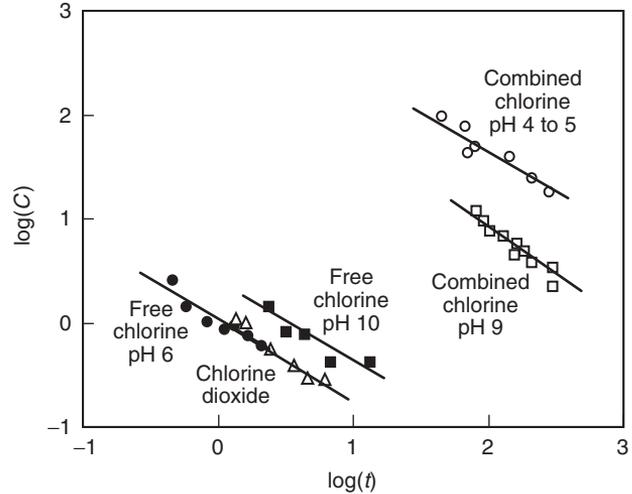

In the same year that Chick proposed her model, Herbert Watson proposed that the time needed to reach a specific level of disinfection was related to the disinfectant concentration by the equation (Watson, 1908)

$$C^n t = \text{constant} \quad (13-2)$$

where  $C$  = concentration of disinfectant, mg/L  
 $n$  = empirical constant related to concentration, unitless  
 $t$  = time required to achieve a constant percentage of inactivation (e.g., 99%)  
 constant = value for given percentage of inactivation, dimensionless

Watson demonstrated the concept by plotting data showing equal inactivation on a plot of  $\log(C)$  versus  $\log(t)$ . The slope of the log-log plot,  $n$ , is often called the coefficient of dilution, which reflects the effect of diluting the disinfectant (Morris, 1975). Such plots are still used today, and an example is shown on Fig. 13-3. As a matter of convention, Watson plots are generally constructed with data corresponding to a removal of 99 percent. In such plots, the dilution coefficient is generally found to be approximately 1, and given the inaccuracies involved in collecting disinfection data, there is little evidence for a dilution coefficient other than unity. A dilution coefficient equal to 1 suggests that disinfection concentration and time are of equal importance for inactivating microorganisms.

With the knowledge that disinfection concentration and time are of equal importance, Chick's law and the Watson equation can be combined

**Figure 13-3**

Watson plot of requirements for 99 percent inactivation of poliovirus type I. (Adapted from Scarpino et al., 1977.)

and are often referred to as the “Chick–Watson model” (Haas and Karra, 1984):

$$r = -\Lambda_{CW} CN \quad (13-3)$$

where  $\Lambda_{CW}$  = coefficient of specific lethality (disinfection rate constant),  
L/mg·min

$C$  = concentration of disinfectant, mg/L

Most laboratory disinfection studies are conducted using completely mixed batch reactors (CMBR). Using concepts presented in Chap. 6, a mass balance on a batch reactor can be written and integrated, leading to

$$\ln \left( \frac{N}{N_0} \right) = -\Lambda_{CW} Ct \quad (13-4)$$

where  $N_0$  = concentration of organisms at time = 0, org/L

$t$  = time, min

It is important to note that even though laboratory disinfection studies typically use batch reactors, the rate equation (Eq. 13-3) can be applied to other reactors using the concepts presented in Chap. 6.

When Chick did her work, she plotted the organism concentration directly against time on a semilog graph [ $\log(N)$  vs.  $t$ ]. Now that Eq. 13-4 has received broad recognition, it is more common to plot the log or natural log of the survival ratio, where  $S = N/N_0$ , versus time [ $\ln(N/N_0)$  or  $\log(N/N_0)$  vs.  $t$ ]. In disinfection studies, however, it is typically difficult to get an accurate measurement of the initial concentration of organisms,  $N_0$ , even with several replicates of the tests. As a result, a line fit through the data may not pass through zero

[i.e.,  $\ln(N/N_0)_{t=0} \neq 0$ ]. Although it is not consistent with the definition of  $N_0$  [at  $t = 0, \ln(N/N_0) \equiv 0$ ], it is often best to find the coefficient of specific lethality without forcing the regression line to pass through zero.

Equation 13-4 was derived using calculus so the term on the left is a natural logarithm (i.e., base  $e$ ). However, disinfection effectiveness is typically expressed using the log removal value (LRV), which uses base 10 logarithms as described in Sec. 4-5. Thus, it is necessary to convert between natural and base 10 logarithms when evaluating disinfection data. The use of Eq. 13-4 to determine the coefficient of specific lethality for a disinfection reaction is demonstrated in Example 13-1.

### Example 13-1 Application of the Chick–Watson model

Plot the data shown on Fig. 13-2, as given below, according to Eq. 13-4. Determine the coefficient of specific lethality and the coefficient of determination ( $r^2$ ). The data for the inactivation of poliovirus type I with bromine (Floyd et al., 1978) are provided in the following table:

C, mg/L	Time, s	$\log(N/N_0)$	C, mg/L	Time, s	$\log(N/N_0)$
21.6	0	0	12.9	1.5	-2.5
21.6	0.5	-1.1	12.9	2	-2.7
21.6	1	-2.2	4.7	1	-0.8
21.6	1.5	-2.8	4.7	2	-1.3
21.6	2	-3.4	4.7	3	-2.2
12.9	0.5	-0.8	4.7	4	-2.5
12.9	1	-1.5			

#### Solution

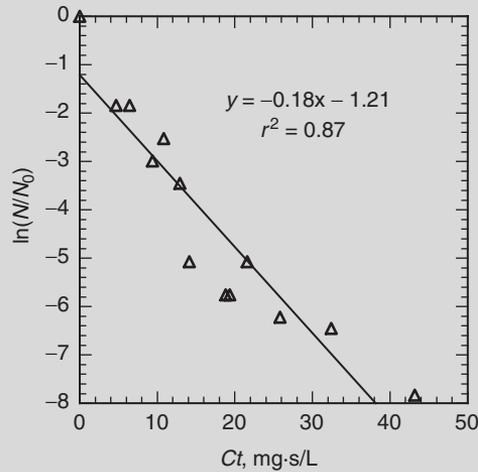

1. Determine the values of  $Ct$  and  $\ln(N/N_0)$  for each organism survival value.
  - a.  $Ct$  is calculated simply by multiplying  $C$  by  $t$ .
  - b. To convert from base 10 to base  $e$  logarithms, recall the logarithmic identity  $\log_b(x) = \log_a(x)/\log_a(b)$ , thus:

$$\ln(N/N_0) = \frac{\log(N/N_0)}{\log(e)} = 2.303 \log\left(\frac{N}{N_0}\right)$$

c. The required data table is shown below:

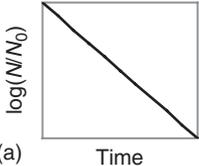

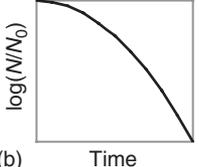

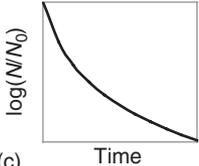

Time, s	C, mg/L	Ct, mg · s/L	$\ln(N/N_0)$	Time, s	C, mg/L	Ct, mg · s/L	$\ln(N/N_0)$
0.5	21.6	10.8	-2.53	1.5	12.9	19.4	-5.76
1	21.6	21.6	-5.07	2	12.9	25.8	-6.22
1.5	21.6	32.4	-6.45	1	4.7	4.7	-1.84
2	21.6	43.2	-7.83	2	4.7	9.4	-2.99
0.5	12.9	6.5	-1.84	3	4.7	14.1	-5.07
1	12.9	12.9	-3.45	4	4.7	18.8	-5.76

- Prepare a plot of  $\ln(N/N_0)$  as a function of Ct and fit a linear trendline through the data. Select trendline options to display the equation and  $r^2$  value.
- The required plot is shown below.

- The slope of the line in the above plot corresponds to the coefficient of specific lethality,  $\Delta_{CW}$ . From the plot  $\Delta_{CW} = 0.18$  and  $r^2 = 0.87$ .

Disinfection data do not always conform to Chick's linear semilog plot. Two anomalies, accelerating rate and decelerating rate, as illustrated on Fig. 13-4, sometimes occur. Reasons often cited in the literature for these particular curve shapes and the circumstances (organism, disinfectant, and magnitude of disinfection) under which each type of curve is sometimes found are also given. Contemporary kinetic models that describe these alternate forms of disinfection data are described in the next section.

Shape of semilog plot of disinfection data	Reasons for shape	Examples
 <p>(a)</p>	<p><b>Pseudo-first order</b> The most common form of disinfection data.</p> <ol style="list-style-type: none"> <li>1. Data fit Chick's law.</li> </ol>	<p><b>Free chlorine:</b> <i>E. coli</i>, poliovirus</p> <p><b>Ozone:</b> Poliovirus, <i>E. coli</i>, <i>G. Lamblia</i>, and <i>C. parvum</i></p> <p><b>UV:</b> <i>C. parvum</i>, MS2 (&lt;4 log), and <i>G. lamblia</i> (&lt;3 log)</p>
 <p>(b)</p>	<p><b>Accelerating rate</b> Often observed at low disinfectant doses. Possible reasons include:</p> <ol style="list-style-type: none"> <li>1. Disinfectant must react with more than one critical site in organism (Rahn, 1973; et al., 1975).</li> <li>2. Disinfectant must take time to diffuse to critical site (Collins and Selleck, 1971).</li> <li>3. Natural heterogeneity in resistance among organisms (Kim et al., 2002a).</li> </ol>	<p><b>Combined chlorine:</b> Most organisms at low inactivation</p> <p><b>Any disinfectant:</b> Suspension of aggregated virus particles of multicellular organisms</p> <p><b>Chlorine dioxide:</b> <i>C. parvum</i>, endospores</p>

**Figure 13-4**  
Graphical forms of disinfection data.

As discussed earlier, only a limited understanding of the specific mechanisms for the various disinfection reactions is now available. Substantially different kinetics mechanisms may control the rate of inactivation of different microorganisms with the same disinfectant or the same microorganisms with different disinfectants. There is extensive literature on disinfection modeling; two of these models are presented in the following discussion because they are useful in modeling many common disinfection reactions. The models discussed below may be used to model disinfection data for reactions with accelerating and/or decelerating rates on a semilog plot (Figs. 13-4b,c).

## Contemporary Kinetic Models

**RENNECKER–MARIÑAS MODEL (ACCELERATING RATE)**

Some organisms do not exhibit significant inactivation until a certain  $Ct$  value has been exceeded. This inactivation response is observed, for example, when chemical disinfectants are applied to oocysts and endospores. The Mariñas group at the University of Illinois has recently addressed this situation by proposing the use of a lag coefficient,  $b$  for Eq. 13-4 (Kim et al., 1999; Rennecker et al., 1997, 2001). The Rennecker–Mariñas model can be summarized as follows:

$$\ln\left(\frac{N}{N_0}\right) = \begin{cases} 0 & \text{for } Ct < b \\ -\Lambda_{CW}(Ct - b) & \text{for } Ct \geq b \end{cases} \quad (13-5)$$

where  $b$  = lag coefficient,  $\text{mg} \cdot \text{min}/\text{L}$

The lag coefficient  $b$  is the maximum value of  $Ct$  at which  $\ln(N/N_0) = \ln(S_0) = 0$  (i.e., no inactivation has occurred). When  $b$  is zero, Eq. 13-6 corresponds to Eq. 13-4. It should be noted that the presentation of the mathematics used in the analysis of Eqs. 13-5 and 13-6 is consistent with but not identical to the approach used by Rennecker et al. (1997). The Rennecker–Mariñas model is demonstrated in Example 13-2.

### Example 13-2 Application of the Rennecker–Mariñas model

Apply the Rennecker–Mariñas model to evaluate the coefficient of specific lethality and the lag coefficient for the inactivation of *C. parvum* using chlorine dioxide ( $\text{ClO}_2$ ) based on the data given below. As shown in the data table, inactivation was measured at three concentrations of  $\text{ClO}_2$  and at several time intervals. In analyzing the data, do not assume that it was possible to measure  $N_0$  accurately (i.e.,  $N/N_0 \neq 0$  for  $Ct < b$ ; instead, require  $N/N_0 = \text{constant}$  for  $Ct < b$ ). Analyze the data by developing a spreadsheet solution and use the Solver function in Excel to determine the model parameters. Also calculate the coefficient of determination ( $r^2$ ). Data for the inactivation of *C. parvum* by  $\text{ClO}_2$  (Corona-Vasquez et al., 2002) are provided in the following table:

C, mg/L	t, min	$\log(N/N_0)$	C, mg/L	t, min	$\log(N/N_0)$
0.96	0.0	-0.21	0.48	122.0	-1.08
0.96	15.5	-0.25	0.48	152.0	-1.68
0.96	30.8	-0.38	4.64	0.0	-0.15
0.96	46.1	-0.55	4.64	2.1	0.02

C, mg/L	t, min	log(N/N <sub>0</sub> )	C, mg/L	t, min	log(N/N <sub>0</sub> )
0.96	61.2	-1.04	4.64	4.2	-0.11
0.96	76.2	-1.66	4.64	6.2	-0.19
0.96	91.1	-2.03	4.64	8.2	-0.29
0.48	0.0	-0.17	4.64	10.0	-0.56
0.48	32.0	-0.12	4.64	12.0	-0.79
0.48	61.6	-0.31	4.64	13.9	-1.19
0.48	92.0	-0.60	4.64	15.8	-1.47

### Solution

Construct a spreadsheet, as shown below, for analysis of the data and determination of the model parameters. Because the Solver function will be used, some of the calculations will need to be automated using advanced features of Excel, including the IF function, as described below.

1. Compute the value of  $Ct$  for each experiment and enter the corresponding inactivation value into the spreadsheet.
2. The measured log survival ratios are entered into the column labeled Data in the table below.
3. The value of the model parameters can be determined using an IF statement of the form "IF [ $Ct < b, \log(S_0), \log(S_0) + \text{slope}(b - Ct)$ ]."
4. Solver is used to minimize the sum of the  $[\text{Data} - \text{model}]^2$  column by varying  $b$ , slope, and  $\log(S_0)$ . The results are displayed in the following table and figure:

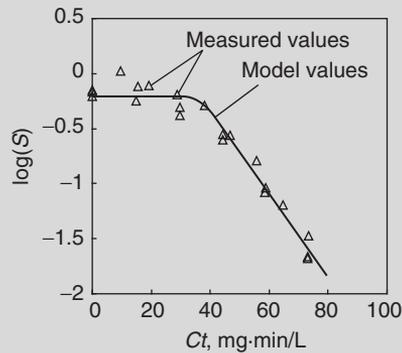

### Spreadsheet setup for model evaluation

Ct, mg · min/L	log(N/N <sub>0</sub> )		[Data-Model] <sup>2</sup>	[Data-Data <sub>avg</sub> ] <sup>2</sup>
	Data	Model		
0.0	-0.21	-0.2	0.001	0.216
14.9	-0.25	-0.2	0.004	0.182
29.6	-0.38	-0.2	0.036	0.089
44.3	-0.55	-0.5	0.001	0.015
58.8	-1.04	-1.0	0.000	0.138
73.2	-1.66	-1.6	0.010	0.972
87.5	-2.03	-2.1	0.001	1.852
0.0	-0.17	-0.2	0.000	0.259
15.4	-0.12	-0.2	0.005	0.310
29.6	-0.31	-0.2	0.016	0.130
44.2	-0.60	-0.5	0.007	0.005
58.6	-1.08	-1.0	0.002	0.167

*(continued)*

(continued)

Ct, mg · min/L	log(N/N <sub>0</sub> )		[Data-Model] <sup>2</sup>	[Data-Data <sub>avg</sub> ] <sup>2</sup>
	Data	Model		
73.0	-1.68	-1.6	0.017	1.016
0.0	-0.15	-0.2	0.001	0.277
9.7	0.02	-0.2	0.043	0.483
19.3	-0.11	-0.2	0.006	0.319
28.8	-0.19	-0.2	0.000	0.230
38.2	-0.29	-0.3	0.000	0.147
46.6	-0.56	-0.6	0.002	0.012
55.6	-0.79	-0.9	0.020	0.013
64.6	-1.19	-1.3	0.003	0.271
73.5	-1.47	-1.6	0.009	0.642
Average:	-0.67	Sum:	0.184	7.745

5. Solver minimizes the value of the sum of the [Data-model]<sup>2</sup> when the following values are used:

$$b = 34.9 \text{ mg} \cdot \text{min/L}$$

$$\text{Slope} = 0.036$$

$$\log(N/N_0) = -0.19$$

6. Since the data was plotted on a log (base 10) scale, the coefficient of specific lethality is calculated by dividing the slope by log(e):

$$\Delta_{CW} = (\text{slope base } e) / \log(e) = 0.036 (2.303) = 0.083 \text{ L/mg} \cdot \text{min}$$

7. The coefficient of determination ( $r^2$ ) is calculated using the data in the spreadsheet as follows:

$$r^2 = 1 - \frac{\sum [\text{Data} - \text{model}]^2}{\sum [\text{Data} - \text{data}_{\text{ave}}]^2} = 1 - \frac{0.184}{7.745} = 0.98$$

**COLLINS–SELLECK MODEL (DECELERATING RATE)**

The Collins–Selleck model was developed specifically to address the inactivation of coliform organisms in domestic wastewater using free and combined chlorine (Collins and Selleck, 1971; Selleck and Saunier, 1978; Selleck, et al., 1970), but it has proven valuable for modeling the behavior of a number of other disinfection alternatives as well. The Collins–Selleck model is particularly useful when a declining rate of disinfection is observed (convex curve on Fig. 13-4c). The form of the Collins–Selleck model first published in the literature did not include a lag effect (Selleck et al., 1970). Although the final formulation was published shortly after that (Collins and Selleck, 1971), it did not appear in the peer-reviewed literature until sometime later (Selleck and Saunier 1978), and there was some discussion about its form even at that time (Haas, 1979; Selleck et al., 1980). Collins and Selleck began with a simple formulation that describes a declining rate of inactivation with time as proposed by Gard (1957) and adapted it to the lag in inactivation often observed in real systems. For batch reactors, the model has the form

$$\ln\left(\frac{N}{N_0}\right) = \begin{cases} 0 & \text{for } Ct < b & (13-7) \\ -\Lambda_{CS}[\ln(Ct) - \ln(b)] & \text{for } Ct \geq b & (13-8) \end{cases}$$

where  $\Lambda_{CS}$  = Collins–Selleck coefficient of specific lethality, unitless  
 $b$  = lag coefficient, mg · min/L

An anomaly in the Collins–Selleck model is that the initial conditions are undefined because  $\ln(Ct)$  at  $t = 0$  is indeterminate. Nevertheless, there is a close parallel between the Collins–Selleck and Rennecker–Mariñas models. They have a similar form, but in the Rennecker–Mariñas model, the observed data are fit with a straight line when log survival is plotted versus  $Ct$ , whereas in the Collins–Selleck model, the data can be fit with a straight line when log survival is plotted versus  $\log(Ct)$ . Each model has only two parameters,  $\Lambda_{CW}$  or  $\Lambda_{CS}$  and  $b$ . Based on a large number of tests, it has been found that most disinfection data can be fit to one of these two models.

### Example 13-3 Comparison of Chick–Watson and Collins–Selleck models

The Collins–Selleck model is particularly useful for modeling a declining rate of disinfection such as observed in the disinfection of coliform in wastewater above a  $Ct$  value of approximately 100 mg · min/L. Data from Selleck and Saunier (1978) for the disinfection of total coliform in wastewater with chloramines are presented below. Fit the Chick–Watson model to the data for  $Ct$  values less than 100 mg · min/L and construct a plot of the

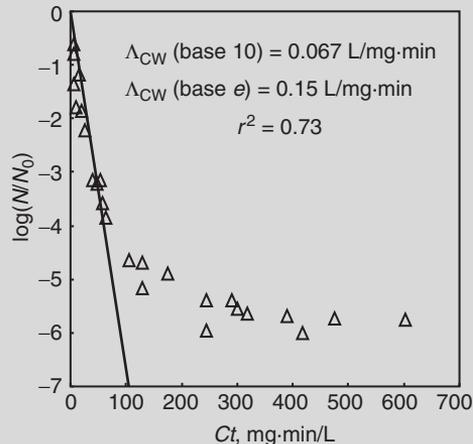

results. Also plot the remainder of the data for  $Ct$  values greater than 100 mg · min/L on the same plot. Prepare a separate plot to fit the data using the Collins–Selleck model.

$Ct$ , mg · min/L	$\log(N/N_0)$	$Ct$ , mg · min/L	$\log(N/N_0)$	$Ct$ , mg · min/L	$\log(N/N_0)$
5	-0.79	48	-3.21	244	-5.39
6	-0.61	54	-3.14	244	-5.96
6	-1.36	58	-3.57	291	-5.39
10	-1.79	64	-3.86	300	-5.54
15	-1.18	106	-4.64	319	-5.64
19	-1.86	130	-4.68	390	-5.68
26	-2.21	130	-5.16	417	-6
39	-3.14	175	-4.89	476	-5.74
				602	-5.75

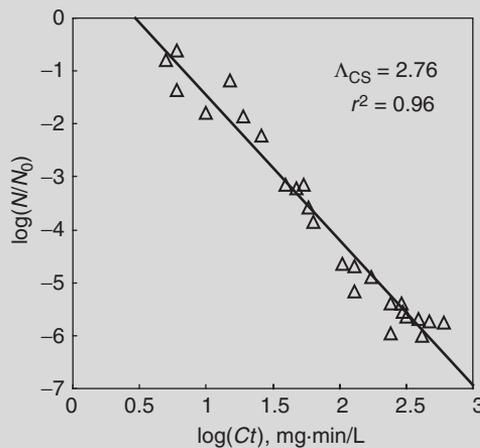

### Solution

1. Application of the Chick–Watson model:
  - a. The 12 data points with  $Ct$  values less than 100 mg · min/L are put in an Excel spreadsheet and  $\log(N/N_0)$  is plotted as a function of  $Ct$ .
  - b. Use the trendline function to fit a line through the data. Select options to fit the line through the origin and to display the equation. As shown in the plot, the slope of the linear trendline (base 10) is 0.067 L/mg · min. Converting to base  $e$  by dividing by  $\log(e)$ , the following value is obtained:

$$\Delta_{CW} (\text{base } e) = 0.067(2.303) = 0.15 \text{ L/mg} \cdot \text{min}$$

2. Application of the Collins–Selleck model:
  - a. All 25 data points are put in an Excel spreadsheet and  $\log(N/N_0)$  is plotted as a function of  $\log(Ct)$ .
  - b. The linear trendline is used to determine the slope of the best-fit line.
  - c. The slope of the trendline that corresponds to  $\Delta_{CS}$  (base 10) is equal to 2.76. The value of the intercept  $b$  (base 10) is 1.32 mg · min/L. The corresponding base  $e$  values are the same. These results are displayed below:

### Comment

As shown in this example, the Collins–Selleck model was used effectively to model declining rate disinfection. Based on numerous studies, it has been found that the Collins–Selleck model can be used for a variety of organism–disinfectant combinations where both a declining rate of disinfection and a lag in disinfection are important.

Some important characteristics of the disinfection models presented in this section are summarized in Table 13-2. The Chick–Watson model (Eq. 13-4) is not shown because it is a special case of the Rennecker–Mariñas model when  $b = 0$ . A selection of kinetic constants gathered from the literature are reported in Table 13-3. Constants are offered for the disinfection of total coliform from wastewater because this has long been a target organism in effluent reuse. Constants are presented for *E. coli* and poliovirus because these organisms have long been the targets of classical disinfection regulations. Constants are presented for *Giardia* and *Cryptosporidium* because the difficulty in inactivating these organisms is having profound effects on

water treatment regulations. Constants are presented for *Bacillus subtilis* because its behavior in disinfection is thought to be similar to *B. anthracis*, a possible organism that may be used by terrorists.

Chick's experiments were conducted with constant disinfectant concentrations because excess disinfectant was present. In the laboratory, researchers generally attempt to maintain a constant disinfectant concentration so that disinfection rates can be measured with maximum precision. Given the complexities that exist in the microbiological world that can influence the outcome of such experiments, it is important to minimize variations in chemistry and physical conditions. A constant residual of combined chlorine can usually be achieved in full-scale contactors as well. With free chlorine and chlorine dioxide, a constant residual concentration can be maintained for short contact times. For these same disinfectants at longer contact times or for ozone at any contact time, one must account for residual decay.

Accounting for varying disinfection concentration can be addressed by dividing the problem into two parts: (1) modeling the decay of the disinfectant and (2) integrating that work into the model of the disinfection reaction itself. For all the common oxidizing disinfectants (chlorine, combined chlorine, chlorine dioxide, and ozone), it is often assumed that disinfectant decay can be modeled as first order, that is,

$$r_d = -k_d C \quad (13-9)$$

where  $r_d$  = reaction rate for the decline in disinfectant concentration with time, mg/L·s or mol/L·s  
 $k_d$  = first-order decay rate, s<sup>-1</sup>  
 $C$  = disinfectant concentration, mg/L or mol/L

The decay of these disinfectants is often characterized by two phases, an early phase of rapid decay followed by a later phase with slower decay. When two-phase decay occurs, a second-order model with a fast reaction step and a slow reaction step has been used successfully (Kim et al., 2002a; Lev and Regli, 1992), but this model is rather difficult to use because it cannot be solved analytically. Another alternative is the parallel first-order decay model proposed by Haas and Karra (1984b), in which it is assumed that decay may proceed through two mechanisms, each first order but involving a different component of the chlorine residual:

$$r_d = -xk_{d1}C - (1-x)k_{d2}C \quad (13-10)$$

where  $x$  = fraction of disinfectant decaying by the first mechanism, unitless  
 $C$  = concentration of disinfectant, mg/L or mol/L  
 $k_{d1}, k_{d2}$  = decay coefficient for two different mechanisms, s<sup>-1</sup>

The first component, with an initial concentration of  $x C_0$ , is subject to first-order decay with a faster rate constant,  $k_{d1}$ , and the second component,

## Declining Concentration of Chemical Disinfectant

with an initial concentration of  $(1 - x) C_0$ , is subject to first-order decay with a slower rate constant,  $k_{d2}$ . As noted above, the value of  $x$ , by definition, is between 0 and 1. When  $x = 0$ , the parallel first-order model becomes the simple first-order model; the same is true when  $x = 1$ .

Finding an analytical solution in which the decay reaction and the disinfection reaction are integrated together adds to the complexity of the mathematics used to describe the disinfection process. Where analytical solutions are not available, it is possible to use computer models to simulate the two processes in parallel. Haas and Joffe (1994) have developed an analytical solution for the Chick–Watson model.

### Influence of Temperature on Disinfection Kinetics

The effect of temperature on the rate of a chemical reaction is described by the Arrhenius equation, as discussed in Chap. 5, and is used here to describe the influence of temperature on the pseudo-first-order disinfection rate constant:

$$\ln(k_r) = \ln(A) + \left(-\frac{E_a}{R}\right) \left(\frac{1}{T}\right) \quad (5-85)$$

where  $k_r$  = appropriate reaction rate constant,  $k_c$ ,  $\Delta_{CW}$ ,  $\Delta_{CS}$ , or  $k_d$ .

$E_a$  = activation energy, J/mol

$R$  = universal gas constant, 8.314 J/(mol · K)

$T$  = reaction temperature, K ( $273 + ^\circ\text{C}$ )

$A$  = collision frequency parameter

Once the rate is known at one temperature, the rate at another temperature can be determined if the activation energy  $E_a$  is known. In the disinfection literature, an empirical approach used is to specify  $\theta$  in the following equation:

$$\frac{k_{r,T_1}}{k_{r,T_2}} = \theta^{T_1 - T_2} \quad (13-11)$$

where  $k_{r,T_1}$  = reaction rate constant at temperature 1

$k_{r,T_2}$  = reaction rate constant at temperature 2

$\theta$  = empirical constant, dimensionless

$T_1$  = temperature corresponding to known rate constant  $k_{r,T_1}$ , K ( $273 + ^\circ\text{C}$ )

$T_2$  = temperature corresponding to known rate constant  $k_{r,T_2}$ , K ( $273 + ^\circ\text{C}$ )

Combining Eqs. 5-85 and 13-11 and solving for  $\theta$ , the following expression is obtained:

$$\theta = e^{E_a/RT_1 T_2} \quad (13-12)$$

Because the product  $T_1 T_2$  is somewhat insensitive to changes in temperature, it is reasonable to assume  $\theta$  is constant in empirical approach. Values of  $E_a$  from the literature are summarized in Table 13-4.

**Table 13-4**

<sup>a</sup>Recommended value.

<sup>b</sup>Old oocysts.

The true, detailed kinetics of most chemical disinfectants are exceedingly complex, and they are influenced by the chemistry of the disinfectant as well as the nature of the susceptibility in the organism. Moreover, measuring disinfection effectiveness is difficult to do with great precision, partly because of the complexity of the chemical conditions but also due to the imprecise nature of most microbiological measurements. As a result, it is probably best to employ the simplest approach possible to describe the results of disinfection experiments. In order of increasing complexity, the following alternatives might be considered:

1. *Ct tables*. Numerical *Ct* (concentration × time) values are established to achieve a given degree of inactivation of a specific organism using a defined disinfectant under controlled conditions. This approach is

### Approaches to Relating Disinfection Kinetics to Disinfection Effectiveness

consistent with all the models presented in this section. Furthermore, the U.S. EPA uses this approach in regulating disinfection of drinking water. When required, different tables can be offered for a range of concentrations, as the U.S. EPA did for the inactivation of *G. lamblia* with free chlorine.

2. *Semilog plots of survival versus Ct values.* The use of semilog plots of log survival as a function of  $Ct$  is consistent with the Chick–Watson model and the Rennecker–Mariñas model. In this approach, it is assumed that the log survival values will plot as a linear function of time or the product  $Ct$  on a semilog plot and only one or two constants,  $\Lambda_{CW}$  and  $b$ , are required for application of the model. This approach is often successful when a modest degree of disinfection is required, a reduction of approximately 3 log inactivation, for example.
3. *Log-log plots of survival versus Ct values.* The use of log–log plots is consistent with the Collins–Selleck model. This approach is useful for situations where a lag time is present (complex organisms, slow disinfectants, etc.) or where a declining rate of disinfection with time is observed. This approach is also useful when disinfection requirements are substantial, for example, 4 log reduction or more. In the Collins–Selleck model, it is assumed that the log survival will plot as a linear function against  $\log(Ct)$  and that two constants,  $\Lambda_{CS}$  and  $b$ , are required for application of the model.

Generally, as disinfection models become more complex, the precision with which they can be used to describe the results of a given disinfection experiment improves. However, comparing the constants of the simpler models provides better perspective on the performance of different disinfectants and on the resistance of different organisms. The ability to compare results is one of the reasons that Chick's law and the Chick–Watson equation continue to be popular.

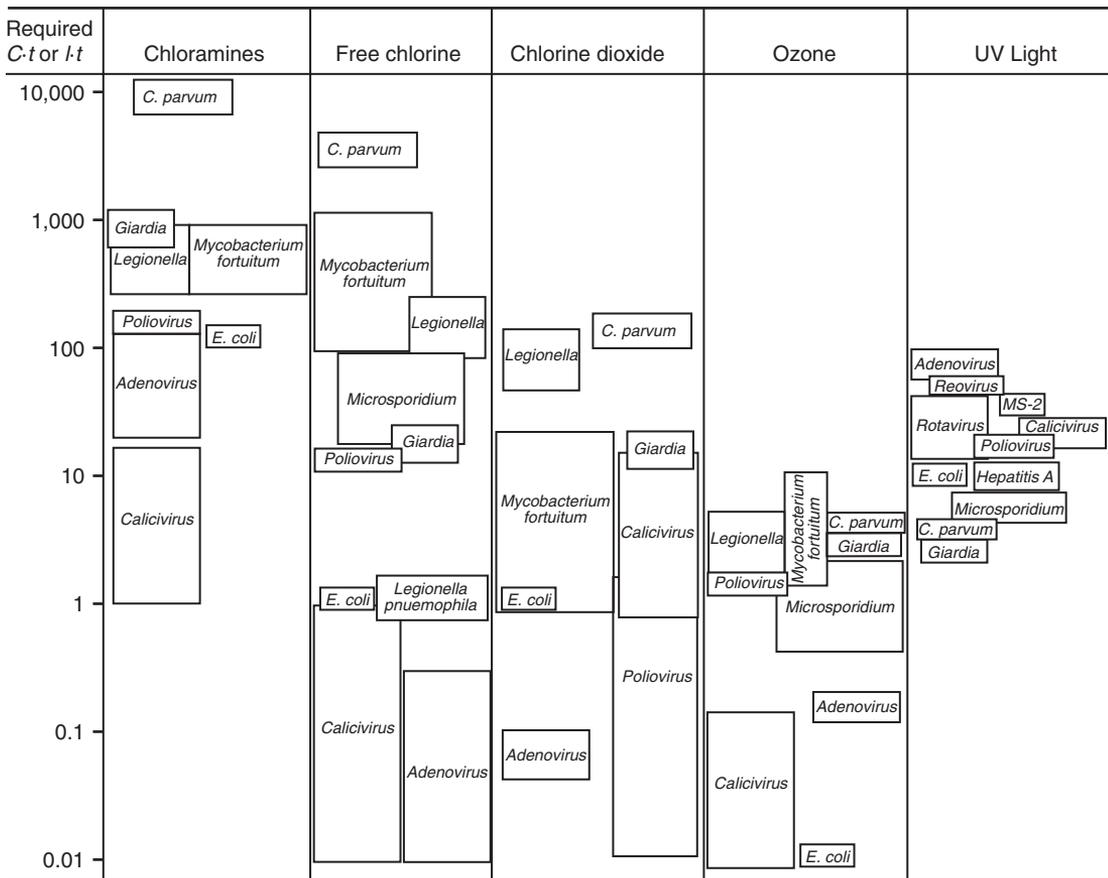

### The $Ct$ Approach to Disinfection

In each of the approaches discussed in the previous section, disinfection effectiveness was related to the product  $Ct$ . In fact, the product  $Ct$  has long been used as a basis for disinfection requirements. It is equally practical when the Collins–Selleck and Rennecker–Mariñas models are used. The  $Ct$  product required for achieving a given level of disinfection for a specific microorganism under defined conditions is a useful way of comparing alternate disinfectants and for comparing the resistance of a variety of pathogens. Indeed, the product  $Ct$  can be thought of as the dose of disinfectant.

The dose concept, analogous to  $Ct$ , is also applicable when UV light is used for disinfection. The product of the UV light intensity ( $\text{mW}/\text{cm}^2$ ) and the time of exposure is used to compute the dose ( $\text{mW}/\text{cm}^2 \times \text{s} = \text{mJ}/\text{cm}^2$ ). This product is often referred to as  $It$  (intensity  $\times$  time). Modeling disinfection with UV light using  $It$  in place of  $Ct$  in Eq. 13-4 has been

successful. There is probably greater justification for this equation for UV light because the mechanism of inactivation is not so much a function of light intensity but a function of exposure of the organism to a quantity of potentially damaging photons.

The *Ct* concept also allows for the development of a broad overview of the relative effectiveness of different disinfectants and the resistance of different organisms. The *Ct* required to produce a 99 percent (2 log) inactivation of several microorganisms using the five disinfection techniques most often used in water treatment is illustrated on Fig. 13-5. Because of the difference in the behavior from one organism and one disinfectant combination to the next, *Ct* and *It* products range over seven orders of magnitude. For example, the *Ct* product required to inactivate *C. parvum* must be three orders of magnitude higher with combined chlorine than with ozone. Comparing

**Figure 13-5** Overview of disinfection requirements for 99 percent inactivation. (Adapted from Jacangelo et al., 1997.)

UV disinfection to disinfection with chemical oxidants, little similarity exists between the  $It$  values and  $Ct$  values for a single organism. While the required UV doses vary over a range of two orders of magnitude, their variation is much less than that for other disinfectants. The reduced variation may be a result of the fact that UV disinfection of all microorganisms results from a similar protein dimerization mechanism.

The U.S. EPA began the practice of specifying  $Ct$  products that must be met as a way of regulating the control of pathogens in water treatment with the promulgation of the Surface Water Treatment Rule (U.S. EPA, 1989). Tables of  $Ct$  and  $It$  values required to meet the primary disinfection requirements are available in the *Surface Water Treatment Rule Guidance Manual* (U.S. EPA, 1991) available on the EPA website.

A limitation of the  $Ct$  approach is that the microorganisms in a real disinfection contactor are exposed to a distribution of contact times according to the contactor's residence time distribution (RTD), rather than all microorganisms being exposed to the disinfectant for the same amount of time. The RTD has a significant impact on disinfection effectiveness, as discussed in detail in the next section.

## 13-4 Disinfection Kinetics in Nonideal Flow-Through Reactors

---

The disinfection kinetics described in Sec. 13-3 were based on studies conducted in completely mixed batch reactors (CMBRs). While the insight obtained from batch reactors is useful, full-scale continuous-flow systems exhibit more complex nonideal behavior. Of particular importance is the impact of dispersion on the progress of the reaction.

Three approaches to modeling the performance of real (nonideal) reactors are introduced in Chap. 6: (1) the tanks-in-series (TIS) model, (2) the dispersed-flow model (DFM), and (3) the segregated-flow model (SFM). The TIS model simulates the effects of dispersion on the RTD curve by an analogy between a real reactor and a series of completely mixed flow reactors (CMFRs). The parameter that describes dispersion in the TIS model is the number of reactors in series,  $n$ . A high value of  $n$  corresponds to low dispersion.

The DFM simulates the effects of dispersion on the RTD by including mass transport by axial dispersion in addition to advection into the mass balance of a plug flow reactor (PFR). In the DFM, dispersion is described using the Peclet number ( $Pe$ ) or the dispersion number ( $d, Pe = 1/d$ ). A high value of  $Pe$  or a low value of  $d$  corresponds to low dispersion.

The SFM, presented in Sec. 6-9, simulates the effects of nonideal mixing by an analogy between a real reactor and a series of parallel PFRs having detention times that, in sum, match the RTD of the real reactor. While the TIS model and the DFM incorporate assumptions about the nature of the RTD curve, an RTD curve must be provided to use the SFM.

In the TIS model, it is assumed that all the reactants are mixed completely throughout each reactor at all times. In the DFM, it is assumed that all

reactants are mixed completely in the lateral direction but axial transport occurs by advection and dispersion. When dispersion is low, the TIS and DFM models produce similar results. In the SFM, it is assumed that the reactants are never completely blended in the reactor; rather the target reactant travels through the reactor in small cells or discrete elements that react with the bulk solution.

Disinfection processes are an ideal application of the SFM because microorganisms actually do travel through the reactor as particles, separate from the fluid, but react with disinfectants in their environment as they pass through (Trussell and Chao, 1977). If disinfection conditions are uniform throughout the reactor (e.g., the reactant residual or the intensity of inactivating irradiance is uniform throughout), the inactivation of each individual microorganism is the same as it would be in a batch reactor after the same residence time. The RTD of a conservative tracer can reasonably be used to describe the RTD of the microorganisms themselves. Thus, the disinfection process can be modeled by the SFM (see Sec. 6-9):

$$\frac{N}{N_0} = \sum_{i=1}^n R(\theta_i) E(\theta_i) \Delta\theta_i \quad (6-123)$$

where

$N$  = number of microorganisms in the effluent from the real reactor, org/mL

$N_0$  = number of microorganisms in the influent to the real reactor, org/mL

$R(\theta_i) = N_i/N_0$  = inactivation of microorganisms achieved in CMBR (or PFR) after reaction time equal to  $\theta_i$

$\theta_i$  = normalized time (time divided by mean residence time,  $t_i/\bar{t}$ ), dimensionless

$E(\theta_i)$  = exit age distribution at time  $\theta_i$  (see Chap. 6)

$\Delta\theta_i$  = differential normalized time step

$i$  = time step in RTD

$n$  = total number of time steps in RTD

Selleck first introduced the approach outlined above to modeling in the early 1970s (Selleck et al., 1970). Trussell and Chao (1977) then employed this approach to demonstrate the influence of dispersion on chlorine contactor performance. Both authors worked on disinfection of coliform bacteria using combined chlorine and, in both studies, the disinfectant residual was assumed to be constant and uniform throughout the reactor. Scheible (1987) introduced a similar approach to the modeling of UV disinfection in the U.S. EPA disinfection design manual (U.S. EPA, 1986). The approach is appropriate for UV disinfection if it is assumed that turbulent flow exists, no short circuiting occurs, and each organism takes a path through the contactor such that its average exposure to UV light is equal to the average intensity of UV light in the reactor.

### Application of the SFM Model to Disinfection

The promulgation of the U.S. EPA's Surface Water Treatment Rule substantially increased disinfection requirements for drinking water in the United States (U.S. EPA, 1989) and, as a result, has stimulated further interest in methods of refining the rule's approach to specifying disinfection. Lawler and Singer (1993) reintroduced the concept again and later Haas demonstrated its application (Haas et al., 1995). Subsequently, the SFM concept was incorporated in the *integrated disinfection design framework*, an effort to further optimize the design and operation of water disinfection systems (Bellamy et al., 1998; Ducoste et al., 2001). An example of the application of the SFM to disinfection is demonstrated in Example 13-4.

### Example 13-4 Application of SFM to estimate disinfection efficiency

Use the disinfection data from Example 13-2 to determine the hydraulic detention time of a contactor designed for the inactivation of *C. parvum* using chlorine dioxide. The contact chamber is to be designed with a hydraulic detention time to provide a  $C\tau$  value equal to the  $Ct$  value that achieves 4 log inactivation in the batch tests. The target chlorine dioxide residual in the full-scale contactor is 0.8 mg/L.

After the full-size contactor was built, tracer tests were conducted to evaluate the hydraulic characteristics of the contactor. Using the procedures outlined in Chap. 6, the tracer curve has been analyzed to produce the exit age distribution. The mean residence time was found to be 178 min and the results of the tracer study are given in the following table:

$\theta_i$	$E(\theta_i)$	$\theta_i$	$E(\theta_i)$	$\theta_i$	$E(\theta_i)$
0.15	0	0.91	1.995	1.67	0.128
0.31	0	1.06	1.541	1.82	0.067
0.46	0.017	1.21	0.928	1.98	0.046
0.61	0.279	1.36	0.446	2.13	0.036
0.76	0.895	1.52	0.251	2.28	0.015

Use the tracer study data and contactor design information: (a) plot the exit age distribution  $E(\theta_i)$  versus  $\theta_i$ ; (b) use the SFM to estimate the level of inactivation,  $\log(N/N_0)$ , that will actually occur in the full-scale reactor with dispersion.

#### Solution

1. Determine the hydraulic detention time for the full-scale contact chamber using the batch data.

- a. The values for the disinfection parameters found in Example 13-2 were  $\Delta_{CW} = 0.083 \text{ L/mg}\cdot\text{min}$  and  $b = 34.9 \text{ mg}\cdot\text{min/L}$ . Thus, inactivation as expressed by the Rennecker–Mariñas model is

$$\ln\left(\frac{N}{N_0}\right) = \begin{cases} 0 & \text{for } Ct < 34.9 \\ -0.083(Ct - 34.9) & \text{for } Ct \geq 34.9 \end{cases} \quad (1)$$

- b. Find the value of  $Ct$  that corresponds to 4 log inactivation. For 4 log inactivation,  $\log(N_0/N) = 4$ , so  $N/N_0 = 10^{-4} = 0.0001$ . Rearranging Eq. 1 to solve for  $Ct$  yields

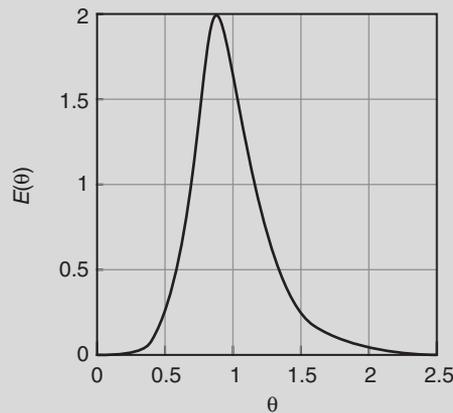

$$\ln(0.0001) = -0.083 \text{ L/mg}\cdot\text{min}(Ct - 34.9 \text{ mg}\cdot\text{min/L})$$

$$Ct = \frac{-\ln(0.0001)}{0.083 \text{ L/mg}\cdot\text{min}} + 34.9 \text{ mg}\cdot\text{min/L} = 145.5 \text{ mg}\cdot\text{min/L}$$

- c. Find the hydraulic detention time that provides a  $Ct$  value of  $146 \text{ mg}\cdot\text{min/L}$  when the chlorine dioxide residual is  $0.8 \text{ mg/L}$ :

$$\tau = t = \frac{Ct}{C} = \frac{145.5 \text{ mg}\cdot\text{min/L}}{0.8 \text{ mg/L}} = 182 \text{ min}$$

2. Plot the exit age distribution using the data provided in the problem statement. The exit age distribution is plotted below:

3. Determine the degree of inactivation achieved with the contactor using the SFM. Using the data given in the problem statement, a spreadsheet is developed using the principles of the SFM shown in Chap. 6. The resulting spreadsheet is shown below. As an example, calculations for the fifth row of the spreadsheet are as follows:
- Columns 1 and 2 contain values of  $\theta_i$  and  $E(\theta_i)$  given in the problem statement.

b. Column 3 ( $\Delta\theta_i$ ):

$$\Delta\theta_i = \theta_i - \theta_{i-1} = 0.61 - 0.46 = 0.15$$

c. Column 4 [ $R(\theta_i)$ ] is developed using an IF statement because the value changes depending on whether  $Ct_i$  is less or greater than  $b$ :

If  $Ct_i < b$ , then  $N_i/N_0 = e^0 = 1$ .

If  $Ct_i \geq b$ , then  $N_i/N_0 = \exp[-\Lambda_{CW} (Ct_i - b)]$ , where  $t_i = \theta_i \bar{t}$ .

$$\frac{N_0}{N_i} = \exp \left\{ -0.083 \text{ L/mg} \cdot \text{min} [(0.8 \text{ mg/L}) (0.61) (178 \text{ min}) - 34.5 \text{ mg} \cdot \text{min/L}] \right\} = 0.013$$

d. Column 5 [ $R(\theta_i)E(\theta_i)\Delta\theta_i$ ]:

$$R(\theta_i) E(\theta_i) \Delta\theta_i = (0.0130) (0.279) (0.15) = 5.42 \times 10^{-4}$$

$\theta_i$	$E(\theta_i)$	$\Delta\theta_i$	$R(\theta_i)$	$R(\theta_i)E(\theta_i)\Delta\theta_i$
0				
0.15	0	0.15	1	0
0.31	0	0.16	0.449	0
0.46	0.017	0.15	0.0763	$1.95 \times 10^{-4}$
0.61	0.279	0.15	0.0130	$5.42 \times 10^{-4}$
0.76	0.895	0.15	$2.20 \times 10^{-3}$	$2.95 \times 10^{-4}$
0.91	1.995	0.15	$3.74 \times 10^{-4}$	$1.12 \times 10^{-4}$
1.06	1.541	0.15	$6.35 \times 10^{-5}$	$1.47 \times 10^{-5}$
1.21	0.928	0.15	$1.08 \times 10^{-5}$	$1.50 \times 10^{-6}$
1.36	0.446	0.15	$1.83 \times 10^{-6}$	$1.22 \times 10^{-7}$
1.52	0.251	0.16	$2.76 \times 10^{-7}$	$1.11 \times 10^{-8}$
1.67	0.128	0.15	$4.69 \times 10^{-8}$	$9.01 \times 10^{-10}$
1.82	0.067	0.15	$7.97 \times 10^{-9}$	$8.01 \times 10^{-11}$
1.98	0.046	0.16	$1.20 \times 10^{-9}$	$8.85 \times 10^{-12}$
2.13	0.036	0.15	$2.04 \times 10^{-10}$	$1.10 \times 10^{-12}$
2.28	0.015	0.15	$3.47 \times 10^{-11}$	$7.81 \times 10^{-14}$
				$\Sigma = 0.00116$

e. The degree of inactivation is the sum of column 5 [ $R(\theta_i)E(\theta_i)\Delta\theta_i$ ].

Thus,  $N/N_0 = 0.00116$  and the log removal value (LRV) is

$$LRV = \log \left( \frac{N_0}{N} \right) = -\log(0.00116) = 2.94$$

**Comment**

Due to dispersion, the full-scale contactor achieves less than 3 log of inactivation when the hydraulic residence time was set equal to the time necessary to achieve 4 log of inactivation in laboratory batch tests (see Sec. 4-5 for additional discussion of expressing removal in terms of log removal) Clearly, a different approach must be used to determine the hydraulic residence time of a full-scale reactor when dispersion is important.

Minimizing dispersion and short circuiting in disinfection contactors is widely accepted. The U.S. EPA limits the credit for disinfection contact time to the time it takes for the first 10 percent of a tracer to pass through a disinfection contactor ( $t_{10}$ ), that is, the value of  $t$  in  $Ct$  is  $t_{10}$  instead of  $\tau$ . California requires the minimum time to the peak concentration on the tracer curve ( $t_{\text{modal}}$ ) to be 90 min and a minimum length-to-width ratio of 40:1 for baffled chlorine contactors in its regulations for reclaiming wastewater for nonrestricted reuse (Cal DHS, 1999).

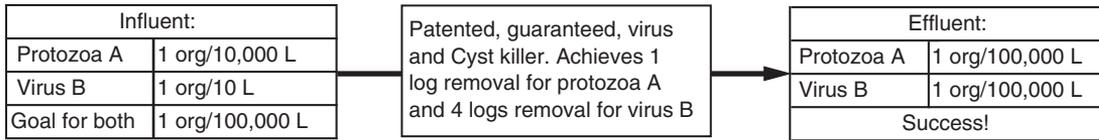

As a general rule, reducing dispersion is more important when disinfection goals are substantial. For example, dispersion is more important in the design of a contactor that must achieve 4 log of inactivation than in the design of a contactor that must achieve 1 log of reduction. This effect is true regardless of the organism under consideration or its specific reaction kinetics.

A thought experiment can be used to illustrate this effect. Assume a disinfection process is designed to achieve a 4 log reduction of a particular virus and a 1 log reduction of a certain protozoa. Further assume the reactor operates as designed and achieves exactly those objectives. A small bypass pipe is installed and 1 percent of the flow coming into the reactor is diverted so that it flows around the reactor and blends, without disinfection, with the treated water from the reactor. The result of the experiment is illustrated on Fig. 13-6. As illustrated, the small diversion has almost no impact on the removal of protozoa (only 9 percent increase in effluent concentration) but severely compromises the removal of the virus, exposing the consumer to virus levels over 100 times higher than the goal that was being sought.

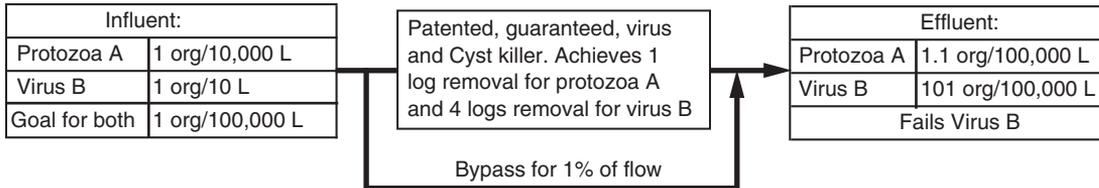

Using the reactor dispersion models presented in Chap. 6, it is possible to compare the performance of a real reactor with dispersion with an ideal plug flow reactor. A model may be prepared to estimate the amount of dispersion that could be allowed without compromising plug flow performance more than 5 percent (in other words, without reducing the log removal more than 5 percent). As shown on Fig. 13-7, which was developed for a first-order reaction and with a removal goal that spans several orders of magnitude, the requirements for controlling dispersion are modest when the required removal is modest. As the removal requirements increase to 3 log or more,

**When Dispersion  
Is Important  
in Disinfection**

Prior to modifications:

After modifications:

Calculations:

$$\text{Effluent protozoa A} = (1)(0.99) + (10)(0.01) = 1.09/100,000 \text{ L}$$

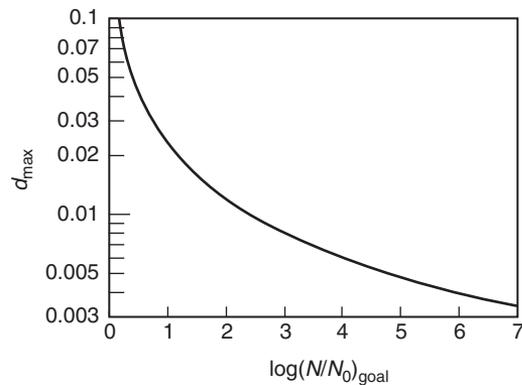

Log removal = 0.96, somewhat below goal

$$\text{Effluent virus B} = (1)(0.99) + (10,000)(0.01) = 101/100,000 \text{ L}$$

Log removal = 2.0, far below goal

**Figure 13-6**

Thought experiment: Dispersion and short circuiting are more important when removal goals are high.

**Figure 13-7**

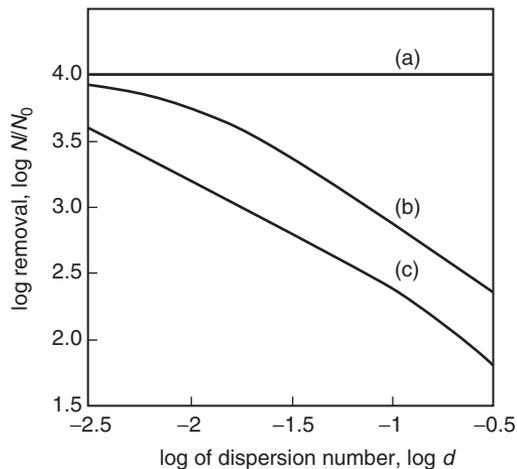

Allowable dispersion for contactor versus inactivation goals. At  $d_{\text{max}}$ , performance is short of goal by 5 percent.

it becomes difficult to prevent the dispersion from being greater than the allowable amount. Removals higher than 3 log generally can only be accomplished by constructing reactors with a significantly greater hydraulic detention time (and greater  $Ct$  value) than predicted by removal measured in a batch reactor. For instance, the reactor in Example 13-4 could meet 4 log inactivation requirements if the mean residence time were 30 percent greater than the time predicted by the batch tests.

A number of indices have been used to assess performance of full-scale disinfection contactors. Some of the more common indices are the dispersion number  $d$ ,  $t_{10}/\tau$ ,  $t_{10}/t_{90}$ , and  $t_{\text{modal}}$ . A reasonable simulation of the original RTD of a reactor can be produced using the dispersion number and the DFM for a closed system (see Chap. 6). The RTD curve generated by the DFM for a given dispersion number can be used as a substitute for actual tracer data to estimate reactor performance using the SFM (Trussell and Chao, 1977) as demonstrated in Example 13-4. As a result, the dispersion number is perhaps the best measure of the suitability of a reactor for accomplishing disinfection. Nevertheless, regulators tend to prefer parameters such as  $t_{10}$  (USEPA, 1986) or  $t_{\text{modal}}$  (Cal DHS, 1999) as these values are easier to determine and more readily understood by operating personnel. Because of the U.S. EPA's regulations,  $t_{10}$  deserves special attention where water treatment is concerned.

To assess whether using the  $t_{10}$  value provides the same level of protection as controlling dispersion, Fig. 13-8 was constructed using Eq. 6-123 and a reaction that would achieve 4 log of removal in a plug flow reactor. The performance estimated by the SFM for the reactor with dispersion (middle curve) is compared to the performance credit that would be allowed for the reactor based on the batch equation and the product  $Ct_{10}$  (bottom curve). The inactivations estimated by the SFM and by the product  $Ct_{10}$  both improve as dispersion is reduced. From the presentation on Fig. 13-8 it can be concluded that the U.S. EPA's  $t_{10}$  approach is effective, but conservative.

The design of disinfection contact chambers that exhibit low dispersion is presented later in this chapter, after sections that describe each of the chemical disinfectants.

**Figure 13-8**  
Reactor disinfection performance predictions: (a) ideal plug flow; (b) segregated-flow model (SFM) with dispersion, derived from residence time distribution (RTD) curve produced using closed-system dispersion flow model (DFM); and (c) predicted using  $t_{10}$  values derived from  $E(\theta)$  curves based on closed-system DFM.

### 13-5 Disinfection with Free and Combined Chlorine

---

Until approximately World War II, free and combined chlorine (chlorine combined with ammonia, also known as chloramines) were both commonly used and viewed as effective disinfectants. In 1943, the U.S. PHS demonstrated that free chlorine exhibits more rapid kinetics in the disinfection of several bacteria (Wattie and Butterfield, 1944). As a result, the use of combined chlorine declined between 1943 and the mid-1970s. In the mid-1970s, it became widely recognized that free chlorine formed chemical by-products (Bellar and Lichtenberg, 1974; Rook, 1974) and that combined chlorine did so to a much lesser degree (Stevens and Symons, 1977). Since that realization, the use of combined chlorine has increased, particularly the addition of ammonia to convert a free-chlorine residual to a combined chlorine residual once primary disinfection has been accomplished. By 2004, about one in four utilities in the United States were using combined chlorine (U.S. EPA, 2004).

#### Chemistry of Free Chlorine

When chlorine gas is injected into water, it dissolves according to Henry's law and then rapidly reacts with the water to form hydrochloric acid and hypochlorous acid:

Hydrochloric acid is a strong acid that dissociates completely, causing a reduction in alkalinity and pH:

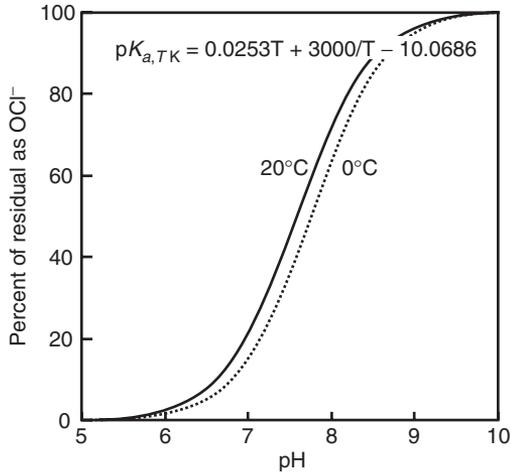

Hypochlorous acid is a weak acid and the extent of dissociation depends on pH (see Chap. 5 for discussion of weak acids):

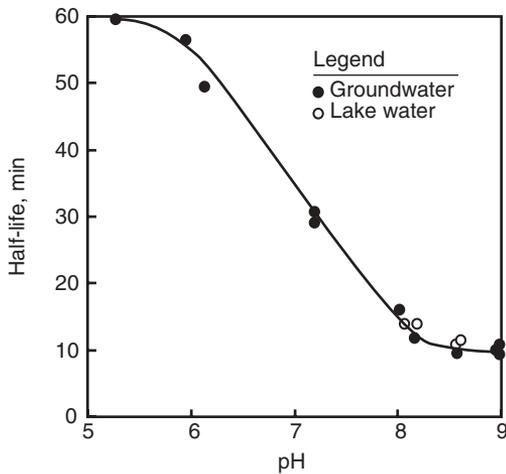

$$K_a = \frac{[\text{H}^+][\text{OCl}^-]}{[\text{HOCl}]} \quad (13-16)$$

The  $pK_a$  for HOCl is 7.6 at 20°C; hypochlorous acid (HOCl) is the predominant form below this pH value and hypochlorite ion ( $\text{OCl}^-$ ) is the predominant form above it. The distribution between HOCl and  $\text{OCl}^-$  is illustrated on Fig. 13-9 as a function of pH and temperature. Hypochlorous acid (HOCl) exhibits faster disinfection kinetics than does hypochlorite ion ( $\text{OCl}^-$ ) (see Table 13-3). Consequently, a pH of 7 or less is desirable where disinfection alone is concerned. As can be seen from Fig. 13-9, temperature has a small effect, warmer waters causing hypochlorous acid to dissociate at somewhat lower pH.

Chlorine is relatively stable in pure water but reacts slowly with the organic matter naturally present in drinking waters and rapidly with sunlight. Where sunlight is concerned, photons react with hypochlorite ion to produce

**Figure 13-9**

Effect of temperature and pH on fraction of free chlorine present as hypochlorous acid. (Adapted from Morris, 1966.)

**Figure 13-10**

Half-life of free chlorine residual in sunlight.

oxygen, chlorite ion, and chloride ion (Buxton and Subhani, 1971). The sensitivity of the reaction rate to pH, a consequence of the fact that the photolytic reaction is with hypochlorite ion and not hypochlorous acid, is illustrated on Fig. 13-10, constructed using the data of Nowell and Hoigné (1992a,b).

Although significant research has investigated the decay of chlorine residuals in the presence of natural organic matter, no universal relationships have evolved. Rather, the decay of free chlorine is often best modeled with the simple first-order reaction depicted in Eq. 13-9. Sometimes the process is modeled as two reactions operating in parallel, a fast reaction with rapidly reducible substances and a slower first-order reaction (Eq. 13-10). Studying data from multiple sources, Powell et al. (2000)

concluded that the activation energy for the chlorine decay reaction is on the order of 62 kJ/mol. Modeling chlorine decay as a first-order reaction is illustrated in Example 13-5.

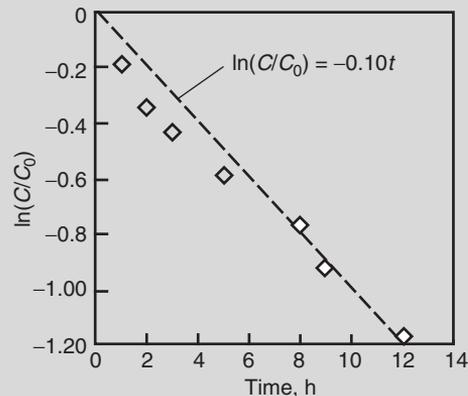

### Example 13-5 Evaluating chlorine residual decay data

One milligram of chlorine was added to 1 L of water. The water was stored in the dark at a constant temperature of 10°C and the chlorine residual was measured periodically. The results of the chlorine decay experiment are given below. Assuming a simple first-order decay reaction, estimate the constant for first-order decay,  $k_d$ , of chlorine. Assuming that the activation energy  $E_a$ , is 62 kJ/mol, what would  $k_d$  be at 25°C? What would the residual have been at the end of the same decay test at 25°C?

Time, h	Concentration, mg/L
0	0.97
1	0.80
2	0.69
3	0.63
5	0.54
8	0.45
9	0.39
12	0.30

#### Solution

- Determine the first-order decay rate constant for 10°C.
  - To find the rate,  $\ln(C/C_0)$  is plotted as a function of time and a linear best fit is forced through zero as shown below:

- b. From the plot,  $k_d$  at  $10^\circ\text{C}$  is estimated to be approximately  $0.10\text{ h}^{-1}$ .
- c. Determine the value of  $k_d$  at  $25^\circ\text{C}$ . The value of  $k_d$  at  $25^\circ\text{C}$  can be computed using Eq. 5-85 (see Chap. 5):

$$\ln(k) = \ln(A) + \left(-\frac{E_a}{R}\right) \times \left(\frac{1}{T}\right)$$

The Arrhenius factor  $A$  needed for computing the  $k_d$  at  $25^\circ\text{C}$  is determined using the  $k_d$  value for  $10^\circ\text{C}$ :

$$\ln(A) = \ln(0.10) + \frac{62,000\text{ J/mol}}{(8.314\text{ J/mol} \cdot \text{K})(273 + 10)\text{ K}}$$

$$\ln(A) = 24.05$$

The  $k_d$  at  $25^\circ\text{C}$  is given below:

$$\ln(k_d) = 24.05 - \frac{62,000\text{ J/mol}}{(8.314\text{ J/mol} \cdot \text{K})(273 + 25)\text{ K}} = -0.976$$

$$k_d = e^{-0.976} = 0.377$$

2. Determine the residual concentration of chlorine:

$$C_{t=12} = C_{t=0} e^{-0.377t} = C_{t=0} e^{(-0.377)(12)}$$

$$= (0.97)(0.0109) = 0.0106\text{ mg/L}$$

When ammonia is present in water, chlorine reacts to form species that combine chlorine and ammonia, known as chloramines. In general, chlorine reacts successively with ammonia to form the three chloramine species as more chlorine is added.

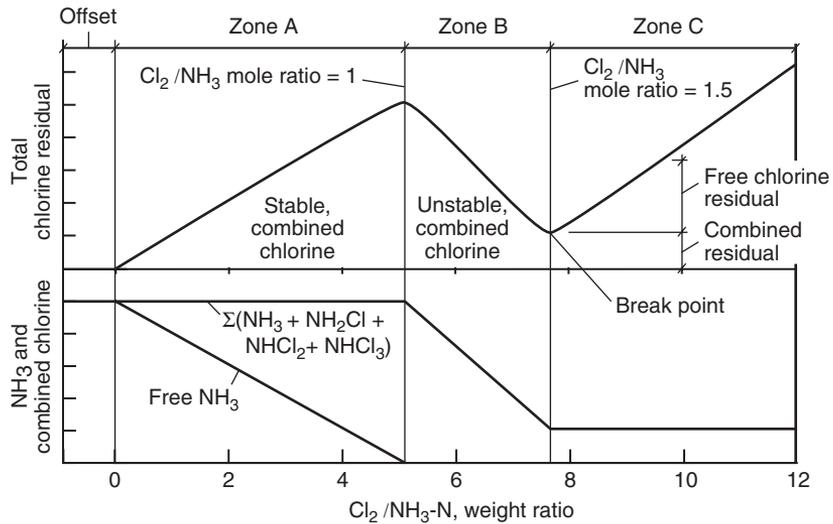

The sum of these three reaction products is called combined chlorine. The total chlorine residual is the sum of the combined residual and any free-chlorine residual. A summary of these definitions is provided below:

All chlorine species are expressed as milligrams per liter as  $\text{Cl}_2$  and the ammonia concentration is expressed as mg/L as nitrogen (i.e., mg/L  $\text{NH}_3 - \text{N}$ ). When small amounts of chlorine are added to water, the reactions

are much like the simple model above. However, as the amount of chlorine added increases, the reactions become more complex. These reactions and their behavior are partially illustrated by the three zones on Fig. 13-11. At first, as depicted in zone A, the total chlorine residual increases by approximately the amount of chlorine added until the molar ratio of chlorine to ammonia approaches 1 (a weight ratio of 5.07 as  $\text{Cl}_2$  to  $\text{NH}_3 - \text{N}$ ), assuming no other species that consume chlorine are present.

Beyond a molar ratio of 1, the addition of more chlorine decreases, rather than increases, the total chlorine residual (zone B) because the chlorine is oxidizing some of the chloramine species. Eventually, essentially all of the chloramines species are oxidized. The point at which the

Parameter	Offset	Zone A	Zone B	Zone C
Time to metastable equilibrium	Fraction of a second	Seconds to a few minutes	10 to 60 min	10 to 60 min
Composition of metastable residual.	Reduction of readily oxidizable substances such as Fe(II), Mn(II), and H <sub>2</sub> S.	Mostly monochloramine, some dichloramine and traces of trichloramine at neutral or acid pH or at high Cl <sub>2</sub> /NH <sub>3</sub> ratios.	A mixture of monochloramine and dichloramine, some free chlorine and traces of trichloramine at low pH.	Mostly free chlorine, trichloramine can be significant (aesthetically, but not as fraction of residual) at neutral pH, but especially in acid region.

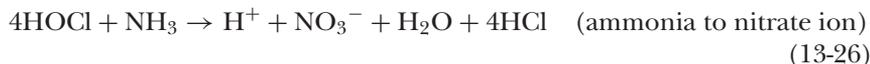

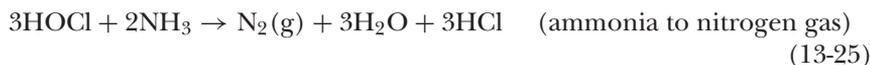

**Figure 13-11**  
Overview of chlorine break-point stoichiometry.

oxidation of chloramine species is complete is called the break point and is the beginning of zone C. The exact locations of maximum residual and breakpoint (minimum residual) are influenced by the presence of dissolved organic matter, organic nitrogen, and reduced substances [e.g.,  $S^{2-}$ , Fe(II), Mn(II)]. The presence of any of these will shift all three zones to the right. The degree to which they shift the point of maximum residual depends on how easily they are oxidized. The shift in the breakpoint corresponds to their stoichiometric chlorine demand. After the breakpoint is reached, the free-chlorine residual increases in proportion to the amount of additional chlorine added. Prior to concerns about disinfection by-products, “break-point” chlorination was often used as a simple means of ammonia removal.

In zone A, monochloramine forms rapidly and with little interference. Nevertheless, the species present in zone A are influenced by pH. At low pH values, dichloramine can form via the following reactions:

Monochloramine is the only chloramine present in zone A at pH 8, but significant amounts of dichloramine can be present at pH 6 (Palin, 1975). In zone B, which is richer in chlorine, some dichloramine will be present even at pH 8 (Palin, 1975). In zone B, hypochlorous acid can oxidize ammonia to nitrogen gas and nitrate ion, resulting in the complete loss of chlorine residual. Between these, the conversion to nitrogen gas is the dominant reaction commonly observed (Saunier and Selleck, 1979):

Although break-point chlorine can be described with equilibrium reactions, the behavior of the  $Cl_2 - NH_3$  system is actually quite dynamic, and the break-point curve shown on Fig. 13-11 should be considered more of a metastable than an equilibrium state. As a result, laboratory studies to construct a breakpoint curve require precise timing to be reproducible, especially for  $Cl_2/NH_3$  mole ratios above 1. Above this ratio the reaction proceeds rapidly until the metastable state is reached. Anywhere along the curve, the rate at which the reaction progresses is strongly influenced by the pH (Fig. 13-12), particularly in the vicinity of the break point itself. Near the break point, the reaction is at its maximum rate at a pH between 7 and 8. The rate decreases rapidly at pH values outside that range. Facilities engineered to accomplish ammonia removal via the break-point reaction should be designed to accommodate the time for this reaction. Even in the optimum range, the reaction time can be significant.

### Example 13-6 Estimating break-point chlorine requirements

Ammonia is added to pure water in the laboratory to reach a concentration of 1 mg N/L. Estimate the chlorine dose needed to reach break point for the following conditions: (1) all the ammonia is converted to nitrogen gas and (2) all the ammonia is converted to nitrate ion. When using breakpoint chlorination to remove ammonia, which reaction requires less chlorine?

#### Solution

1. Determine the chlorine dose needed to convert ammonia to nitrogen gas. From Eq. 13-25, 3 mol of HOCl is needed for every 2 mol of NH<sub>3</sub>:

$$\text{Weight ratio} = (1.5 \text{ mol/mol}) \frac{71 \text{ g Cl}_2}{14 \text{ g N}} = 7.61 \text{ mg Cl}_2/\text{mg N}$$

$$\text{Required dose} = 7.61 \text{ mg Cl}_2/\text{mg N} \times 1 \text{ mg N/L} = 7.61 \text{ mg Cl}_2/\text{L}$$

2. Determine the chlorine dose to convert ammonia to nitrate. From Eq. 13-26, 4 moles of HOCl is needed for each mole of NH<sub>3</sub>:

$$\text{Weight ratio} = (4 \text{ mol/mol}) \frac{71 \text{ g Cl}_2}{14 \text{ g N}} = 20.2$$

$$\text{Required dose} = 20.2 \text{ mg Cl}_2/\text{mg N} \times 1 \text{ mg N/L} = 20.2 \text{ mg Cl}_2/\text{L}$$

3. The reaction to nitrogen gas uses less chlorine.

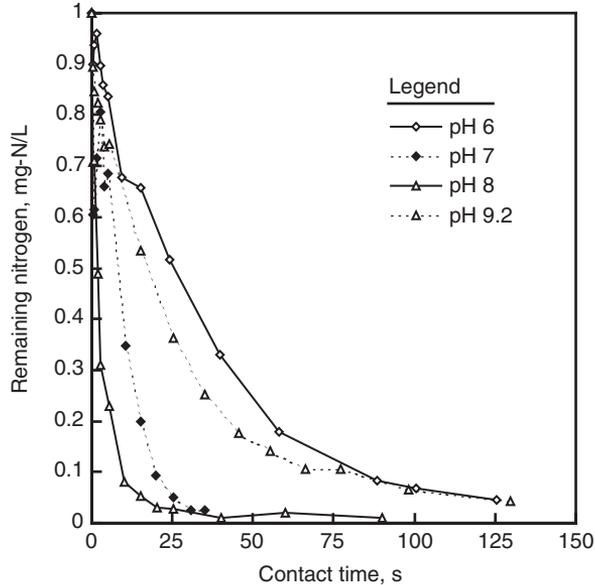

#### Forms of Chlorine (Liquid, Gas, Hypochlorite, etc.)

The forms of chlorine most often used in the treatment of drinking water are chlorine gas and sodium hypochlorite solution. Calcium hypochlorite powder is also used in some smaller systems. In the United States, chlorine gas can be purchased in 68-kg (150-lb) cylinders, in 908-kg (1-ton) cylinders (in Europe 1000-kg cylinders are used), by tank truck, or in railroad tank cars of between 14.5 and 49.9 metric tons in capacity (16 and 55 American tons). Generally the cost of chlorine is lower when it is shipped in larger volumes, the cost delivered in 1-ton cylinders being approximately half the cost delivered in 68-kg cylinders but nearly twice that when delivered by rail. As a result, some very large utilities purchase liquid chlorine by rail and repackage it for use at various sites.

#### Liquid Chlorine

The elements of a chlorination facility address each of the following:

1. Storage of liquid chlorine gas
2. Conduits for the transport of liquid chlorine
3. Evaporation of liquid chlorine

**Figure 13-12**

Effect of pH on break-point chlorination. (Data from Saunier and Selleck, 1979, Temp. 15 to 18.5°C,  $[\text{NH}_3]_0 = 1 \text{ mg/L}$ , and  $[\text{Cl}_2/\text{NH}_3]_0 \sim 10$ .)

4. Conduits for the transport of chlorine gas under pressure
5. Regulation of the chlorine feed rate
6. Conduits for the transport of chlorine gas under vacuum
7. Chlorine-to-water mass transfer
8. Mixing of chlorine water with the process flow
9. The chlorine contact facility
10. Chlorine sampling and analysis
11. Chlorination control system

In small systems many of these elements are found in one device and other elements, such as the control system, are very rudimentary. In large chlorination systems, each of these elements can sometimes present a separate, specific design challenge. Each of these elements requires different materials and different design considerations apply to each.

#### DESIGN ISSUES WITH LIQUID CHLORINE

The details of the design of systems for handling the delivery, storage, and dosing of liquid chlorine are beyond the scope of this book. An overview of a variety of the more important issues is provided in Table 13-5. Chlorine is truly a hazardous material so it is important that care be taken in the design of these facilities. White's (1999) handbook is an excellent source for design details.

**Table 13-5**

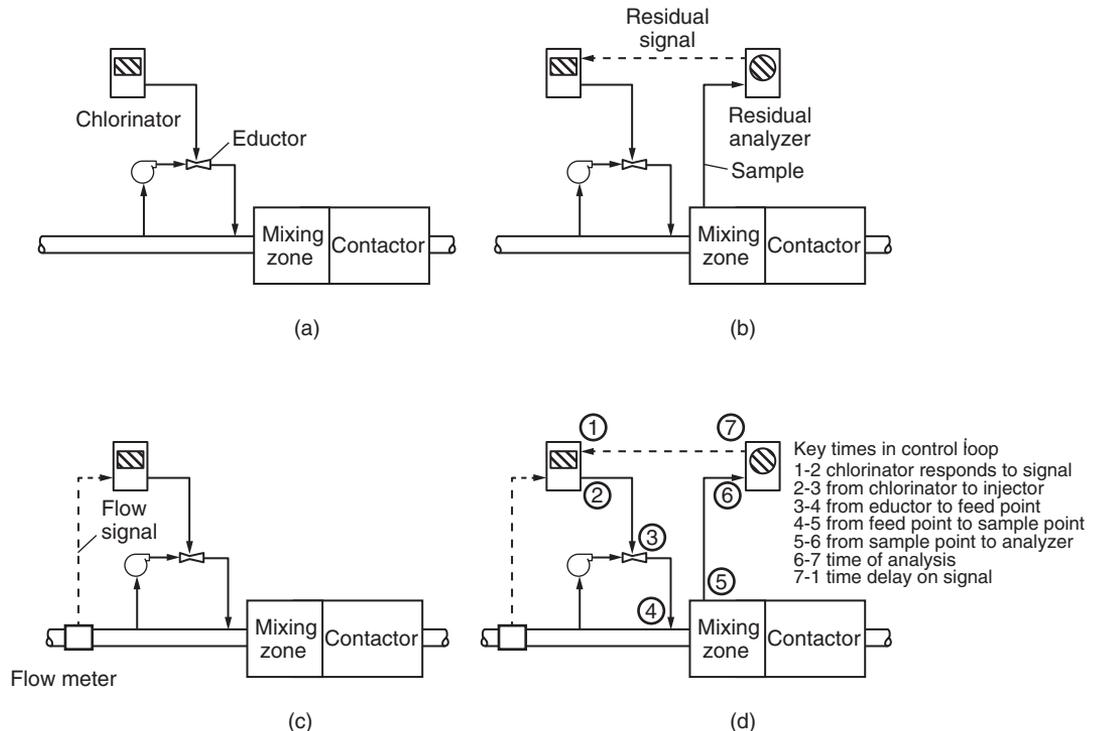

Overview of key design issues for chlorination systems

Item	Description
Delivery	In cylinders 68 kg (150 lb) and 908 kg (1 ton); in tank trucks 13,600–18,200 kg (15–20 tons); and in rail cars 14,500–49,900 kg (16–55 tons).
Storage	In cylinders; in tank trucks; in rail cars or in custom tanks.
Conduits for liquid chlorine	Schedule 80 stainless steel (SS), schedule 80 carbon steel, or cast iron (DO NOT USE PVC). Should be seamlessly welded. Use cast-iron valves. Use pipe sizes recommended by White (1999) to avoid “flashing.”
Evaporation of liquid	Can use vapor pressure of container to feed up to 19 kg/d (40 lb/d) with 68-kg cylinder and up to 150 kg/d (330 lb/d) with 908-kg cylinders. Multiple cylinders are often used with automatic switchover. At feed rates above 680 kg/d (1.5 tons/d) a separate evaporator is recommended to convert liquid chlorine to chlorine gas.
Conduits for chlorine gas under pressure	Use schedule 80 SS, schedule 80 carbon steel-or cast iron (DO NOT USE PVC). Should be seamlessly welded. Use cast-iron valves.
Regulation of chlorine gas feed rate	Accomplished by the chlorinator. Most chlorinators include four principal elements: (a) a pressure-reducing valve, (b) a rotometer, (c) a control valve, and (d) a vacuum regulator.
Conduits for transport of chlorine gas under vacuum	Often constructed of schedule 80 PVC or reinforced fiberglass pipe. Piping should be carefully sized to maintain pressure drop below 50–60 mm Hg (see White, 1999).
Chlorine-to-water mass transfer	Chlorine is highly soluble and reacts vigorously with water to form hypochlorous and hydrochloric acids. Chlorine-to-water mass transfer is normally accomplished via chlorine injector, a venturi-type device. The maximum solution strength downstream of the injector is approximately 3.5 g/L. The injector is also used to create the vacuum in the system.
Blending of chlorine water into process flow	Under normal conditions, blending must be accomplished before the chlorine residual monitoring point. With normal turbulent flow in a conduit, this requires travel down the conduit an axial distance of 40–200 times the hydraulic radius. Blending can be expedited with devices normally used for rapid mixing or via flow structures that dissipate energy (e.g., a hydraulic jump or a fall over a sharp-crested weir). When ammonia is present, it is important that chlorine be rapidly blended with the bulk flow. If not, both chlorine and ammonia are lost in localized breakpoint reactions and disinfection is compromised. In this case rapid mixing is required.
Chlorine contact facility	Historically, the contact time in existing facilities (e.g., sedimentation basins, clearwells) has been used. Modern treatment plants use specially designed chlorine contact tanks. The most efficient designs, from the standpoint of dispersion, are long, straight pipelines and carefully designed, serpentine contact chambers. Most contact chambers are of concrete.
Chlorine sampling and analysis	Reliable equipment for the sampling and analysis of free and total chlorine has been available for some time. Several devices are available on the market.
Chlorination control system	Historically control systems were manual, feed-forward, feedback, and compound loop in design. Today control systems and methods of sampling and analysis have improved so complex control is possible.

### Control of Gas Chlorination

Four methods have traditionally been used for controlling the feed rate of chlorine gas when it is used for residual control in drinking water systems. Each is displayed on Fig. 13-13: (1) manual control, (2) feed-forward control, (3) residual feedback control, and (4) compound loop control. Through the middle of the twentieth century, manual control was the most common. Significant operator attention was required to ensure that a suitable residual was reliably provided, especially when the flow rate through the plant was adjusted. By the mid-1950s flow measurement and chlorine metering techniques improved until feed-forward control systems began to appear. This important advance allowed automatic adjustment for flow but still required the operator to adjust for any changes in the water quality (chlorine demand) or any drifts in monitoring and feed rates.

By the mid-1960s direct residual control began to appear. In principle, the feedback method of control is more robust than feed-forward control, but residual measurement did not approach suitable levels of reliability and precision for two more decades. As a result, compound loop control evolved as a compromise. With this method, changes in flow could be

**Figure 13-13**

Control of chlorine gas feed rate: (a) manual control, (b) feedback or residual control, (c) feed forward control, and (d) compound loop control.

accommodated via the flow signal and an additional control increment could be added via residual control for minor water quality changes. Properly maintained, compound loop control was the first system to provide reliable, continuous residual control.

During the last decade of the twentieth century, computerized supervisory control systems had evolved to the point where these same inputs (flow and residual) could be combined with other measurements to provide improved reliability. None of these control systems, however, is an adequate substitute for vigilant attention from the operator.

#### *Residual control system*

The sequence of events in the residual control system must be carefully designed and controlled. All the elements shown and labeled in the diagram as “compound loop control” on Fig. 13-13 must be considered in designing the system and envisioning its method of control. The time between the instant when a change in chloride feed rate is made and when the change in residual is detected by the control system has a significant effect on the effectiveness of the control system. The instructions of the supervisory control and data acquisition (SCADA) system must be designed with a full understanding of the effect of timing delays in each element of the system.

The time required for the chlorinator to completely respond to an instruction from the SCADA system is normally not too significant. The time required for the change in feed rate established by the chlorinator to be recognized at the eductor must be considered. This time to change feed rates is normally not too long either, but it can be too long when the chlorinator is located a long way from the injector and when the chlorine feed rate is very low. White (1999) suggests that this time be estimated by assuming that the change in pressure will travel in a wave about three times as fast as the gas flow in the line.

Next, the time for the water in the chlorine water line to travel from the eductor to the application point must be considered. This time is a function of the distance between the eductor and the application point and the flow rate (velocity) in the chlorine water line. Again, designs with long distances between the eductor and the application point can cause trouble for control. Ideally the chlorine is stored near the application point so that both the time in the vacuum line and the time in the chlorine line are minimized. When nearby storage is not possible, it is usually best to lengthen the vacuum line, not the chlorine water line, as a signal ordinarily travels much faster down a vacuum line.

#### *Sampling point*

Another important constraint is the time between the chlorine application point and sampling point. There is an inherent design conflict in the distance between these locations. Putting these points too close together

can result in poor blending before the treated water reaches the sampling point. When this happens, the control system constantly “searches” for control but can never quite find it. Putting them too far apart can result in too much delay between when a change in dose is made and when it is detected by the control system. To avoid control problems, the residual for sample control must be taken after mixing is satisfactory. Depending on the method of chlorine introduction and the criteria used for mixing, the distance downstream to accomplish satisfactory blending is between 40 and 200 times the hydraulic radius of the water conduit. Problems associated with this distance are aggravated in larger applications because of the larger conduit diameters that are used.

The time required for the sample to travel from the sample point to the analyzer is also important. Sample travel time can be a significant complication if the analyzer is located in some central location far from the sampling site. The time for the analyzer to assay the sample (normally between 15 and 20 s) can also be important in some applications. In designing such a control system, it is important to analyze all these times and the sequence in which they operate at both high- and low-flow conditions, both early and late in the life of the design, to ensure that problems do not occur after the installation is complete.

### **Example 13-7 Establishing time between chlorine application and residual control sampling**

Consider two treatment plants A and B. In plant A the filtered water line is 305 mm (12 in.) in diameter. In plant B, the filtered water line is 3050 mm (120 in.) in diameter. Both pipelines are designed for a velocity of 1.5 m/s (5 ft/s). Assume that both have equivalent mixing at the point of chlorine injection and that the flow in both pipelines will be suitably blended for sampling at a point 50 pipe diameters downstream (100 hydraulic radii).

Estimate how far down the pipeline the sample point must be and how long it will take for the water to travel from the point of chlorine injection to the sampling point in each case.

#### **Solution**

1. Estimate the travel time from application point to sampling point (4 to 5 on Fig 13-13d):
  - a. For plant A, pipe diameter is 305 mm, 50 pipe diameters equal 15 m, and at a velocity of 1.5 m/s the travel time is ~10 s.
  - b. For plant B, pipe diameter is 3050 mm, 50 pipe diameters equal 150 m, and at a velocity of 1.5 m/s the travel time is ~100 s.

## Sodium Hypochlorite

When chlorine was first used for disinfection, it was often applied in the form of hypochlorite. Sodium hypochlorite (NaOCl), or liquid bleach, came into use near the beginning of the Great Depression in the late 1920s. Later, chlorination using liquid chlorine became predominant because of its lower cost, but now hypochlorite is again becoming more common because of the hazardousness of liquid chlorine.

Sodium hypochlorite is the most widely used form of hypochlorite today. It is widely used not only in disinfection of water but also for a myriad of other household and industrial uses. Calcium hypochlorite [Ca(OCl)<sub>2</sub>] is used by some small utilities.

Whereas chlorine gas is prepared by an electrolytic process that breaks sodium chloride solution into chlorine gas and sodium hydroxide, ironically, sodium hypochlorite is generally prepared by mixing sodium hydroxide and chlorine gas together:

On a weight basis, 1.128 kg of NaOH reacts with 1 kg of chlorine to produce 1.05 kg of NaOCl and 0.83 kg of NaCl. The process is complicated by the fact that the reaction generates a significant amount of heat. It is common practice to add an excess of NaOH because, as will be shown, hypochlorite is more stable at higher pH values. As a result, the density of one hypochlorite solution is not necessarily the same as another, even if both have the same strength (percent Cl<sub>2</sub>). This density difference occurs because the final density depends on the amount of excess NaOH added during manufacture. Liquid bleach usually has a pH between 11 and 13. Hypochlorite can also be manufactured via onsite generation; this process is becoming more common.

### STABILITY OF HYPOCHLORITE

Under some conditions, the strength of hypochlorite can decline significantly in just a few days. In fact, stability is one of the major issues that must be addressed in both designing and operating a hypochlorite facility. A utility should not consider using hypochlorite unless it is prepared to dedicate time and energy to a regular program of monitoring and controlling its decay. Of considerable significance is the fact that, when hypochlorite does decay, chlorate ion is one of the principal by-products of the reaction. The stability of hypochlorite is affected by the strength of the solution, the storage temperature, the pH, and the contamination of heavy metals, which can catalyze its decay. Light is also a problem. As a general rule, the rate of decay is accelerated by (1) higher concentration, (2) higher temperature, (3) lower pH, (4) exposure to sunlight, and (5) the presence of certain heavy metals, notably copper and nickel.

Under basic conditions, the decomposition of hypochlorite ion to chlorate ion follows a disproportionation reaction, which exhibits second-order

reaction kinetics and the following overall stoichiometry (Gordon et al., 1995a,b):

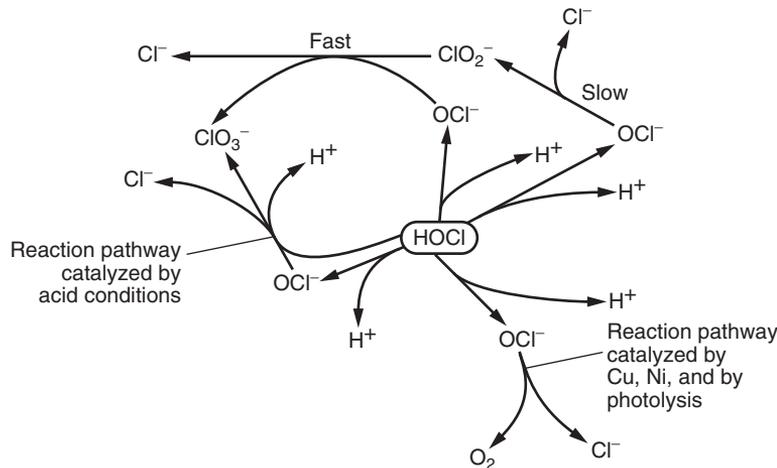

The second reaction, as given by Eq. 13-29, is the faster of the two. As a result, the first reaction is the rate-limiting step in the consumption of hypochlorite ion. Bleach also decays via a slow reaction that forms oxygen and an acid-forming reaction that also forms chlorate ion, as shown in the following reactions:

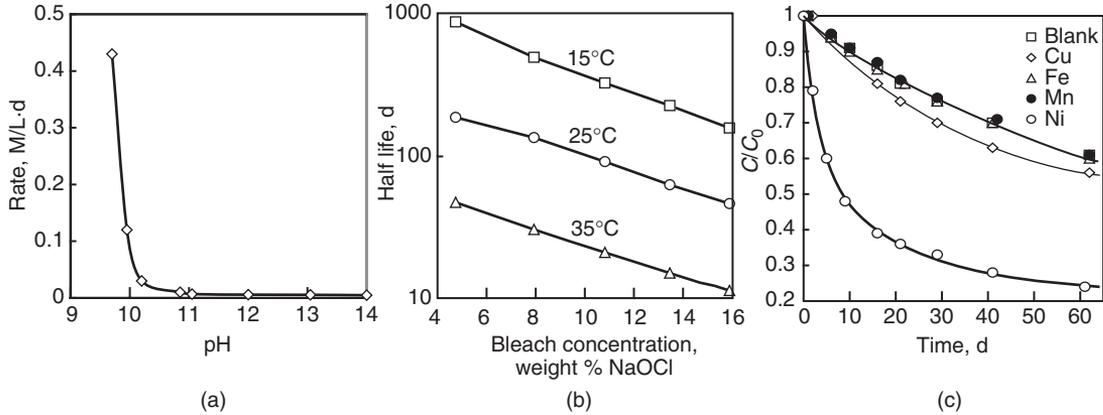

Gordon and colleagues (1995a,b) have shown that copper and nickel catalyze oxygen formation (see Eq. 13-31) and research at the Swiss Federal Institute for Environmental Science and Technology (EAWAG) has shown that a similar reaction occurs via proteolysis (Nowell and Hoigné, 1992a,b). The relationships between the three principal reactions that result in hypochlorite decay are displayed on Fig. 13-14.

The pH at which a sodium hypochlorite solution is stored has important impacts on its rate of decay, as shown on Fig. 13-15a (Gordon et al. 1995a,b). The rate of decay is low at pH 11 and above but increases rapidly below pH 10. Some evidence suggests that a decay minimum occurs between pH 12 and 13. As liquid bleach is normally delivered at pH 12 or above, low-pH decay is normally not a problem with the undiluted product. Often

**Figure 13-14**  
Decay reactions of hypochlorite.

**Figure 13-15**

Factors that influence decay of sodium hypochlorite: (a) effect of pH on rate of decay of hypochlorite; (b) effect of temperature and concentration on decay of hypochlorite; and (c) effect of trace metals on rate of decay of hypochlorite. (Data from Gordon et al., 1993, 1995a,b.)

it is delivered with enough excess hydroxide to allow a 50 percent dilution without increasing the rate of decay. Nevertheless, pH monitoring and control are important in a hypochlorite management program.

As mentioned earlier, the rate of the dominant decay reaction in liquid bleach (Eq. 13-30) is a second-order reaction (Gordon et al., 1995a,b). As a result, a stronger bleach solution will decay faster. This effect can be illustrated by the solution of the second-order rate equation for a completely mixed batch reactor:

$$\frac{C}{C_0} = \frac{1}{1 - k_d C_0 t} \quad (13-33)$$

where  $C$  = bleach concentration after time  $t$ , mol/L  
 $C_0$  = bleach concentration at time 0, mol/L  
 $k_d$  = second-order decay coefficient, L/mol · s  
 $t$  = time, s

The effects of bleach strength and temperature are illustrated on Fig. 13-15b. Based on the data in this figure, diluting bleach delivered at a concentration of 15 percent to a concentration of 7.5 percent will increase its half-life from about 50 to about 140 days (at 25°C). If the 7.5 percent bleach is also stored at 15°C instead of 25°C, the combined effect of dilution and temperature control will increase its half-life to more than 500 days.

Finally, since the work of Lister (1952, 1956), bleach technologists have understood that certain metals can catalyze the decomposition of bleach. In the mid-1950s rhodium, iridium, cobalt, copper, manganese, iron, and nickel were issues. Today the principal concerns are copper and nickel, and manganese has also been shown to exacerbate the destructive effect of nickel. Gordon et al. (1995a,b) conducted tests to examine the effect

of a concentration of 1 mg/L of copper, iron, manganese, and nickel, individually, on the decay of a 13.5 percent bleach. These are illustrated on Fig. 13-15c. The authors recommended that copper and nickel be kept below 0.1 mg/L. Bleaches are also filtered in an attempt to reduce metals contamination, but, with one exception, additional filtering of modern commercial bleaches showed only small improvements (Gordon et al., 1995a,b). It appears that many modern bleaches are produced in such a condition that additional filtering is of little benefit.

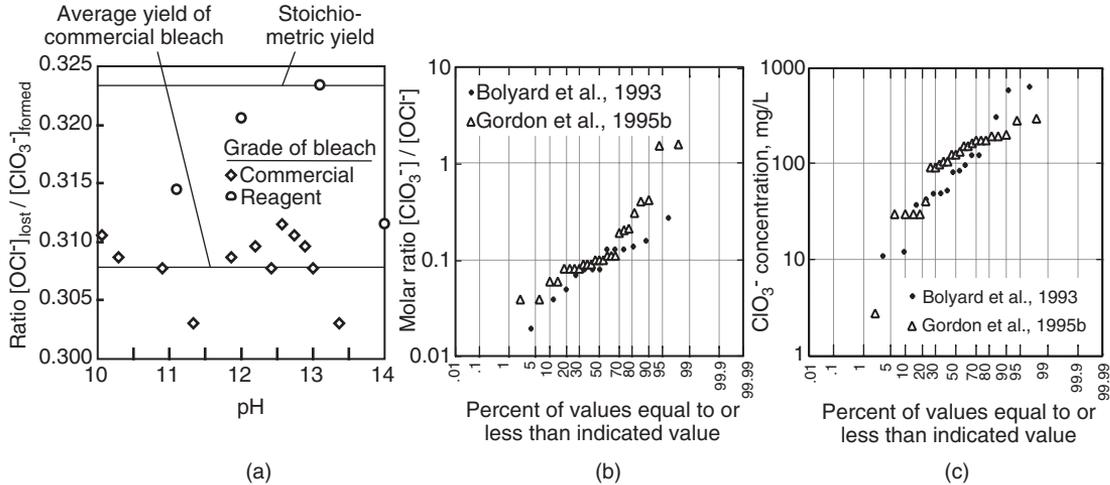

#### FORMATION OF CHLORITE AND CHLORATE ION

In 1992, the U.S. EPA discovered that hypochlorite solutions containing significant concentrations of chlorate ion were responsible for introducing chlorate ions into drinking water (Bolyard et al., 1992). Of special significance in this regard is the fact that the principal bleach decay reaction results in the production of chlorite ( $\text{ClO}_2^-$ ) and chlorate ( $\text{ClO}_3^-$ ) ions (see Eqs. 13-28 and 13-29). Chlorite is regulated by the U.S. EPA. Chlorate is regulated in some jurisdictions; for example, the State of California has set an action limit of 0.8 mg/L (Cal DHS, 2002). As a result, it seems prudent to limit the production of chlorate as well.

As noted earlier, the disassociation of chlorite to chlorate and chloride (Eq. 13-29) is much faster than the disproportionation of hypochlorite ion to chlorite and chloride (Eq. 13-28), and this minimizes the formation of chlorite ion. As a result, it is estimated that chlorite normally stays below 0.5 percent of the hypochlorite concentration (Gordon et al., 1997). Thus, a chlorine dose of 1 mg/L delivers less than 0.005 mg/L of chlorite ion into solution (Gordon et al., 1997), considerably less than the MCL of 0.8 mg/L. Thus, even though chlorite generally does not pose a problem in hypochlorite solutions; the same is not true for chlorate.

If hypochlorite decomposition were only the result of Eq. 13-30, the chlorate generated would be about 33 percent of the hypochlorite decomposed (molar basis). But other pathways for hypochlorite decay (decomposition catalyzed by light and metals) normally produces oxygen and not chlorate (Eq. 13-31). Gordon et al. (1995b) examined chlorate production in 12 tests with commercial bleaches and found that the actual production of chlorate was slightly less, about 31 percent (Fig. 13-16a). As a rule of thumb, it is conservative to assume that one-third of the bleach lost to decomposition ends up as chlorate ion.

Two surveys were also conducted to evaluate the contribution of chlorate ion to water systems using sodium hypochlorite for disinfection (Bolyard et al., 1993; Gordon et al., 1993). Both authors looked at the ratio of chlorate ion and hypochlorite ion in the bleaches being used as well as the concentration of chlorate ion in the drinking water system itself. A probability plot of the chlorate/hypochlorite ratio in the bleaches from both surveys is presented on Fig. 13-16b. In both cases, the median was slightly less than  $0.1 \text{ mol}[\text{ClO}_3^-]/\text{mol}[\text{OCl}^-]$ . On the other hand, levels greater than

**Figure 13-16**

Formation of and impacts of chlorate in hypochlorite feedstock: (a) chlorate formation during decomposition of reagent and commercial hypochlorite; (b) surveys of chlorate content in bleach; and (c) surveys of chlorate content in systems using bleach. (Data from Bolyard et al., 1993; Gordon et al., 1993, 1995a,b, 1997.)

1 mol  $[\text{ClO}_3^-] / \text{mol}[\text{OCl}^-]$  and as low as 0.02 mol  $[\text{ClO}_3^-] / \text{mol}[\text{OCl}^-]$  were observed, indicating that bleach manufacturing and storage practices can result in substantial differences. At a ratio of 0.1, a chlorine dose of 3 mg/L would cause chlorate concentrations of approximately 0.1 mg/L. Thus the chlorate that is found in bleach under typical conditions of use should not be a significant issue. Many of the considerations that affect the stability of bleach are also important in limiting its chlorate content. Nevertheless, surveys of chlorate in systems using hypochlorite did sometimes show the presence of significant chlorate (Fig. 13-16c), suggesting that utilities using hypochlorite should occasionally monitor for chlorate and consider modifying their practice if significant amounts are observed.

#### STORAGE AND FEEDING OF SODIUM HYPOCHLORITE

Experience with materials for the construction of large hypochlorite tanks has not been uniformly good. Early projects in Chicago had unsatisfactory experience with filament-wound fiberglass tanks and with underground concrete tanks with fiberglass lining. These tanks were replaced with hand lay-up fabricated fiberglass tanks using a vinyl resin binder and with plastic, continuous-weld, full-weight carbon steel tanks lined with a fiberglass-reinforced polyester material at a thickness of 0.9 mm (35 mil). The latter gave acceptable performance (White, 1999). Properly fabricated fiberglass tanks or steel tanks with a rubber or polyvinyl chloride (PVC) lining give satisfactory service as well.

Hypochlorite is an extremely aggressive chemical, and no equipment used to store or feed it can be expected to last indefinitely. Some particularly robust diaphragm and solenoid metering pumps have been successfully used, and this is the approach found in most plants (White, 1999). In very large plants (>380 ML/d or 100 mgd), White recommends metering the chemical by gravity from the storage tank through a Teflon-lined magnetic flowmeter and rate-modulating valve to the point of application.

Hypochlorite can be transported in schedule 80 PVC piping; except where exposed to sunlight, chlorinated polyvinyl chloride (CPVC) should be used. Ball valves and plug valves made of steel lined with PVC or propylene should be avoided. In general, precautions should also be taken for the potential for precipitation of calcium carbonate whenever the hypochlorite is mixed with carrying water or at the application point with the water being treated.

The high specific gravity of hypochlorite solution must be overcome to accomplish effective mixing at the point of application. This can be accomplished by using a diffuser and carrying water (be cautious about the potential formation of  $\text{CaCO}_3$ ) or by the use of a pumped jet mixer like that often used for coagulants. Mixing can also be accomplished by introducing the hypochlorite at a point of significant turbulence.

Ammonia can be supplied for water treatment applications in three forms: as a pure liquid (anhydrous ammonia), dissolved in water (aqueous ammonia), or as a dry ammonium salt, usually ammonium sulfate. Ammonia is not expensive, but the relative cost of these alternative forms of ammonia varies from one location and one application to another. For reasons of convenience, aqua ammonia is the form most commonly used. Exposure to high concentrations of ammonia vapor can be fatal. At concentrations of several hundred parts per million by volume ( $\text{ppm}_v$ ), it causes throat and eye irritation, and at higher concentrations it can cause convulsions or even rapid asphyxia. While not addressed in this discussion, appropriate precautions should be taken both in design and operation of ammonia facilities.

## Ammonia

### STORAGE AND FEEDING OF ANHYDROUS AMMONIA

At normal temperatures and pressures, anhydrous ammonia (>99 percent  $\text{NH}_3$ ) is a gas. However, it can be easily liquefied and is commonly stored and transported in liquid form in pressurized containers of the same size and same design as those used for chlorine (they are usually a different color). At atmospheric pressure, liquid anhydrous ammonia has a density of  $680 \text{ kg/m}^3$  ( $42.6 \text{ lb/ft}^3$  or  $5.7 \text{ lb/gal}$ ), approximately two-thirds that of water. Anhydrous ammonia containers comply with International Code Council (ICC) regulations, which require a minimum working pressure of 1760 kPa (256 psig) with safety valves set to release at that pressure. Valves and fittings used for anhydrous ammonia are normally rated at 2070 kPa

(300 psig). In the United States, bulk shipments of anhydrous ammonia are normally made in 23- and 73-metric-ton (25- and 80-U.S.-ton) rail tank cars, in 18-tonne (20-U.S.-ton) tank trailers, and cylinders the same size and design as those used to deliver 908 and 68 kg of liquid chlorine. It is common for vendors to provide storage tanks. Permanent (stationary) storage tanks for anhydrous ammonia can also be custom fabricated to any desired size. Such tanks must meet the same pressure restrictions as the shipping containers and are usually made of carbon steel. No copper, bronze, or brass fittings should be used because ammonia attacks copper-based alloys. Storage tanks should be sheltered from the sun to prevent excessive pressure buildup. The vapor pressure of anhydrous ammonia at 10°C is slightly more than 611 kPa (89 psig). At 30°C it nearly doubles to 1183 kPa (172 psig). The formula below may be used to estimate the vapor pressure at temperatures between 0 and 40°C:

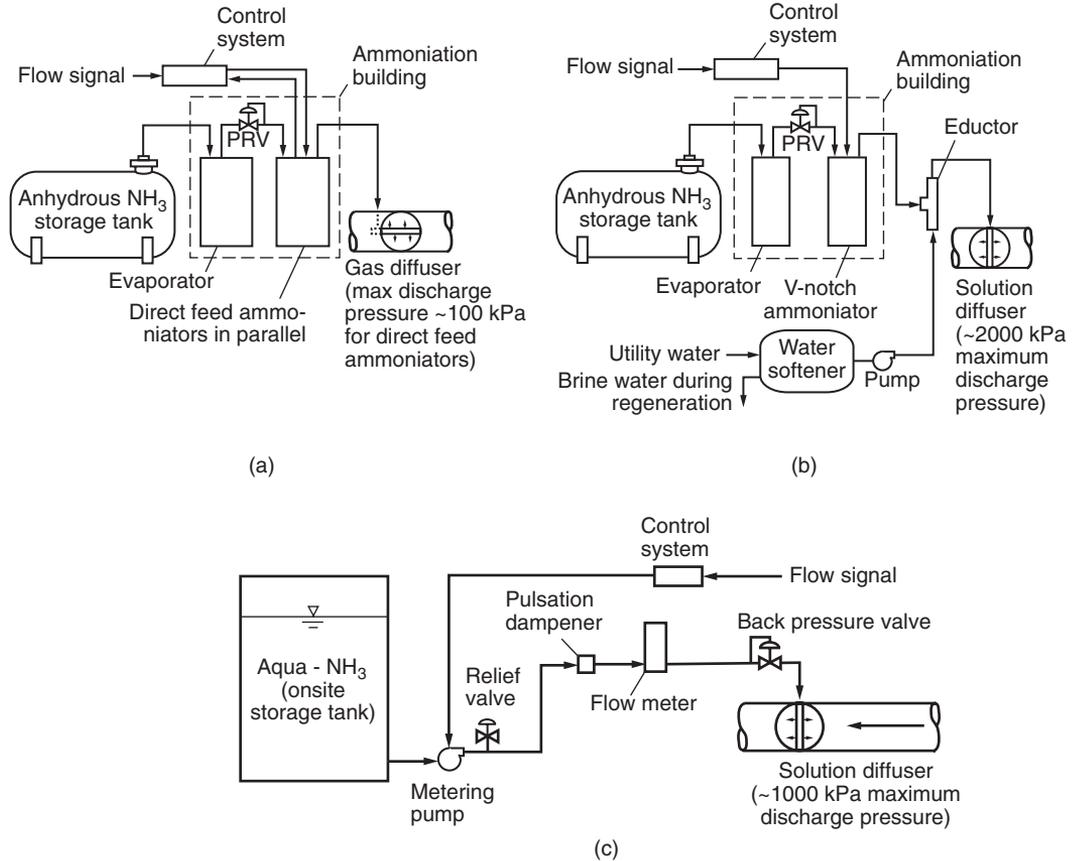

$$P_{v,\text{NH}_3} = 434.9 + 13.96T + 0.3645T^2 \quad (13-34)$$

where  $P_{v,\text{NH}_3}$  = vapor pressure of anhydrous ammonia, kPa  
 $T$  = temperature, °C

Anhydrous ammonia can be fed by two methods: direct feed and solution feed. In direct gas feed, the ammonia gas is directly introduced into the water to be treated. Unless the plant is very small, this method often suffers from poor distribution at the application point because of the low flow rate of ammonia gas. The solution feed method is analogous to the technology used to feed chlorine, except the vapor pressure of ammonia is higher. Precipitation of  $\text{CaCO}_3$  is often a problem in the vicinity of the application point.

#### *Direct gas feed*

Direct gas ammonia feeders are commercially available and differ only with respect to minor material changes from chlorinators in that they include an ammonia pressure-regulating valve, pressure gauges, a pressure relief valve, rotameters, and a control valve with back-pressure regulator, all in a modular cabinet. The ammoniator meters gaseous ammonia into the process stream under positive pressure. The high pressure in the storage tank is normally reduced to approximately 276 kPa (40 psi) using the pressure regulator. At this reduced pressure the ammonia flows through the rotameter where the gas flow can be read directly in mass/time units (In the United States the units are usually pounds per hour or pounds per day). Finally, the gas flows through the back-pressure valve, which maintains a constant back pressure on the system. This pressure is limited to a range of 101 to 122 kPa (15 to 18 psig). The back-pressure valve is used to keep the feed rate constant with changes in the pressure at the application site. Ammoniators should be housed separately from chlorination equipment. A direct-feed ammonia application is illustrated on Fig. 13-17a. For completeness, an evaporator is

**Figure 13-17**

Schematics of alternate ammonia feed systems: (a) direct feed of anhydrous ammonia; (b) solution feed of anhydrous ammonia; and (c) aqua ammonia feed system.

shown, although these are not always required. If ammonia feed rates are high enough, the anhydrous liquid would be withdrawn from the bottom of the storage tank and converted to gas in the evaporator prior to entering the ammoniator. The largest direct-feed ammoniators have a maximum feed capacity (determined by the rotameter rating) of 455 kg/d (1000 lb/d).

#### *Solution feed of anhydrous ammonia*

The design of these systems closely parallels the design of modern gas chlorination systems. An ammoniator and a gas diffuser are often used to feed the anhydrous ammonia solution (see Fig. 13-17a). A solution-feed ammoniator (see Fig. 13-17b) is typically recommended when higher feed rates or greater discharge pressures prohibit the use of direct-feed ammoniators. (It is important to remember that direct-feed ammoniators

are limited by their back-pressure valve to a pressure of approximately 100 kPa.) An important difference between ammoniation and chlorination systems is that the utility water for a solution ammoniation system must be softened to prevent the deposition of  $\text{CaCO}_3$  in the system.

#### **STORAGE AND FEEDING OF AQUA AMMONIA**

Ammonia is very soluble in water. As an example, 1 volume of water will dissolve 1150 volumes of anhydrous ammonia at a temperature of  $0^\circ\text{C}$  and atmospheric pressure. As a consequence, ammonia is commercially available as an aqueous solution of between 20 and 30 percent strength "aqua ammonia." It is usually dissolved in deionized or softened water and stored in low-pressure tanks. The vapor pressure of 30 percent aqua ammonia at  $37.8^\circ\text{C}$  ( $100^\circ\text{F}$ ), a temperature common in many parts of the world, is greater than 1 atm. To prevent off-gassing of ammonia in these locations, a slightly pressurized tank should be used. In contrast, the vapor pressure of 20 percent aqua ammonia is less than 1 atm, permitting storage in a nonpressure tank with a minimum of off-gassing. Aqua ammonia is not commonly shipped long distances; hence the largest transport vessel in the United States is a 28,300-L (7500-gal) tank trailer. There seems to be less standardization for onsite aqua ammonia storage tanks, probably because low-pressure tanks are acceptable. Steel and fiberglass tanks are both used in water treatment applications.

Depending on the concentration of aqua ammonia, excessive temperatures can cause ammonia gas to come out of solution. Off-gassing should be considered in design, and a slightly pressurized storage tank with a relief valve vented to a water trap or ammonia scrubber may be necessary to keep vapors from escaping to the atmosphere.

Aqua ammonia can sometimes be fed directly to the process stream using a metering pump. Suitable metering pumps are commercially available. Progressive cavity pumps have also been successfully used. The storage tank is a permanent onsite facility and should have enough storage for at least 10 days of maximum usage. The tank should have a liquid-level monitor to allow monitoring of the inventory in the tank. The flow metering pump should be located in the proximity of the tank and below its hydraulic grade to minimize chances of ammonia vaporization in the piping. If necessary, the metering pumps can be sheltered in a building; however, the pumps themselves do not necessarily require shelter as do the anhydrous ammonia feed equipment mentioned earlier. An aqua ammonia feed system is illustrated on Fig. 13-17c.

#### **STORAGE AND FEEDING OF AMMONIUM SULFATE**

The most common salt of ammonia used in water treatment is ammonium sulfate,  $(\text{NH}_4)_2\text{SO}_4$ . This form of ammonia has the advantage that it does not raise the pH as much as the others do. As a result, it is easier to combine it with dilution water to obtain proper mixing. Mixing can be an important

consideration when adding ammonia to water containing free chlorine to arrest the formation of DBPs.

#### MIXING

Adding chlorine to water that already has ammonia in it can result in undesirable reactions while mixing takes place. To prevent free ammonia and thus minimize nitrification, it is common for water systems today to add ammonia at a total dose that is at the peak of the breakpoint curve (a 1:1 molar ratio). By definition, the ratio of chlorine to ammonia in the entire mixing zone is on the left side of the breakpoint curve. This condition necessitates that the mixing be rapid relative to the time for the irreversible oxidation of ammonia. That is,

$$t_{\text{mix}} \ll t_{\text{rx}} \quad (13-35)$$

where  $t_{\text{mix}}$  = time required to obtain mixing to microscale, s

$t_{\text{rx}}$  = half-life of breakpoint reaction, s

Although this circumstance is easily described in a qualitative way, it is quite difficult to characterize quantitatively because  $t_{\text{rx}}$  is a function of not only the pH but also the local  $\text{Cl}_2/\text{NH}_3$  ratio (affected by the degree of mixing). When ammonia is added to a chlorinated water to arrest the formation of disinfection by-products, very good mixing is required to ensure that chemicals are efficiently used (see Chap. 6).

#### MANAGING COMBINED CHLORINE (CHLORAMINE) RESIDUALS

Maintaining a combined chlorine residual involves some considerations that are not important when a free-chlorine residual is used. Chloramines have the advantage that their odor threshold is lower (Krasner and Barrett, 1984), that they are more effective in controlling microbial growth on pipe surfaces (Le Chevallier et al., 1988), and that they are generally much more stable (Trussell and Kreft, 1984). It should be noted that combined chlorine residuals are subject to destruction by biological nitrification, especially if temperatures are warm and if ammonia is used in excess. Also there is recent evidence that the use of combined chlorine can result in the formation of low levels of NDMA, a suspected human carcinogen (Najm and Trussell, 2000, 2001). Some of the conditions that aggravate NDMA formation, namely a high chlorine-to-ammonia ratio, are the same things that discourage nitrification.

## 13-6 Disinfection with Chlorine Dioxide

---

When the regulation of the chlorination by-products began, chlorine dioxide (along with ozone) was a fairly high-profile disinfection alternative (U.S. EPA, 1979). Chlorine dioxide is widely used in continental Europe,

particularly Germany, Switzerland, and France, and produces almost no identifiable organic by-products, except low levels of a few aldehydes and ketones (Bull et al., 1990). Chlorine dioxide was known to produce two inorganic by-products, chlorite and chlorate ion. As a result, most applications of chlorine dioxide were on low-TOC waters that did not require a high dose to overcome oxidant demand. Late in the 1980s, concern about the toxicity of chlorite ion and chlorine dioxide itself reached a peak. Also, based on field experience, it was found that the use of chlorine dioxide was sometimes responsible for a very undesirable “cat urine” odor (Hoehn et al., 1990). As a precautionary measure, the State of California banned the use of chlorine dioxide for the disinfection of drinking water and several other states followed.

Eventually, when the disinfectant by-product rule was promulgated (U.S. EPA, 1998), an MCL of 0.8 mg/L was set for chlorite ion and a maximum disinfectant residual limit (MDRL) of 1 mg/L was set for chlorine dioxide. No MCL was placed on chlorate ion, but utilities were encouraged to be cautious about the production of chlorate and, again as a precautionary measure, the State of California has set an action level of 0.8 mg/L. Methods for reducing the concentration of chlorite ion downstream of the use of chlorine dioxide have been demonstrated (Griese et al., 1991; Iatrou and Knocke, 1992), and it has been established that the cat urine odor only occurs when chlorite ion is exposed to a free chlorine residual. As a result, it appears that chlorine dioxide may indeed play an important role in DBP control, particularly in systems using combined chlorine for residual maintenance and looking for a small boost in primary disinfection.

### Generation of Chlorine Dioxide

The principal reactions that occur in most chlorine dioxide generators have been known for a long time. In industry, large-scale chlorine dioxide generators use chlorate as a feedstock, but for potable water applications chlorine dioxide is usually generated onsite using a 25 percent sodium chlorite solution. Although a sodium chlorite feedstock is a common starting point, a number of different approaches are used to convert the chlorite to chlorine dioxide. These include reactions with gaseous chlorine ( $\text{Cl}_2$ ), aqueous chlorine ( $\text{HOCl}$ ), or acid (usually hydrochloric acid,  $\text{HCl}$ ). The reactions are

The stoichiometry of Eq. 13-36 requires 0.5 kg of chlorine and 1.34 kg of sodium chlorite to produce 1 kg of chlorine dioxide. Several of the alternative approaches used for the generation of chlorine dioxide are summarized in Table 13-6.

**Table 13-6**  
Chlorine dioxide generation alternatives

Generator Type	Main Reactions, Reactants, By-products, Key Reactions, and Chemistry Notes	Special Attributes
<i>Acid–chlorite:</i> (direct acid system)	$5\text{NaClO}_2 + 4\text{HCl} \rightarrow 4\text{ClO}_2(\text{g}) + 5\text{NaCl} + 2\text{H}_2\text{O}$ <input type="checkbox"/> Low pH <input type="checkbox"/> $\text{ClO}_3^-$ also possible <input type="checkbox"/> Slow reaction rates	Chemical feed pump interlocks required; production limit ~10–15 kg/d (25–30 lb/d); maximum yield is ~80% of stoichiometric yield.
<i>Aqueous chlorine–chlorite:</i> ( $\text{Cl}_2$ gas ejectors with chemical pumps for liquids or booster pump for ejector water)	$\text{Cl}_2 + \text{H}_2\text{O} \rightarrow \text{HOCl} + \text{HCl}$ $\text{HOCl} + 2\text{NaClO}_2 \rightarrow \text{ClO}_2(\text{g}) + \text{NaCl} + \text{NaOH}$ <input type="checkbox"/> Low pH <input type="checkbox"/> $\text{ClO}_3^-$ also possible <input type="checkbox"/> Relatively slow reaction rates <input type="checkbox"/> Excess $\text{Cl}_2$ or acid to neutralize NaOH	Production rates limited to ~450 kg/d (1000 lb/d); high conversion but yield only 80–92%; more corrosive effluent due to low pH (~2.8–3.5); three chemical systems pump HCl, hypochlorite, chlorite, and dilution water to reaction chamber
<i>Recycled aqueous chlorine–chlorite:</i> (saturated $\text{Cl}_2$ solution via a recycling loop prior to mixing with chlorite solution)	$2\text{HOCl} + 2\text{NaClO}_2 \rightarrow 2\text{ClO}_2 + \text{Cl}_2 + 2\text{NaOH}$ <input type="checkbox"/> Excess $\text{Cl}_2$ or HCl needed due to NaOH formed <input type="checkbox"/> Concentration of ~3 g/L required for maximum efficiency	Production rate limited to ~450 kg/d (1000 lb/d); yield of 92–98% with ~10% excess $\text{Cl}_2$ reported; highly corrosive to pumps; drawdown; calibration needed; maturation tank required after mixing
<i>Gaseous chlorine–chlorite:</i> (gaseous $\text{Cl}_2$ and 25% solution of sodium chlorite; pulled by ejector into the reaction column)	$\text{Cl}_2(\text{g}) + 2\text{NaClO}_2 \rightarrow 2\text{ClO}_2(\text{g}) + 2\text{NaCl}$ <input type="checkbox"/> Neutral pH <input type="checkbox"/> Rapid reaction <input type="checkbox"/> Potential scaling in reactor under vacuum due to hardness of feedstock	Production rates 2300–55,000 kg/d (5000–120,000 lb/d); ejector based, with no pumps; motive water is dilution water; near-neutral pH effluent; no excess $\text{Cl}_2$ ; turndown rated at 5–10X with yield of 95–99%; less than 2% excess $\text{Cl}_2$ ; highly calibrated flowmeters with minimum line pressure ~275 kPa (40 psig) needed

Source: Adapted in part from U.S. EPA (1999).

The differences between Eqs. 13-36, 13-37, and 13-38 help to explain how generators can differ even though the same feedstock chemicals are used and why some should be pH controlled and others are less dependent on pH. In most generators, more than one reaction may be taking place.

Chlorine dioxide generators are relatively simple mixing chambers. The reactors are frequently filled with media (Teflon chips, ceramic, or Raschig rings) to generate hydraulic turbulence for mixing. A sample petcock valve on the discharge side of the generator is desirable to allow for monitoring of the generation process. An excellent source for additional information on chlorine dioxide generation may be found in Masschelein (1992).

### **Sodium Chlorite**

Sodium chlorite is used as a solution, normally with a concentration of approximately 25 percent sodium chlorite or less. It is commercially available as a 25 or 38 percent solution. The major safety concern for solutions of sodium chlorite is the unintentional and uncontrollable release of high levels of chlorine dioxide gas. Levels that approach an explosive mix can sometimes occur if the sodium chlorite is exposed to acid.

Another concern to be addressed with sodium chlorite is crystallization. Like most salts, sodium chlorite solutions are prone to crystallization at low temperatures and/or higher concentrations. When crystallization occurs, it may obstruct flow in pipelines, valves, and other equipment.

Sodium chlorite is not stable as a powder. If dried, it is a fire hazard and can ignite when in contact with combustible materials. A sodium chlorite explosion may occur if too much water and inappropriate firefighting techniques are used to quench such a fire. Burning sodium chlorite will quickly generate enough heat to turn water to steam. At high temperatures, the breakdown products of sodium chlorite include oxygen. As a result, highly trained firefighters are required to extinguish closed containers or dry material that has been ignited.

Stratification in holding tanks for sodium chlorite solutions may also occur and, when it does, will adversely influence the chlorine dioxide yield in the generator. As stratification develops, the sodium chlorite solution being fed gradually changes from low to high density as the generator operates. In stratified tanks, excess chlorite will be fed to the generator as the bottom of the tank will have denser material, and this material will have more chlorite than required. Similarly, the bulk tank will later yield chlorite that is too dilute. Although infrequent, such stratification is not readily apparent and may likely remain unnoticed by an operator unless the generator performance is evaluated frequently. Operators should be aware of the possibility of stratification and crystallization during delivery conditions.

## **13-7 Disinfection with Ozone**

---

Ozone is the strongest of the chemical disinfectants and its use is becoming increasingly common. Ozone ( $O_3$ ) is an allotrope of oxygen with three oxygen atoms. The word *ozone* comes from the Greek word *ozein*, which means “to smell.” In air, ozone has a pungent odor that is noticeable to

most persons at levels above 0.1 ppm<sub>v</sub>. Ozone is generated at the treatment plant site as a gas and is then injected into water.

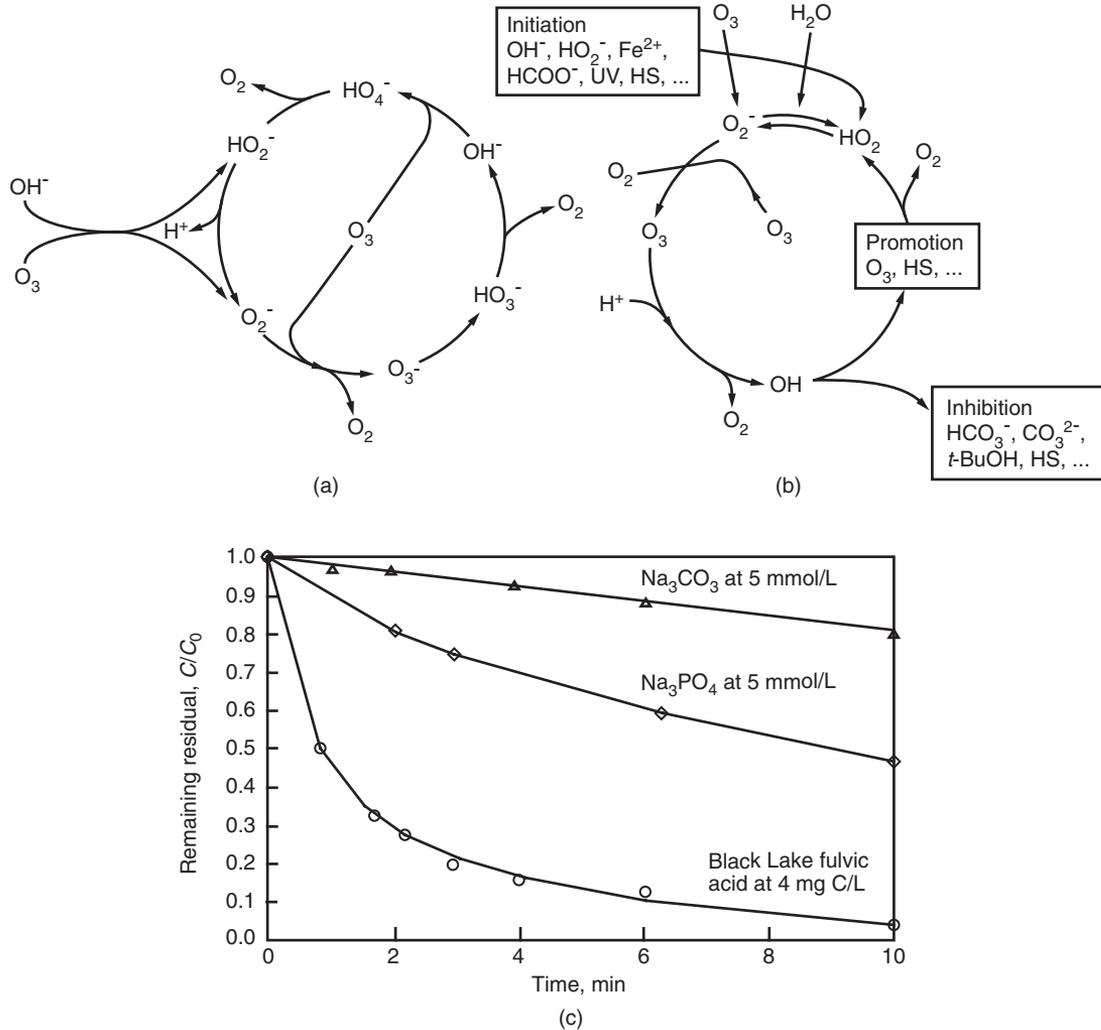

Once dissolved in water, ozone begins a process of decay that results in the formation of the hydroxyl radical (HO·). Ozone reacts in two ways with contaminants and microbes: (1) by direct oxidation and (2) through the action of hydroxyl radicals generated during its decomposition. The consensus is that action of ozone as a disinfectant is primarily dependent on its direct reactions; hence it is the residual of the ozone itself that is important.

The ozone demand is the ozone dose that must be added before any ozone residual is measured in the water. It corresponds to the amount of ozone consumed during rapid reactions with readily degradable compounds. Ozone decay is the rate at which the residual ozone concentration decreases over time when the ozone dose is greater than the ozone demand. The overall rate of ozone decay in water is generally consistent with first-order kinetics. Like chlorine, it can be modeled successfully using a parallel first-order decay model, as shown in Eq.13-9. Although simple reactions serve as good phenomenological models for ozone decay, it is unlikely that they correctly characterize the actual mechanism of decay. From work done in this area (Grasso and Weber, 1989; Gurol and Singer, 1982; Hermanowicz et al., 1999; Staehelin and Hoigné, 1982, 1985; Tomiyasu et al., 1985), it appears more likely that ozone decay consists of a large number of *n*th-order reactions operating in parallel that, in sum, appear to be simple first order.

An introduction to ozone decay based on the models developed by Staehelin and Hoigné (1982, 1985) is provided on Fig. 13-18. The cyclic nature of the ozone decay process in pure water is illustrated on Fig. 13-18a. The process must be initiated by a reaction between ozone and the hydroxide ion to form superoxide radicals (O<sub>2</sub><sup>-</sup>) and peroxide ions (HO<sub>2</sub><sup>-</sup>), a slow process. As a result, decay is accelerated at higher pH. Once completed, the decay reactions enter a cyclic process represented in the figure by a circle. The cyclic reactions are promoted by ozone itself. If the concentration of ozone is increased, the cycle is accelerated.

In natural waters, other “initiators” besides hydroxide ion can be present as shown on Fig. 13-18b. Prominent among them are the ferrous ion and hydrogen peroxide. In natural waters certain natural organic materials have also been shown to promote the cycle, accelerating decay. Finally, the continuation of the cycle depends on the action of the hydroxyl radical on the ozone residual. As a result, scavengers that react with the hydroxyl radical, removing it from the process, also slow the rate of decay. The carbonate and bicarbonate ions are important examples of such inhibitors. The data of Reckhow and co-workers (Reckhow et al., 1986), are shown on Fig. 13-18c to illustrate the action of fulvic acids as initiators and promoters and carbonate and bicarbonate ions as HO· traps or inhibitors. The factors that influence the stability of ozone residuals are summarized in Table 13-7.

### Ozone Demand and Ozone Decay

**Figure 13-18**

Understanding ozone reaction pathways and decay of residual ozone in natural waters: (a) the ozone decay wheel—reaction pathways in pure water (adapted from Hoigné and Bader, 1976); (b) influence of initiators, promoters, and inhibitors (adapted from Hoigné and Bader, 1976); (c) effect of fulvic acid and carbonate on ozone decay—all tests conducted at 20°C with GAC filtered, deionized tap water adjusted to pH 7, and  $C_0 \sim 8$  mg/L. (Adapted from Reckhow et al., 1986).

### Bench Testing for Determining Ozone Disinfection Kinetics

The conceptual design of any ozonation system requires a means for estimating mass transfer of ozone into the water, an understanding of the kinetics of ozone decay, and an understanding of the disinfection kinetics. These components are often investigated using bench and pilot testing. Both batch and flow-through reactors have been used for bench testing, as described in the following sections.

**Table 13-7**

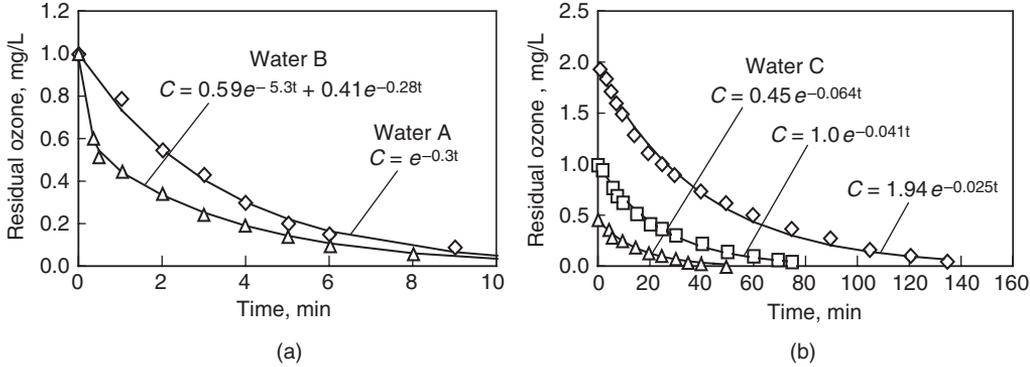

Factors that influence stability of aqueous ozone residuals

Increases Stability	Reduces Stability
Low pH	High pH
High alkalinity	Low alkalinity
Low TOC	High TOC
Low temperature	High temperature

#### ANALYSIS USING BATCH REACTORS

Batch testing is often conducted by bubbling ozone directly into a gas wash bottle containing the sample of interest. The ozone concentration is measured in the gas entering and exiting the bottle, and the difference constitutes the ozone added to or consumed by the sample. For a number of reasons, the preferred technique is to prepare the ozonated water first and then add that to the sample of interest. In this case, the batch reactor might be a 1- or 2-L jar or a 0.5- to 1-L Teflon bag containing the water of interest. The concentrated ozone solution is prepared in a separate container by continuously bubbling ozone gas into a small volume of distilled–deionized (DI) water. At ambient temperature, the maximum ozone solution concentration may be about 15 mg/L. To prepare a more concentrated solution, the DI water can be chilled in an ice bath. At temperatures close to 1°C, the concentration of ozone in the stock solution can be as high as 40 mg/L. Aliquots of the ozone stock solution are then drawn and injected into the test water sample. The volume of each aliquot is calculated to deliver a predetermined ozone dose to the test water sample. Water samples are then drawn from the test water at various times after the ozone is added and analyzed for ozone residual concentration. This test is repeated using various ozone doses.

The profile of ozone residual concentration versus time can then be plotted. Two example ozone decay profiles in two waters dosed with 1.0 mg/L ozone are shown on Fig. 13-19a. Both waters have relatively high ozone demand, particularly water B. The profile of ozone decay in water A is typical of most moderate TOC, well-oxygenated surface waters. The curve fit through the data points is that of a pseudo-first-order decay equation with a decay coefficient of  $0.3 \text{ min}^{-1}$ . The decay of ozone in some waters does not always follow this uniform first-order decay model. Water B is an example of common ozone decay profiles where the ozone experiences an initial period of a high decay rate followed by a second period of slower decay. The curve fit through the data points for water B was accomplished using Eq. 13-9: Although this equation is based on the progress of two parallel first-order reactions, it should be viewed as a phenomenological model, not a mechanistic one. Based on experimental evidence, ozone, and

**Figure 13-19**

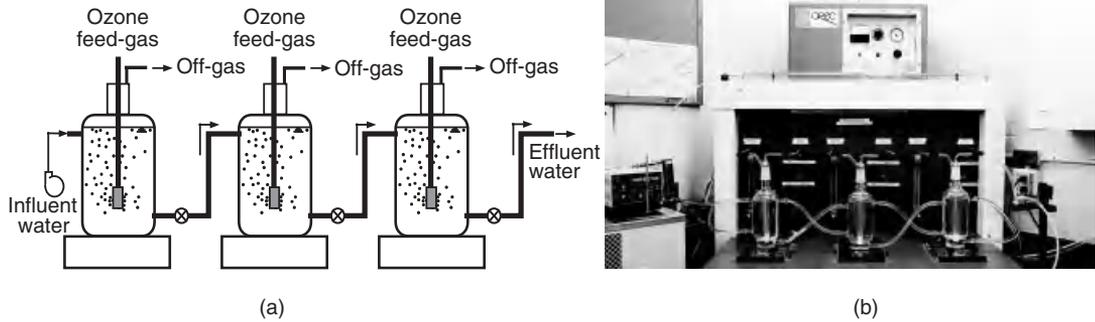

Typical batch ozone decay curves for three different waters: (a) waters A and B and (b) water C.

particularly the hydroxyl radical that is produced when it decays, participate simultaneously in many reactions of different orders at the same time.

Another result of this complexity is that with ozone, as with chlorine, the rate of decay observed in a batch test is also influenced by the ozone residual at the beginning of the decay period, as illustrated on Fig. 13-19b using the data from a pure mountain water supply. In general, these curves exhibit a low rate of decay; nevertheless they also show a rate of decay that decreases as the residual at the beginning of the decay process ( $C_0$ ) increases. As with chlorine, the change in decay rate is approximately inversely proportional to  $C_0$ . As a result of these complexities, if only batch testing is conducted to determine the basis of design, a wide variety of test conditions must be evaluated to get an adequate database for design. Even with such data, a number of assumptions and approximations must be made during the process of design.

#### ANALYSIS USING FLOW-THROUGH REACTORS

Continuous-flow reactors (see Fig. 13-20) are better than batch reactors for gathering information for design of ozonation facilities, especially for an over-under ozone contactor with ozone addition via diffusers. In full-scale designs of this type, the ozone is generally added in the first few compartments of the design, and then the residual is allowed to decay as the water travels throughout the rest of the reactor. This approach to design and operation can be simulated by operating the small-scale continuous-flow unit so that it has the same detention time as the ozone addition compartments will have in the full-scale design. Once the reactor has reached steady-state operation, both the flow of water and the ozone dosing can be stopped and the decay of ozone residual can be observed as a function of time. The continuous operation simulates the ozone addition

**Figure 13-20**  
Bench-scale continuous-flow ozonation test system: (a) schematic and (b) photograph.

compartments and the decay curve can be used to estimate the residual in downstream compartments.

A continuous-flow setup requires measuring the ozone gas flow rate, water flow rate, ozone concentration in the feed gas, and ozone concentration in the off-gas. The ozone dose to the reactor is then calculated with a mass balance as

$$\text{Ozone dose, mg/L} = \frac{Q_g}{Q_l} \times (C_{g,\text{in}} - C_{g,\text{out}}) \quad (13-39)$$

where  $Q_g$  = gas flow rate, L/min  
 $Q_l$  = water flow rate, L/min  
 $C_{g,\text{in}}$  = concentration of ozone in feed gas, mg/L  
 $C_{g,\text{out}}$  = concentration of ozone in off-gas, mg/L

For each ozone dose, the operating conditions are kept constant until steady-state conditions are reached. This stabilization period can be between three and five times the hydraulic residence time of the reactor. It is essential that the continuous reactors be operated with approximately the same detention time as the ozone addition compartments in the full-scale design. An RTD curve similar to the full-scale reactor is also highly desirable. Unfortunately, tall, narrow pilot columns with long aspect ratios are often used because they achieve more efficient ozone transfer. The use of tall columns is not a particularly good choice because they much more closely approach plug flow than full-scale designs. This test must also be conducted at various doses because it is important to understand the relationship between the ozone dose and the ozone residual in the water exiting the ozone addition section of the reactor. The ozone decay rate downstream of these compartments will vary with this residual as well.

### Example 13-8 Analysis of bench-scale ozone data

A municipality wishes to build a treatment plant incorporating an ozonation reactor and using water from a particular lake as a raw-water source. The lake water was studied using a bench-scale continuous-flow test unit (see Fig. 13-20), which included a three-compartment ozonation system, providing a total of 3.8 min of contact time (all three compartments). The system was operated at four different ozone doses. Samples were collected using two methods: (a) continuous-flow tests and (b) batch decay tests. In the continuous-flow test, the effluent from the third compartment was sampled for ozone residual after 15 min operation at each dose. For the batch test the system was shut down and the residual in the final compartment was sampled with time. The summary results of the testing program are given below. Using these data, estimate the ozone demand and the decay rate constant at each initial ozone residual.

For the sizing of the full-scale ozonation system, estimate the  $Ct$  product that can be achieved if the system is designed for an ozone dose of 3 mg/L at a temperature of 27°C. Assume the following conditions apply: (1) all ozone is added in the first compartment, which has a residence time of 3.8 min, (2) no  $Ct$  credit is allowed for the first compartment, and (3) the total residence time of the remaining compartments is 15 min.

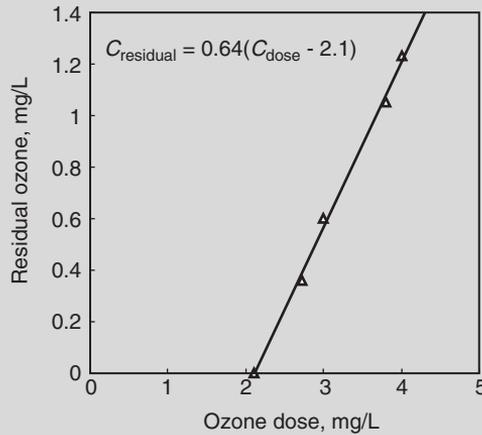

Results from Continuous-Flow Tests		Results from Batch Decay Tests			
Ozone Dose, mg/L	O <sub>3</sub> Residual, mg/L	Time, min	O <sub>3</sub> Residual, mg/L	Time, min	O <sub>3</sub> Residual, mg/L
2.10	0	0.0	1.23	0.0	0.60

#### Solution

1. Analysis of continuous-flow data: The continuous-flow data for  $\tau = 3.8$  min and  $T = 27^\circ\text{C}$  are plotted below. The best-fit line can be described using the equation

$$C_{\text{Residual}} = a(C_{\text{dose}} - C_{\text{demand}})$$

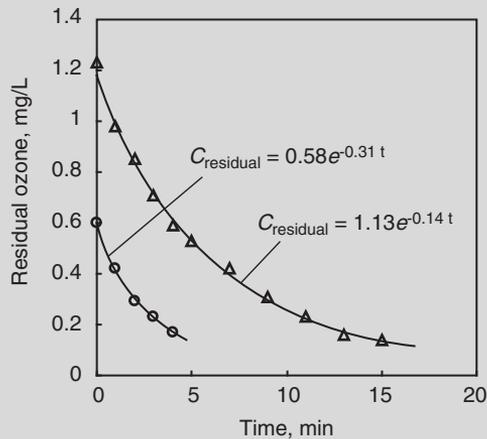

Using the form of the equation shown above, the best-fit line parameters from the plot are  $a = 0.64$  and  $C_{\text{demand}} = 2.1$  mg/L. The above equation can be used to estimate the dose required to achieve a specified residual exiting the ozone dosing compartment in the reactor.

2. Analysis of the batch decay data: The batch decay data are plotted below. The best-fit parameters are obtained using an exponential curve fit. The corresponding equations are

$$\text{For } C_0 = 1.23 \text{ mg/L (dose} = 4 \text{ mg/L): } C_{\text{residual}} = 1.13e^{-0.14t}$$

$$\text{For } C_0 = 0.60 \text{ mg/L (dose} = 3 \text{ mg/L): } C_{\text{residual}} = 0.58e^{-0.31t}$$

3. Determine the maximum  $Ct$  credit for the full-scale system assuming an ozone dose of 3 mg/L. Use the results from the batch decay data for the ozone dose of 3 mg/L.
- a. The maximum  $Ct$  credit can be estimated by numerical integration of the equation developed in step 2.

$$\Sigma Cdt = 1.86 \text{ mg} \cdot \text{min/L}$$

### Comment

Dispersion and short circuiting are not considered in the above calculations.

## Generation of Ozone

At high concentrations (>23 percent) ozone is unstable (explosive) and under ambient conditions it undergoes rapid decay. Therefore, unlike chlorine gas, it cannot be stored inside pressurized vessels and transported to the water treatment plant. It must be generated onsite. Ozone can be generated by photochemical, electrolytic, and radiochemical methods, but the corona discharge method is the most commonly used in water treatment. In this method, oxygen is passed through an electric field that is generated by applying a high-voltage potential across two electrodes separated by a dielectric material (see Fig. 13-21). The dielectric material

**Figure 13-21**  
Ozone generation by corona discharge.

**Table 13-8**

Influence of increasing four key design factors on generator performance

Design Factor	Effect on Ozone Production
Frequency of applied current	Increases ozone production
Voltage of applied current	Increases ozone production
Gap between generator electrodes	Decreases ozone production
Dielectric constant of dielectric separating electrodes	Decreases ozone production

prevents arcing and spreads the electric field across the entire surface of the electrode. As the oxygen molecules pass through the electric field, they are broken down to highly reactive oxygen singlets ( $O\cdot$ ), which then react with other oxygen molecules to form ozone. The thickness of the gap through which the oxygen-rich gas stream passes is 1 to 3 mm wide. Because most of the energy used in ozone generation is lost as heat, cooling of the ozone generator is necessary to avoid overheating and subsequent decomposition of the ozone generated. Cooling is normally accomplished by passing a continuous stream of cooling water next to the ground electrode. Some of the key design factors that influence ozone generator performance are summarized in Table 13-8.

The equation below, while not intended to be quantitative, provides a general idea of the significance of a number of the variables of importance to the design of a corona discharge ozone generator:

$$Q_{O_3} \propto \left( f \frac{V^2 A}{d \varepsilon} \right) Q_{O_2} \quad (13-40)$$

where  $Q_{O_3}$  = ozone generation, kg/s  
 $f$  = frequency of applied emf  
 $V$  = emf across electrodes, V  
 $A$  = surface area of electrodes, m<sup>2</sup>  
 $d$  = distance between electrodes, m  
 $\varepsilon$  = dielectric constant  
 $Q_{O_2}$  = oxygen flow rate, kg/s

## Oxygen Source

Ozone can be generated directly from the oxygen in air or from pure oxygen. Pure oxygen is generated onsite from ambient air at larger plants or provided through the use of liquid oxygen (commonly referred to as LOX), which is generated offsite and transported to the plant. The most suitable method for providing oxygen for ozone generation in a particular plant depends on economic factors, the principal ones being the scale of the facility and the availability of industrial sources of liquid oxygen.

### USE OF PREPARED, AMBIENT AIR

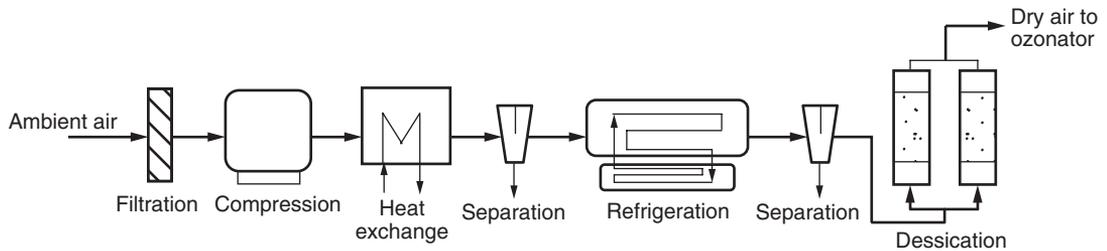

The most accessible oxygen source is ambient air, which contains about 21 percent oxygen by volume. Ambient air used to be the most common source of oxygen for ozone systems, but it has largely been replaced by liquid oxygen except for small, remote systems. Ambient air contains significant levels of particulates and water vapor, which must be removed. Water vapor is detrimental to corona discharge ozone generators for two reasons: (1) the presence of water vapor significantly reduces the ozone generation efficiency and (2) trace levels of water can react with the nitrogen present in the air and the generated ozone to form nitric acid, which attacks the ozone generator itself:

The moisture content of a gas is often defined by its dew point, which is the temperature to which the gas needs to be cooled to reach 100 percent saturation. The lower the dew point of a gas, the lower is its moisture content. For example, air with a dew point of 30°C contains about 28,000 ppm<sub>v</sub> of water, whereas air with a dew point of 5°C contains about 5000 ppm<sub>v</sub> of water. The dew point specified for many ozone generators is as low as -80°C, which corresponds to a moisture content of less than 1.5 ppm<sub>v</sub>. Drying ambient air to this level is usually accomplished by a three-step process of compression, refrigeration, and desiccant drying. Compression and refrigeration help because the water vapor capacity of air decreases with increased pressure and decreased temperature, reducing the load on the desiccant system. Desiccant drying, however, is required to achieve the specifications for ozone generation. A schematic of all the components of such a system is shown on Fig. 13-22.

### LIQUID OXYGEN DELIVERY

Liquid oxygen is widely available as a commercial, industrial-grade chemical and is the most common source of oxygen for ozone systems. Water treatment plants can purchase commercially available LOX, store it at the plant, and use it as the oxygen source for ozone generation. Liquid oxygen is delivered in trucks and stored in insulated pressurized tanks. Liquid oxygen is then drawn from the tank and piped to a vaporizer that warms and converts the oxygen to the gaseous form. Commercially available

**Figure 13-22**

Preparation system for ozone generation from ambient air.

**Figure 13-23**

Liquid oxygen (LOX) storage container tanks at a large water treatment plant.

LOX is inherently low in contaminants and water vapor as a result of the manufacturing process. Therefore, minimal additional processing of the oxygen stream is required before it is introduced to the ozone generator. A LOX storage system at a large water treatment plant is shown on Fig. 13-23.

The use of LOX for ozone generation has several advantages over the use of ambient air, including (1) simpler operation and maintenance because fewer processes are required, (2) a smaller facility with lower capital cost, and (3) a smaller number of ozone generators. The disadvantages of LOX include (1) increased truck traffic caused by the need for regular LOX deliveries and (2) susceptibility to market pricing. Safety concerns associated with the storage of a large volume of concentrated oxygen must also be addressed. However, the advantages are significant and LOX has largely displaced the use of ambient air as the most common source of oxygen for ozone systems.

**ONSITE OXYGEN GENERATION**

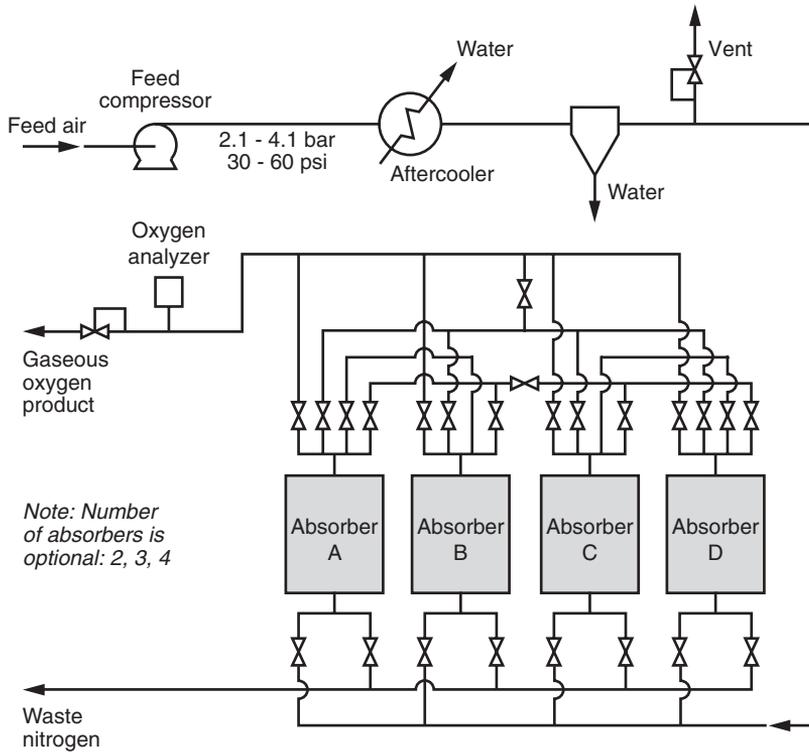

Two types of onsite oxygen separation and concentration processes are used in water treatment plants that require oxygen: (1) pressure swing or vacuum swing adsorption (PSA or VSA) processes and (2) cryogenic oxygen generation processes. Generally, the economics of these processes improve as oxygen requirements increase. None are more economical than LOX feed systems in small applications. VSA systems are viable for systems requiring as much as 100 tonnes/d (110 tons/d) (Lotepro, 2002), and PSA systems can be used for smaller systems needing onsite oxygen generation. Cryogenic oxygen generation was installed at a few very large ozone systems in the past but are generally not economically competitive today for drinking water applications.

The PSA and VSA processes take advantage of the effect of gas pressure on the differences in the adsorption characteristics of the various constituents of ambient air on specialty adsorption resins. For the generation of oxygen, the affinity of the resin for nitrogen, water, and carbon dioxide is higher than that for oxygen and increases with increased pressure. Therefore, the PSA or VSA system cycles between “high” and “low” pressures. During the high-pressure period, water moisture, carbon dioxide, nitrogen, and any hydrocarbons present preferentially adsorb onto the resin while oxygen, now constituting about 90 to 95 percent of the remaining gas, passes through. Once the resin is saturated with the constituents removed, the system cycles to the low pressure, resulting in the desorption of the adsorbed material, which is then exhausted to the atmosphere before the cycle is repeated. For a PSA system, the high-pressure setting ranges from 200 to 400 kPa (30 to 60 psig), while the low setting is atmospheric pressure. In a VSA system, the high-pressure setting is at 20 to 70 kPa (3 to 10 psig), while the low setting is achieved using a vacuum pump. VSA systems are favored over PSA for large systems because they utilize less energy. However, a VSA system requires additional equipment compared to a PSA system in the form of a vacuum pump as well as a downstream compressor to boost the pressure of the oxygen stream to the level required by the ozone generator. The need for an extra pump translates into higher capital cost and higher maintenance cost. The schematic layout of a typical PSA system is illustrated on Fig. 13-24.

Regardless of whether air or pure oxygen is used for ozone generation, the efficiency of ozone generators is relatively low. When ambient air is used as the feed gas, ozone content in the generator outlet is typical between 1 and 4 percent by weight. With pure oxygen, typical generators produce about 6 to 16 percent ozone by weight.

**Ozone Injection Systems**

The addition of ozonation in a water treatment plant requires two components in the process treatment train: (1) a device for injecting the ozone

**Figure 13-24**  
Schematic of pressure swing adsorption system for producing pure oxygen.  
(Adapted from Lotepro, Inc.)

into the water and (2) a contact chamber in which the disinfection reaction takes place. For several decades, the most common approach to ozonation has been to combine these components by introducing the ozone into the water in large, deep basins using porous diffusers. More recently, the injection and contact systems are designed separately. For injection systems, side-stream injection using venturi injectors with or without side-stream degassing has become more common than fine bubble diffusers. Ozone contactors can be pipeline contactors, serpentine basins, or over-under baffled contactors and are described in Sec. 13-8. Details of the design of side-stream ozone injection systems can be found in Rakness (2005) and are described briefly below.

In side-stream injection, a portion of the process flow is withdrawn from the main process line and pumped through a venturi injector. Low pressure in the throat of the injector draws ozone gas in from the ozone generator. After dissolution of the ozone gas, the side stream is injected back into the process stream through nozzles that provide good blending of the

ozonated side stream into the main flow. In some systems, the side stream passes through a degassing tower before being injected into the process stream. After the ozone is injected, the process water flows to a pipeline or serpentine basin contactor. Design of contactors is presented in the next section.

The purpose of the degasser in the side stream is to allow undissolved and supersaturated gases to separate from the water prior to injection to the main process flow and to minimize bubbles in the ozone contactor. Since the carrier gas for the ozone is typically pure oxygen, the process flow can become supersaturated with oxygen, which can lead to problems with downstream processes such as air binding in rapid granular filters. If the side stream does not contain a degas vessel, a mechanism for stripping supersaturated oxygen, such as by diffusing air after the ozone contactor, should be provided.

An advantage of side-stream injection coupled with pipeline or serpentine basin contactors is that these contactors can be designed with less dispersion and short-circuiting than over-under baffled contactors. The importance of dispersion in disinfection was presented in Sec. 13-4. In the case of ozonation, dispersion not only reduces the effectiveness of the disinfection reaction but also increases the formation of bromate.

### Off-Gas Treatment

Because ozone is a strong oxidant, extended exposure to ozone-containing air is harmful. Even with the most efficient ozone contactor designs, off-gas ozone concentrations substantially exceed acceptable levels and, as a result, off-gas treatment is required. In the United States, the Occupational Safety and Health Administration (OSHA) sets an 8-h workday ozone exposure limit of 0.1 ppm<sub>v</sub> by volume at standard temperature and pressure (STP), which is equivalent to 0.0002 mg/L in air (*Federal Register*, 1993). In general, the concentration in the ozone gas entering the contactor can range anywhere from 5000 to 160,000 ppm<sub>v</sub>; so ozone contactors would have to achieve removals in excess of 99.998 percent to meet these standards directly. The efficiencies actually achieved in these reactors range from 90 to 99 percent, rarely higher. Therefore, the off-gas cannot be vented to the atmosphere before the residual ozone is destroyed.

Ozone in the off-gas stream can be destroyed thermally with or without the use of solid catalysts. When a catalyst is not used, ozone destruction is accomplished by heating the off-gas to a temperature between 300 and 350°C. At this temperature, the required contact time through the destruction unit is less than 5 s. Newer destruction units combine the use of specialty metal catalysts with moderate heating to achieve ozone destruction. Depending on the type of catalyst used, the off-gas temperature need only be raised to somewhere between 30 and 70°C (AWWARF, 1991).

### Example 13-9 Estimating ozone concentration in contactor off-gas

An ozonation system produces ozone from air at a concentration of approximately 12 percent by volume. Assume the ozone contactor achieves a transfer efficiency of 99.5 percent. Estimate the concentration of ozone in the contactor off-gas from the contact chamber and compare it to OSHA standards.

#### Solution

1. Determine the downstream ozone concentration.
  - a. Convert 12 percent by volume to ppm as follows:

$$12\% = \frac{12}{100} \left( \frac{10,000}{10,000} \right) = \frac{120,000}{1,000,000} = 120,000 \text{ ppm}_v$$

- b. Downstream of the contactor, the concentration is

$$C_{\text{off-gas}} = 120,000 \text{ ppm}_v \times (1 - 0.995) = 600 \text{ ppm}_v$$

2. How does the off-gas concentration compare to OSHA standards? To reduce the ozone concentration from 600 to 0.1 ppm, greater than 99.9 percent additional removal is required.

## 13-8 Design of Disinfection Contactors with Low Dispersion

Throughout much of the twentieth century, the design of specialized disinfectant contactors was not a particular concern. Chlorine was added early in the treatment process and the chlorine residual carried throughout the plant. Following the THM rule in 1980, many utilities moved the point of chlorine addition to the end of the treatment process. Later, when the first Surface Water Treatment Rule came about, many utilities struggled to find a way to get more credit for contact time in their existing facilities, often by baffling them to increase  $t_{10}$ . Because dispersion is so important in disinfection effectiveness (see Sec. 13-4), disinfectant contactors are now typically designed as a separate unit process. Engineered disinfectant contactors are typically of three types: (1) pipelines, (2) serpentine basins, and (3) over-under baffled contactors. Chlorine, combined chlorine, and chlorine dioxide contactors are typically pipelines or serpentine basins. Ozone contactors can be any of the three common types, and additionally deep U-tube contactors have also been used. Additional detail on dispersion and the design of reactors is presented in Chap. 6.

### Design of Pipeline Contactors

A long channel or pipeline with plug flow characteristics can be an ideal disinfectant contactor. Occasionally, a long pipeline leaving the plant has sufficient contact time to make it an attractive alternative for chlorine or chloramines disinfection. Axial (longitudinal) dispersion in pipeline flow is the most straightforward case that will be considered. Taylor (1954) demonstrated that the longitudinal dispersion coefficient ( $D_L$ ) can be described as

$$D_L = 5.05Dv^* \quad (13-42)$$

where  $D_L$  = longitudinal dispersion coefficient, m<sup>2</sup>/s  
 $D$  = diameter of conduit, m  
 $v^*$  = shear velocity, m/s

In the above formula the shear velocity or friction velocity ( $v^*$ ) may be defined in terms of the velocity of flow and the friction factor:

$$v^* = \sqrt{\frac{fv^2}{8}} \quad (13-43)$$

where  $f$  = Darcy-Weisbach friction factor, unitless  
 $v$  = velocity of flow in pipe, m/s

The dispersion number is defined in terms of the longitudinal dispersion coefficient, the velocity of flow, and a characteristic length, in this case, the length of the pipe:

$$d = \frac{D_L}{vL} \quad (13-44)$$

where  $d$  = dispersion number, dimensionless

Combining Eqs. 13-42 through 13-44 results in a formula that can be used to describe the dispersion of flow in a pipe:

$$d = 5.05 \left( \frac{D}{L} \right) \sqrt{\frac{f}{8}} \quad (13-45)$$

Available data from laboratory experiments confirm Taylor's theory within a factor of 2. Generally, more dispersion is found in field-scale measurements than is predicted from the theory. For this reason, Sjenitzer (1958) gathered a great number of measurements, both in the laboratory and in the field, and correlated them to produce the empirical expression

$$d = 89,500f^{3.6} \left( \frac{D}{L} \right)^{0.859} \quad (13-46)$$

Using Sjenitzer's data, Trussell and Chao (1977) demonstrated that Eq. 13-46 provides a significantly better fit of the data than Eq. 13-45. Even Sjenitzer's equation, however, is only accurate for a long pipeline without

bends, restrictions, or other disturbances to flow. Generally, the flow in a pipeline with 30 min of contact time, a flow rate greater than 3785 m<sup>3</sup>/d (1 mgd), and a velocity greater than 0.6 m/s (2 ft/s) will be nearly ideal plug flow in behavior.

### Example 13-10 Dispersion in pipelines

A treatment plant with a capacity of 25,000 m<sup>3</sup>/d (6.6 mgd) is planning to use a 1-km treated-water pipeline as a chlorine contactor. Determine the diameter of the pipeline needed for a hydraulic residence time ( $\tau$ ) of 30 min and the resulting dispersion number of the flow in the pipeline. Using Fig. 13-7, determine whether dispersion will have a significant impact on achieving 4 log of inactivation with this pipeline. The Darcy–Weisbach friction factor is 0.018.

#### Solution

1. Determine the diameter  $D$  of the pipeline.

$$\tau = \frac{V}{Q} = \frac{AL}{Q} = \frac{[\pi/4D^2]L}{Q}$$

Rearranging and solving for  $D$  yields

$$D = \sqrt{\frac{4Q\tau}{\pi L}} = \sqrt{\frac{(4)(25,000 \text{ m}^3/\text{d})(30 \text{ min})}{(\pi)(1000 \text{ m})(1440 \text{ min}/\text{d})}} = 0.81 \text{ m}$$

2. Estimate the dispersion factor using Eq. 13-46:

$$d = 89,500(0.018)^{3.6} \left( \frac{0.81 \text{ m}}{1000 \text{ m}} \right)^{0.859} = 0.000104$$

3. Assess whether dispersion will have a significant impact on achieving 4 log of inactivation in the pipeline.

#### Comment

To achieve 4 log of inactivation with less than 5 percent deviation from the inactivation goal, the dispersion number must be less than 0.006 (see Fig. 13-7). Since the calculated dispersion number is less than that, the impact of dispersion on this contactor will be minimal. It should also be noted that pipe must be purchased in standard sizes, and the actual inside diameter of the pipeline would likely be larger than the calculated value, leading to an increase in  $\tau$ , which would provide additional inactivation.

### Design of Serpentine Basin Contactors

A pipeline is convenient if it is already necessary for some other purpose, but long, baffled, serpentine basins are generally more cost-effective means of achieving low dispersion. Serpentine basins are capable of achieving dispersion numbers less than 0.01 (Markse and Boyle 1973; Sepp, 1981; Trussell and Chao, 1977) and  $t_{10}/\tau$  of 0.8 (Crozes et al., 1999). An optimal basin would be long and narrow, similar to the contactor discussed in the previous section. In the following discussion, the design of serpentine basins to achieve a specified level of dispersion is addressed first and then, because of U.S. regulatory requirements, designing these same facilities to meet a specified  $t_{10}$  will also be discussed. Computational fluid dynamics can be used to optimize the design of any large disinfection contactor (DuCoste, 2001; Hannoun et al., 1999).

#### DESIGNING FOR A SPECIFIED DISPERSION NUMBER

To develop a better understanding of design criteria, it is useful to start with a more general form of Eq. 13-42 (the Taylor equation):

$$D_L = CR_h v^* \quad (13-47)$$

where  $D_L$  = longitudinal dispersion coefficient,  $m^2/s$   
 $C$  = coefficient, unitless  
 $R_h$  = hydraulic radius of channel, m  
 $v^*$  = shear velocity, m/s

The coefficient  $C$  is a function of channel geometry and the Reynolds number. Elder (1959) applied Taylor's concept of dispersion to a logarithmic velocity profile and suggested that the coefficient  $C$  should have a value of approximately 5.9 for the circumstances in most chlorine contact chambers. For uniform flow in an open channel, the shear velocity can be defined as follows:

$$v^* = \frac{3.82 nv}{R_h^{1/6}} \quad (13-48)$$

where  $v$  = velocity of flow in channel, m/s  
 $n$  = Manning coefficient, unitless

Combining Eqs. 13-48, 13-47, and 13-44, the following approximate formula for dispersion coefficient in a long open channel is obtained:

$$d = \frac{22.7 n R_h^{5/6}}{L} \quad (13-49)$$

Equation 13-49 may be rewritten to describe dispersion using the channel volume and height and length aspect ratios (Trussell and Chao, 1977):

$$d = 22.7 \frac{n}{\beta_L} \left( \frac{\beta_H}{2\beta_H + 1} \right)^{5/6} \left( \frac{\beta_H \beta_L}{V_{ch}} \right)^{1/18} \quad (13-50)$$

where  $\beta_H$  = height aspect ratio or  $H/W$  (channel height/channel width)

$\beta_L$  = length aspect ratio or  $L/W$  (channel length/channel width)

$V_{ch}$  = channel volume,  $m^3$

The dispersion values computed using Eq. 13-50 are not sensitive to the range of  $\beta_H$  values typical for concrete contact chambers (1 to 3). As a result, the following abbreviated form of Eq. 13-50 can be used satisfactorily (Trussell and Chao, 1977):

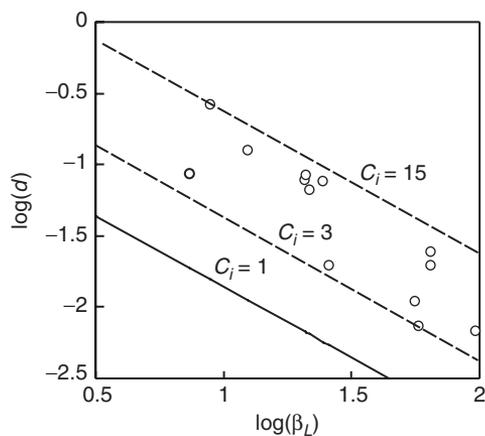

$$d = \frac{0.14}{\beta_L} \quad (13-51)$$

A plot of dispersion coefficients from field-scale tracer studies conducted on 17 different field-scale basins is illustrated on Fig. 13-25. Because the field tests were conducted in baffled, serpentine contactors, not long straight channels, none of the studies resulted in the performance predicted using Eq. 13-51. These basins include entrance effects, exit effects,  $180^\circ$  turns, and other nonidealities that would be expected to increase dispersion. Nevertheless, the results shown on Fig. 13-25 are encouraging for two reasons: (1) confirmation of the implication of Eq. 13-51 that dispersion is inversely proportional to the length aspect ratio and (2) the basins fall short of ideal performance, as expected. Recognizing this situation, a coefficient of ideality  $C_i$  was proposed (Trussell and Chao, 1977) such that

$$d = \frac{0.14C_i}{\beta_L} \quad (13-52)$$

where  $C_i$  = coefficient of ideality

Lines corresponding to  $C_i$  values between 3 and 15 are also displayed on Fig. 13-25 and all the data lie on or between them. Based on the data

**Figure 13-25**  
Impact of contactor aspect ratio on dispersion. (Adapted from Trussell and Pollock, 1983).

presented on Fig. 13-25, it appears that a good design should be able to equal or exceed the performance estimated by Eq. 13-52 with a  $C_i$  value of 3. A best-fit line corresponding to a  $C_i$  of 7.1 approximates the performance of a typical older reactor design.

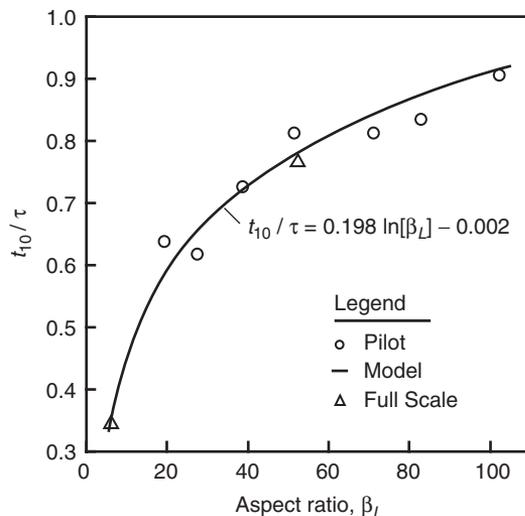

#### DESIGNING FOR A SPECIFIED $t_{10}/\tau$

Although the dispersion number is probably the most suitable means of assuring disinfection performance, a means of estimating  $t_{10}/\tau$  must be used to be sure that the design will meet regulations (U.S. EPA, 1989). The impact of baffling rectangular contact tanks to improve hydraulic performance was evaluated by Crozes et al. (1999). A pilot contactor was baffled with nine different configurations having length aspect ratios ranging from 4.8 to 98. In addition, tracer tests were conducted on a full-scale, 34 ML/d (9-mgd) contactor before ( $\beta_L = 6.1$ ) and after ( $\beta_L = 52$ ) modifications. Finally, an empirical correlation between  $t_{10}/\tau$  and  $\beta_L$  was developed and confirmed (Ducoste et al., 2001):

$$\left(\frac{t_{10}}{\tau}\right) = 0.198 \ln(\beta_L) - 0.002 \quad (13-53)$$

The data and correlation from the study are shown on Fig. 13-26. Note the results from full-scale tests lie close to model predictions.

Although the design of an effective disinfection contact basin requires attention to the length aspect ratio, other design details are also important. Any design detail that causes disturbances in flow is undesirable. Unnecessary gates, ports, or objects that constrict the flow lines are examples. In addition to minimizing the presence of these features, however, special attention should be given to three elements of design in every contactor:

**Figure 13-26**  
Impact of contactor aspect ratio on  $t_{10}$ . (Data from Crozes et al., 1999, and DuCoste et al., 2001.)

(1) inlet configuration, (2) outlet configuration, and (3) turns. Without proper attention, each of these is a likely cause of poor basin performance.

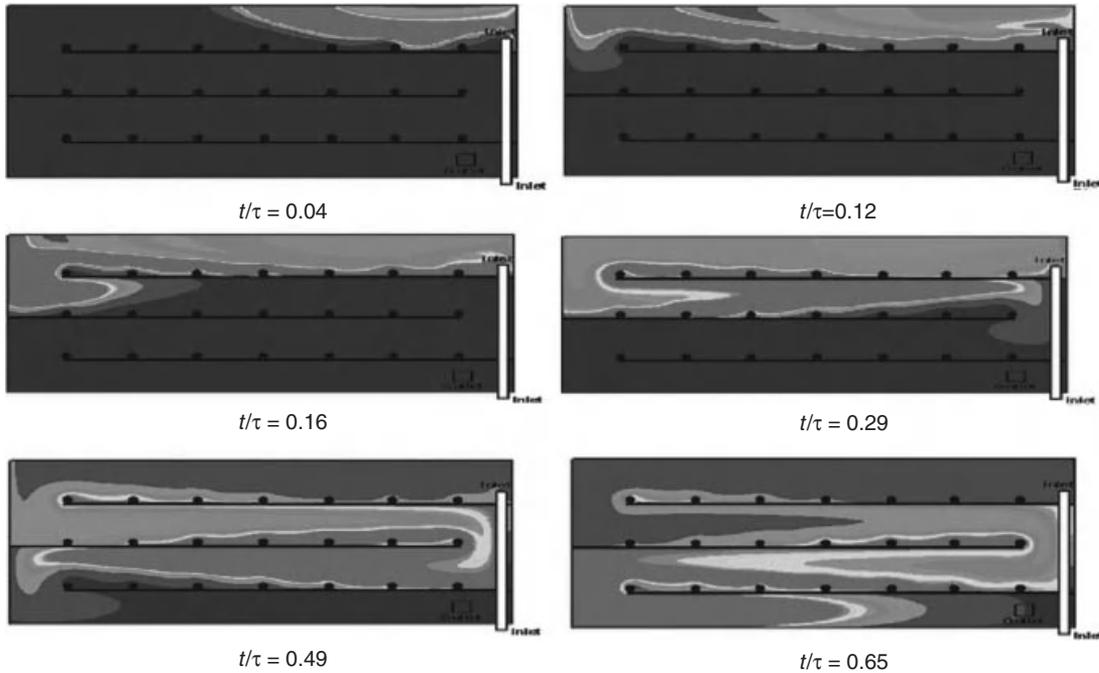

#### **BASIN INLETS AND OUTLETS**

Basin inlets are designed ordinarily as flow over a weir, through a pipe, or through a gate or gate valve into the basin. The momentum of the incoming water can cause significant dispersion in the first pass. When the entrance is a pipe, it is best for the water to exit through a tee so that the flow is not directed down the basin. With any of these inlet configurations (including a pipe with a tee) it is desirable to install a diffuser wall between the inlet of the basin and the first pass. Basin outlets are similar to inlets and have similar problems, although outlet effects are not quite as significant because outlets do not impart momentum to the basin flow. Often a diffuser wall is the best way to manage flow to outlets.

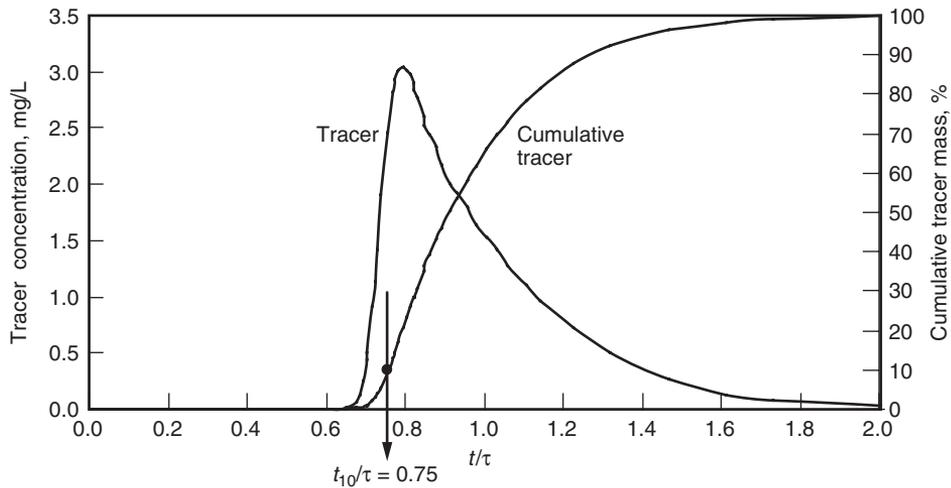

#### **180° TURNS**

To build a compact basin with the best possible length aspect ratio, rectangular basins are baffled in a serpentine fashion. However, the impact of baffling is not entirely benign. While increasing the tank's length-width ratio, the baffles also introduce flow separations at the 180° turns (Graber, 1972). Computational fluid dynamics (CFD) can be used to evaluate the flow in a chlorine contactor design and produce an estimate of the resulting tracer curve as illustrated on Fig. 13-27. A more complete discussion of CFD modeling may be found in Hannoun et al. (1999). Note that although the overall  $t_{10}/\tau$  of the design shown on Fig. 13-27 is quite good, the CFD images illustrate the adverse impact of 180° turns on basin flow patterns. Flow separations can be observed at each turn, and these impact the character of the flow for some distance down each pass. Based on some estimates, as much as 40 percent of the volume in a baffled tank behaves as a dead zone (Louie and Fohrman, 1968). The increased dispersion decreases the effective contact time (early tracer appearance and a great deal of tailing in the tracer curve). Most of the nonideality in the tracer curve on Fig. 13-27 results from the 180° turns.

The primary way to minimize this dispersion is to keep the width of the flow path constant around a turn. A number of methods have been devised for controlling the problem, and some of them, illustrated on Fig. 13-28, are hammerheads and fillets (Louie and Fohrman, 1968; White, 1999), turning vanes (Crozes et al., 1999; Graber, 1972; Louie and Fohrman, 1968), and diffuser walls (Crozes et al., 1999; Hart, 1979). Turning vanes, hammerheads, and fillets are used to reduce or eliminate the flow separation. Diffuser walls, in contrast, redistribute the flow across the channel after the turn is complete. As a result, turning vanes, hammerheads, and fillets have the potential to actually *reduce* the head loss due to the turn as well as to reduce the flow nonideality introduced by the turn.

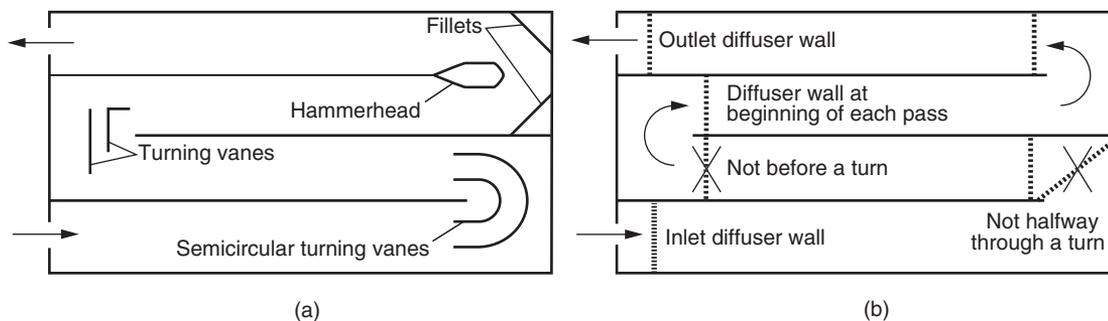

Six snapshots of a simulation of basin performance estimated via CFD

**Figure 13-27**

Using computational fluid dynamics (CFD) to evaluate RTD of disinfection contactor (CFD by Flow Science for an optimized design for the Weber Basin Water Conservancy District in Utah;  $\tau = 110$  min,  $t_{10} = 83$  min).

**Figure 13-28**

Controlling flow separation in serpentine basins using various devices: (a) fillets, hammerhead, and turning vanes (adapted from Louie and Fohrman, 1968) and semicircular turning vanes (adapted from Graber, 1972) and (b) diffusion walls (adapted from Trussell and Chao, 1977; Kawamura, 2000).

Diffuser walls always increase head loss because they depend on head loss to redistribute the flow.

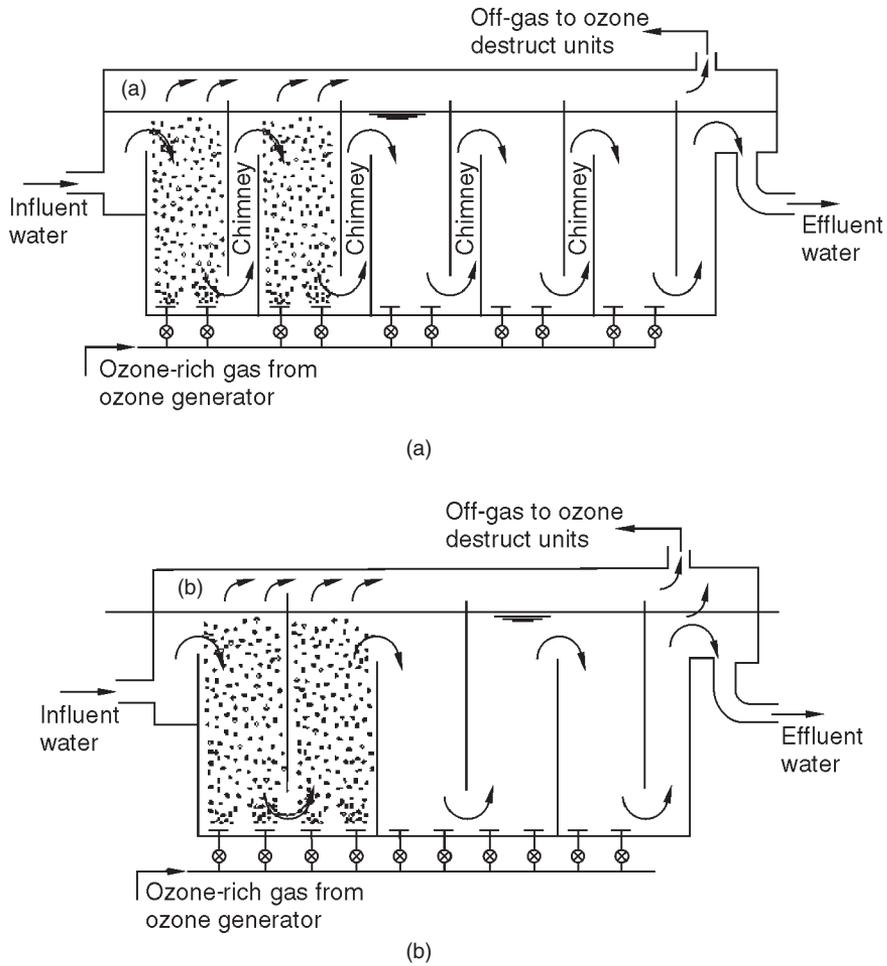

Kawamura (2000) presented some useful criteria for designing diffuser walls between flocculation basins and sedimentation basins. These criteria are also useful for disinfection contact basins:

- Port openings should be uniformly distributed across the baffle wall.
- A maximum number of ports should be provided so that flow is evenly distributed.
- The size of the ports should be uniform in diameter.
- Ports should be 75 mm or larger to avoid clogging.
- Ports should be spaced with consideration to the structural integrity of the baffle. For wood baffles, this leads to 250- to 500-mm spacing.
- Ports should be designed to cause a head loss of 0.3 to 0.9 mm.

While diffuser walls have the advantage that some design criteria are available and they improve flow, they have the disadvantage that they increase the head loss. In fact, head loss and construction are the two major limitations on designing baffled, serpentine basins. Many baffle and channel designs become so narrow that construction is difficult. Moreover the head loss from the 180° turn can become significant. Nevertheless, baffled contactors with length aspect ratios as high as 100 and dispersion numbers below 0.01 are common.

As noted in Sec. 13-7, over-under baffled contactors were the most common type of ozone contactor for many years but are less common now because of increased use of pipe contactors or serpentine basins for ozone contact systems. Pipeline and serpentine basins have better hydraulic characteristics that improve disinfection and minimize bromate formation.

Multichamber over–under baffled contactors often have several chambers where the water alternately flow up over a baffle and down under the next baffle (Rakness, 2005). Schematics of such a contactor are shown on Fig. 13-29. Ozone is typically added to the first one or two chambers via porous stone diffusers situated at the bottom of the chambers. Water enters the first chamber from the top and exits from the bottom. This counter-current flow configuration (between the water and the air) helps increase the overall ozone transfer efficiency. The water depth in the contactor is typically between 4.6 and 6 m (15 and 20 ft) to achieve high transfer efficiency of the added ozone.

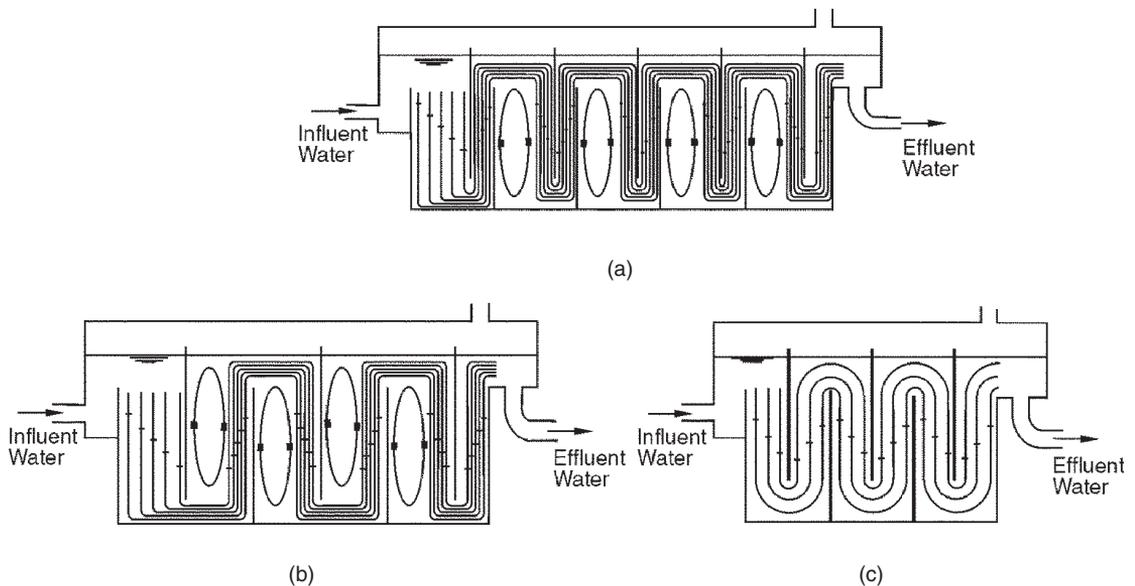

**Figure 13-29**

Schematics cross-sectional views of two alternate designs for five-chamber, over–under ozone contact chamber: (a) with chimneys and (b) without chimneys.

To achieve countercurrent flow in subsequent chambers, the contactor is also designed with segments that return the flow back to the top. A design is shown on Fig. 13-29a, where the water exiting the bottom of the first chamber rises to the surface through a narrow chamber, commonly called a *chimney*, before it enters the top of the second chamber. The chimney design achieves countercurrent flow in all chambers where ozone is added. A design with no chimneys is shown on Fig. 13-29b. In this design, the flow configuration alternates from countercurrent to co-current as the water moves from one chamber to the next. While lower transfer efficiency may take place in the co-current chambers, experience has shown that the impact is minimal. The passage of the water through the narrow chimneys of the alternate design causes a significant flow separation as the water enters and exits each down-flow contact chamber, resulting in high dispersion. On Fig. 13-30, schematic renderings of possible hydraulic flow patterns are shown in a multichamber contactor where the water is forced through a narrow pathway. Chimneys between chambers are indicated on Fig. 13-30a. The design shown on Fig. 13-30b no longer has chimneys but still exhibits significant flow separation at the turns.

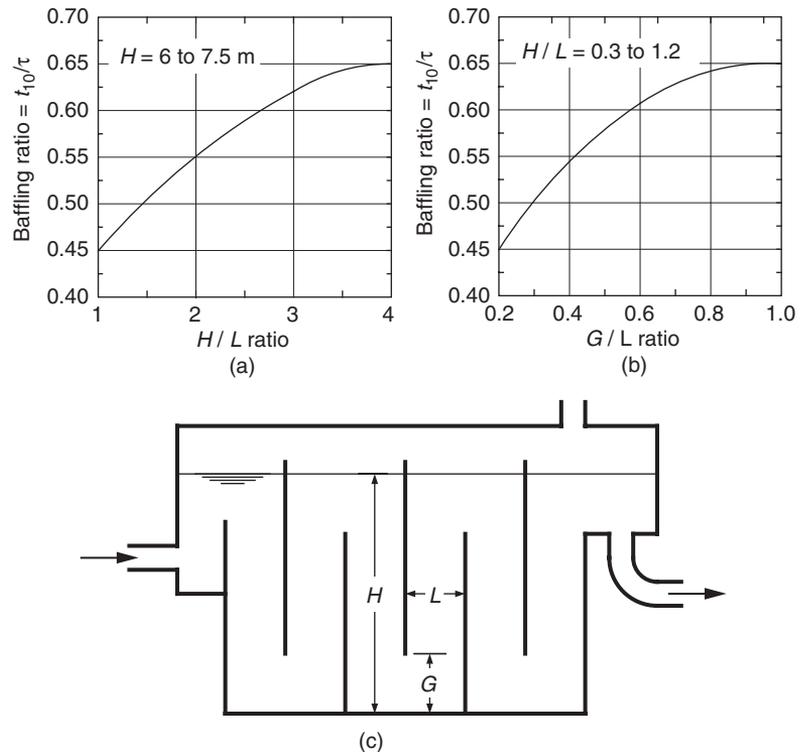

The problem with the contactor design on Fig. 13-30b is that the openings through which the water flows between chambers are too narrow. The same principle that applies in the design of the serpentine basin contactors discussed previously applies here: the width of the flow path must be

**Figure 13-30**

Conceptual impact of ozone contactor design flow hydrodynamics: (a) with chimneys, (b) without chimneys, and (c) with uniform flow path. (Adapted From Henry and Freeman, 1996.)

maintained. The flow path can be maintained by ensuring that the opening between two consecutive chambers is approximately the same width as the downstream chamber. The hydraulic flow pattern in a contactor designed with these considerations in mind is illustrated on Fig. 13-30c. It is noted that the hydraulic flow lines shown on Fig. 13-30 are only conceptual. A more accurate determination of the true hydraulic behavior can be determined using computational fluid dynamic (CFD) modeling of the contactor. Henry and Freeman (1996) conducted such modeling on various ozone contactor designs and determined that the contactor-baffling ratio (defined as the ratio of  $t_{10}/\tau$ ) is greatly impacted by the internal geometry of the contactor. The impact of the  $H/L$  ratio on the baffling ratio, where  $H$  is the water depth and  $L$  is the longitudinal width of the chamber, is shown on Fig. 13-31a (Henry and Freeman, 1996). Increasing the  $H/L$  ratio from 2 to 4 increases the  $t_{10}/\tau$  ratio from 0.55 to 0.65. The impact of the  $G/L$  ratio, where  $G$  is the depth of the flow path under the baffle, on the baffling ratio is illustrated on Fig. 13-31b. Increasing the  $G/L$  ratio from 0.2 to 1.0 increases the  $t_{10}/\tau$  ratio from 0.45 to 0.65. Based on this work, a maximum  $t_{10}/\tau$  ratio can be achieved with an  $H/L$  ratio of 4 : 1 and a  $G/L$  ratio of 1:1.

**Figure 13-31**  
Impact of internal contactor design on its baffling ratio: (a) impact of  $H/L$  ratio; (b) impact of  $G/L$  ratio; and (c) contactor schematic. Dimensions  $H$ ,  $G$ , and  $L$  are defined in contactor schematic. (Adapted from Henry and Freeman, 1996.)

Porous stone diffusers are used in ozone contactors to produce fine bubbles, which greatly increases the overall ozone transfer efficiency from the gas phase to the water, especially when compared to the use of a perforated-pipe diffuser. While both types of diffusers are used, experience has shown that perforated-pipe diffusers produce an excessively large bubble size. The cause of this problem is attributed to the way air exits the diffuser. When the diffuser is positioned horizontally, the air that exits on the underside of the diffuser seems to creep along the circumference of the diffuser before it rises into the water. As this creep occurs, the initial fine bubbles pick up more air and grow to large bubbles by the time they rise into the water column. Dome diffusers do not have this problem as the bubbles rise into the water column immediately after they exit the diffuser. Due to head loss limitations, a commercially available diffuser typically has a maximum gas flow rating that should not be exceeded.

## 13-9 Disinfection with Ultraviolet Light

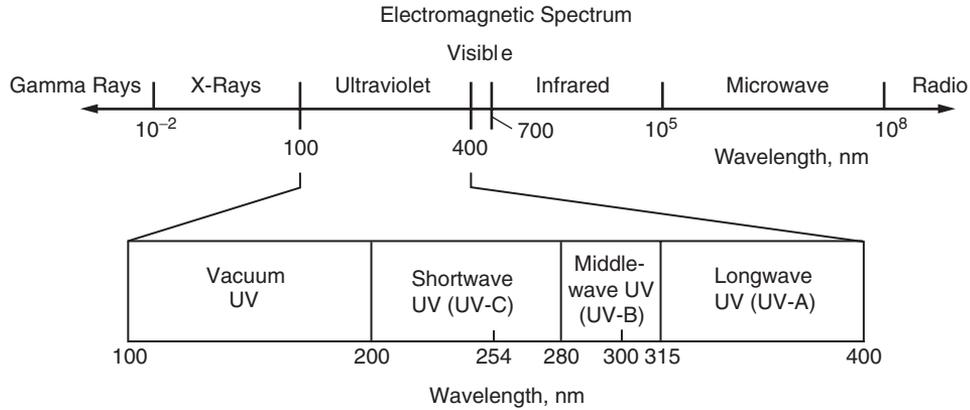

---

All of the disinfectants discussed previously in this chapter are oxidizing chemicals. Disinfection can also be accomplished by other means, heat and electromagnetic radiation among them. Heat is used to disinfect, or “pasteurize,” beverages and even to disinfect water through boiling. Electromagnetic radiation, specifically gamma radiation and UV radiation, is also used for disinfection: gamma radiation in the case of food products and UV radiation in the case of air, water, and some medical surfaces. Of these, only UV radiation has so far found a place in the routine disinfection of drinking water.

Ultraviolet disinfection is not common for drinking water disinfection in the United States, as was shown in Fig. 13-1. It is used more commonly in other countries, however, and its use is growing in the United States. The purpose of this section is to provide a basis for understanding the use of UV radiation for the inactivation of microorganisms. In practice, the design and implementation of UV radiation for water treatment is governed by U.S. EPA (2006) and state guidelines, also discussed in this section.

Ultraviolet light is the name used to describe electromagnetic radiation having a wavelength between 100 and 400 nm. As illustrated on Fig. 13-32, electromagnetic radiation of slightly shorter wavelength has been named “x-rays” and electromagnetic radiation of slightly longer wavelength, visible to the human eye, is referred to as “visible light.” Radiation just long enough to be outside the visible range is referred to as infrared radiation. Light in the UV spectrum is often further subdivided into four segments, vacuum UV, short-wave UV (UV-C), middle-wave UV (UV-B), and long-wave UV (UV-A). These classifications can also be described as follows:

### What Is Ultraviolet Light?

**Figure 13-32**  
Location of the ultraviolet light region within the electromagnetic spectrum.

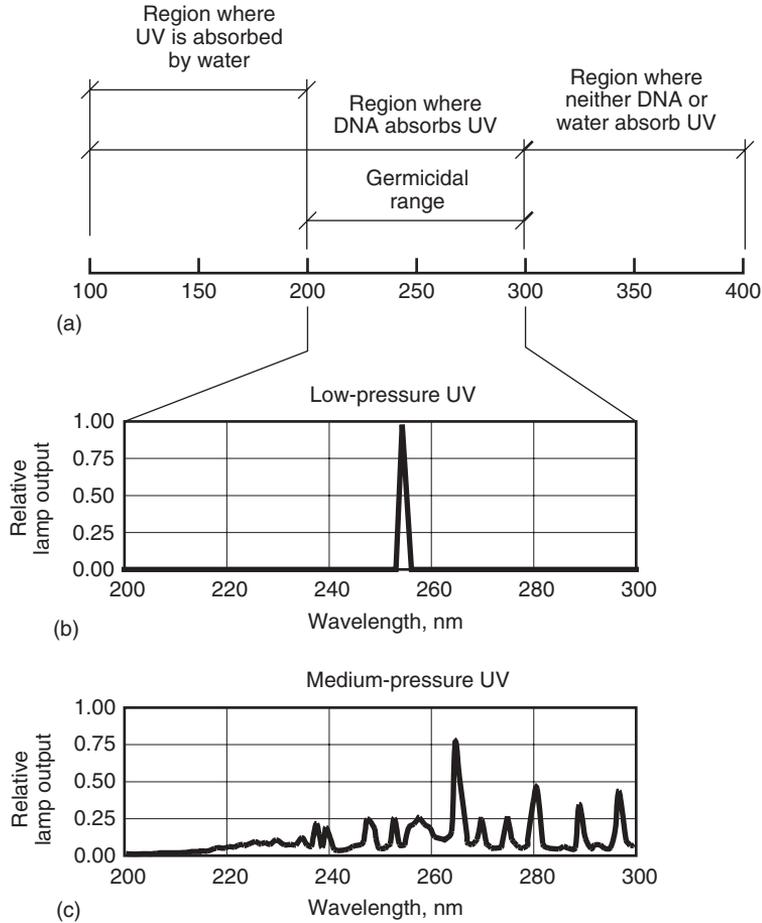

1. Both UV-A and UV-B activate the melanocytes in the skin to produce melanin (“a tan”).
2. UV-B radiation also causes “sunburn.”
3. UV-C radiation is absorbed by the DNA and is the most likely of the three to cause skin cancer.

If electromagnetic radiation is thought of as photons, then the energy associated with each photon is related to the wavelength of the radiation (Einstein, 1905):

$$E = \frac{hc}{\lambda} \quad (13-54)$$

where  $E$  = energy in each photon, J  
 $h$  = Planck’s constant ( $6.6 \times 10^{-34}$  J · s)  
 $c$  = speed of light, m/s  
 $\lambda$  = wavelength of radiation, m

As a general rule, the more energy associated with each photon in electromagnetic radiation, the more dangerous it is for living organisms. Thus, visible and infrared light have relatively little effect on organisms, whereas both x-rays and gamma rays can be quite dangerous. Beyond these broad considerations, there are other factors that determine the fraction of the UV spectrum that is effective in disinfection. The portion of the UV spectrum that is more effective in disinfection is called the “germicidal range.” On the lower end, the germicidal range is limited by the absorption of UV radiation by water. As wavelengths decrease, water becomes an increasingly efficient barrier for UV. For practical purposes, vacuum UV, the fraction of UV with a wavelength below 200 nm, cannot penetrate water. So radiation having a wavelength of 200 nm or less is not considered germicidal. It is also

**Figure 13-33**  
Ultraviolet sources and germicidal range: (a) ultraviolet portion of electromagnetic spectrum, (b) output from low-pressure UV lamp, and (c) output from medium-pressure UV lamp.

well established that UV inactivates microorganisms by transforming their DNA. This transformation cannot happen unless the UV is at a wavelength at which DNA will absorb it, and this absorption does not occur above wavelengths of approximately 300 nm. Therefore the germicidal range for UV is between approximately 200 and 300 nm (Fig. 13-33a).

The UV disinfection units used most commonly in the water industry employ three different types of UV lamps: (1) low-pressure low-intensity lamps, (2) low-pressure high-intensity lamps (also called low-pressure high-output lamps), and (3) medium-pressure high-intensity lamps. The design of these lamps closely approximates that of the common fluorescent light bulb. Low- and medium-pressure, high-intensity lamps are able to achieve a higher UV output in an equivalent space. Of the three technologies,

### Sources of Ultraviolet Light

medium-pressure UV has the greatest output. The spectrum of the UV light output by both types of low-pressure lamps is essentially the same, a very small amount of the light energy emanating at a wavelength of 188 nm and the vast majority of it emanating at a wavelength of 254 nm. The spectrum of the UV light output by medium-pressure lamps includes a number of wavelengths. These spectra are illustrated and compared with the germicidal range on Fig. 13-33b and 13-33c.

Several important characteristics of each of these UV lamps are compared in Table 13-9; however, it must be noted that UV lamp technology is evolving continuously. One of the design engineer's more important challenges is to evaluate the technologies available at the time a design is prepared and to write specifications that will enable new technologies while protecting the owner against innovative, but unproven, alternatives where the prospect for failure can be significant. New UV technologies under development and testing include pulsed UV, narrowband excimer UV (Naunovic et al., 2008), and deep UV (DUV) semiconductor light-emitting diodes (LEDs). The pulsed UV lamp produces polychromatic light at very high intensity, the narrowband excimer lamp produces nearly monochromatic light at

**Table 13-9**  
Characteristics of three types of UV lamps

Item	Unit	Type of lamp		
		Low pressure Low intensity	Low pressure High Intensity	Medium Pressure
Power consumption	W	40–100	200–500 <sup>a</sup>	1,000–10,000
Lamp current	mA	350–550	Variable	Variable
Lamp voltage	V	220	Variable	Variable
Germicidal output/input	%	30–40	25–35	10–15 <sup>b</sup>
Lamp output at 254 nm	W	25–27	60–400	Variable
Lamp operating temperature	°C	35–45	60–100	600–900
Partial pressure of Hg vapor	kPa	0.00093	0.0018–0.10	40–4000
Lamp length	m	0.75–1.5	Variable	Variable
Lamp diameter	mm	15–20	Variable	Variable
Sleeve life	yr	4–6	4–6	1–3
Ballast life	yr	10–15	10–15	1–3
Estimated lamp life	h	8,000–10,000	8,000–12,000	4,000–8,000
Decrease in lamp output at estimated lamp life	%	20–25	25–30	20–25

<sup>a</sup>Up to 1200 W in very high output lamp.

<sup>b</sup>Output in the most effective germicidal range (~255–265 μm).

wavelengths of 172, 222, and 308 nm, and UV LED lamps emit light at 280 to 285 nm.

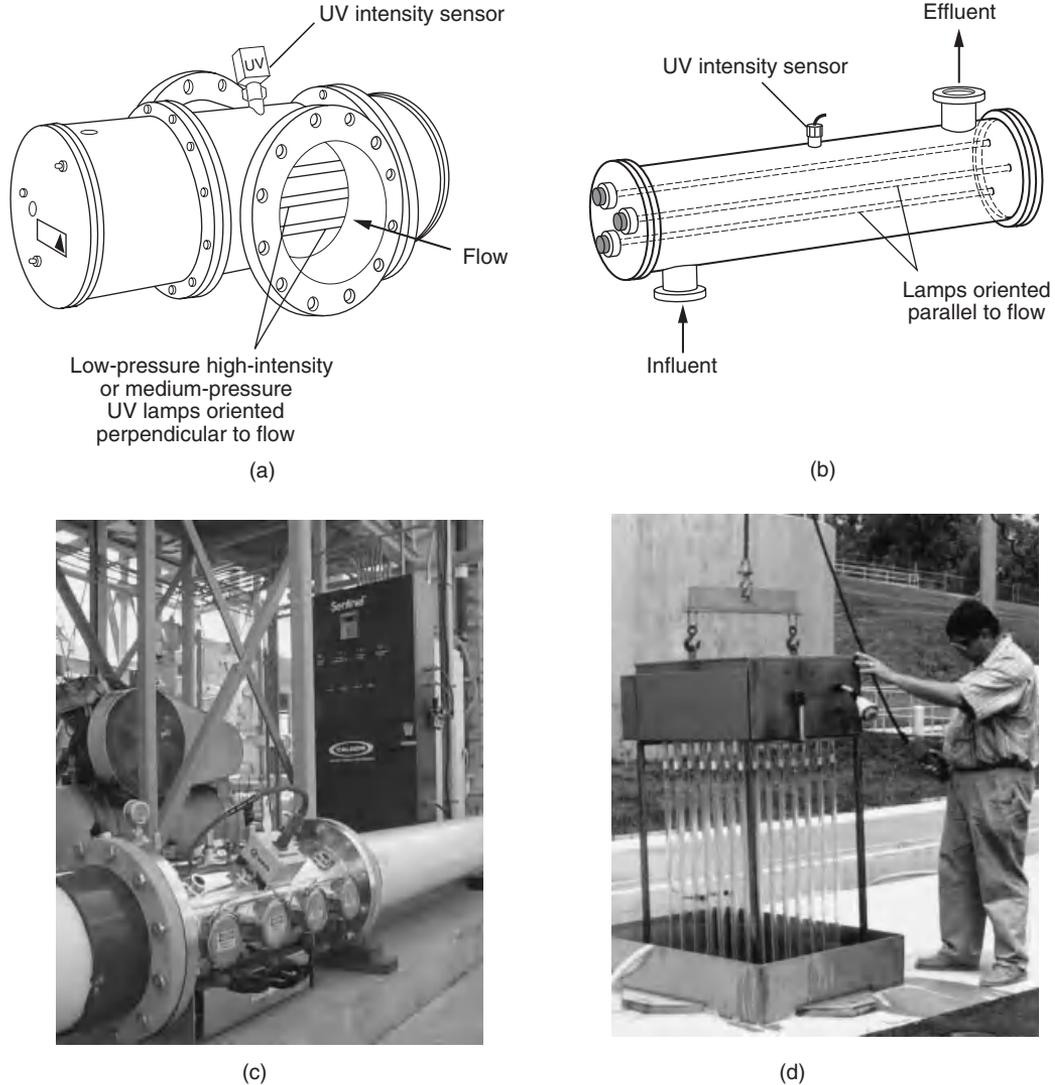

Before discussing the fundamentals of UV disinfection, it will be useful to consider the types of reactors used for UV disinfection, as many of the factors that affect the effectiveness of UV disinfection are related to the reactor configuration. The components of a UV disinfection system consists of (1) the UV lamps; (2) transparent quartz sleeves that surround the UV lamps, protecting them from the water to be disinfected; (3) the structure that supports the lamps and sleeves and holds them in place; (4) the power supply for the UV lamps and cleaning system; (5) online UV dose monitoring sensors and associated equipment, and (6) the cleaning system used to maintain the transparency of the quartz sleeves. By themselves, UV lamps, which use an electrical arc, are not electrically stable because their electrical resistance decreases as their current increases. As a consequence, the electrical system must be ballasted to limit the current to the lamp. Cleaning systems are necessary for low-pressure high-intensity and medium-pressure UV lamps because they operate at such high temperatures (see Table 13-9) that salts with inverse solubility can precipitate, fouling the outer surface of the quartz sleeve and reducing the net UV output. These UV system components are installed in closed-vessel pressurized systems or as open-channel gravity flow systems, as shown on Fig. 13-34. Closed-vessel systems are used most commonly for the disinfection of drinking water, whereas open-channel systems are more common in wastewater disinfection.

#### **CLOSED-VESSEL SYSTEMS**

Whereas most low-pressure systems are designed with open-channel flow, most low-pressure high-intensity and medium-pressure systems for drinking water are designed using closed vessels. These closed-vessel systems have the advantage that they can (and usually do) operate under pressure, and this feature makes them particularly attractive in upgrades and retrofits because it is not necessary to “break head” to use them. The placement of UV lamps in closed systems can be either perpendicular to the flow (see Fig. 13-34a) or parallel to the flow (see Fig. 13-34b). Because low-pressure high-intensity and the medium-pressure systems, operate with a limited number of lamps, more care is required to ensure that short circuiting does not occur. Biodosimetry methods, as discussed subsequently, have evolved that can be used to assess whether a UV reactor will perform as specified.

Of critical importance in the application of UV radiation for the inactivation of microorganisms is the ability to monitor the UV reactor online to be assured that the required UV dose is being delivered. The method used to monitor the UV dose is of importance both in the validation of the of

### **Equipment Configurations**

**Figure 13-34**

Common UV configurations: (a) medium pressure lamps placed perpendicular to the flow in a closed reactor, (b) low-pressure high-intensity lamps placed parallel to flow, (c) view of medium-pressure closed reactor, and (d) view of vertical low-pressure lamp arrangement in open reactor.

UV reactors as well as for monitoring the long-term performance of the UV reactor. The most common methods are:

1. **UV Intensity Set Point:** The reactor UV dose is monitored based on UV intensity, flow rate, and lamp status.

2. **UV Transmittance and UV Intensity Set Point:** The reactor UV dose is monitored based on UV intensity, UV transmittance, flow rate, and lamp status.
3. **Calculated Dose:** The UV dose received by a microorganism is calculated continuously, using a predetermined algorithm, based on the UV transmittance, flow rate, and lamp status including the effects of aging and lamp fouling.

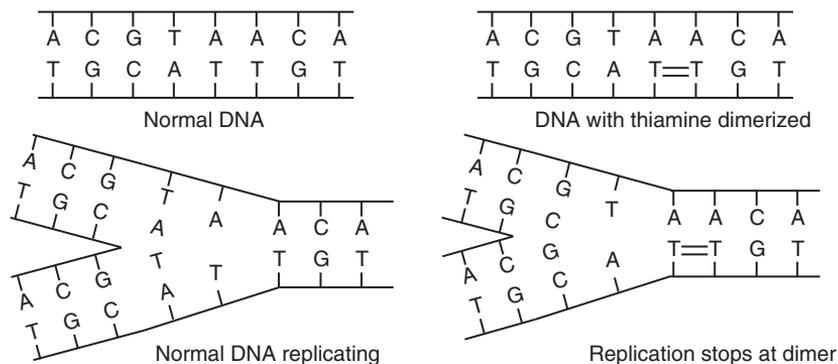

#### OPEN-CHANNEL SYSTEMS

Open-channel designs are available for all types of UV systems. Typically, the UV lamps are retained in modules or racks that are placed in the flow channel (see Fig. 13-34d). Designs are available with lamps placed horizontally parallel to the flow and with lamps placed vertically perpendicular to the flow. Conventional low-pressure low-intensity systems are typically designed so that they can be removed and cleaned easily. Most low-pressure high-intensity and all medium-pressure systems are provided with mechanical or mechanical/chemical self-cleaning systems.

More is known about the specific mechanisms of disinfection by UV than for any other disinfectant used in water treatment. The photons in UV light react directly with the nucleic acids in the target organism, damaging them. The genetic code that guides the development of every living organism is made up of nucleic acids. These nucleic acids are either in the form of deoxyribonucleic acid (DNA) or ribonucleic acid (RNA). The DNA serves as the databank of life while the RNA directs the metabolic processes in the cell. Ordinarily DNA is a double-stranded helical structure that includes the nucleotides adenine, guanine, thymine, and cytosine. Ordinarily RNA is a single-stranded structure with the nucleotides adenine, guanine, uracil, and cytosine (refer to Chap. 3).

Ultraviolet light damages DNA by dimerizing adjacent thymine molecules, inhibiting further transcription of the cell's genetic code (see Fig. 13-35). While not usually fatal to the organism, such dimerization will

#### Mechanism of Inactivation

**Figure 13-35**  
Formation of thymine dimers by UV light interferes with normal replication of microorganisms.

prevent its successful reproduction (Setlow, 1967). Ultraviolet light also forms cytosine–cytosine and cytosine–thymine dimers, but these reactions have a lower quantum yield (they occur less frequently). As a result, organisms rich in thymine tend to be more sensitive to UV irradiation. For example, *C. parvum* and *G. lamblia* both contain DNA and both are inactivated by UV at relatively low doses (see Table 13-3). Most viruses of significance in drinking water have only RNA (which contains uracil instead of thymine) and, thus, are less sensitive to UV radiation. Among the most resistant organisms are viruses such as rotavirus and adenovirus, which incorporate a special double-stranded RNA. Other factors also influence the rate of inactivation, and some are not as well understood. Ultraviolet radiation can also cause damage of a more severe kind, breaking chains, crosslinking DNA with itself, crosslinking DNA with other proteins, and forming other by-products. These effects have an even lower quantum yield, and they are usually observed only at high doses of irradiation.

### Reactivation

Reactivation is a more important consideration in UV disinfection than it is with disinfection by other methods. It is important to note that most forms of life evolved with some exposure to the sun and that sunlight includes significant amounts of UV irradiation. As a result, the process of evolution has addressed UV-induced damage by generating mechanisms for repairing the damage it causes. These mechanisms fall into two basic classes: (1) photoreactivation and (2) dark repair. Photoreactivation only takes place in the presence of light, whereas dark repair has no such requirement. Organisms capable of dark repair generally show much greater UV resistance; however, understanding the importance of photoreactivation requires that special tests be conducted, evaluating samples with and without light exposure to understand its effects.

Certainly when water is being disinfected for discharge into the environment, only the net inactivation after photoreactivation is important. Even in the case of drinking water systems, where light exposure is often more limited, the most conservative approach is to consider photoreactivation as well. Eventually, it may be possible to determine if an organism is capable of photorepair by using its genetic fingerprint to map its position on the evolutionary tree. In general, it is not safe to assume that any organism is incapable of photorepair, unless through testing it has been demonstrated to be the case. Even some viruses have been shown to be capable of photorepair, apparently taking advantage of enzymes in the host organism following infection.

### Concept of Action Spectrum

Until recent years, low-pressure low-intensity lamps were the only source of ultraviolet light available for disinfection of drinking water. The principal light output of these lamps is at only one wavelength, 254 nm. Medium-pressure lamps, on the other hand, emit light at a variety of wavelengths (see Fig. 13-33c). There is no reason to expect that light will have the

same disinfecting power at each wavelength. Earlier, the boundaries of the *germicidal range* of wavelengths were broadly established, the lower boundary (200 nm) being defined by the absorption of light by water and the upper boundary (300 nm) being defined by the lack of absorption of light by DNA. To compare the effectiveness of medium- and low-pressure low- and high-intensity lamps for disinfection, a better understanding is required of possible significance of UV radiation at different wavelengths. A number of researchers have looked at this issue and the results of their research are generally expressed in the form of an action spectrum. To generate the action spectrum, a modification of Eq. 13-3 for UV light of a particular wavelength  $\lambda$  can be used:

$$r_{N_\lambda} = -N\Lambda_\lambda I_\lambda \quad (13-55)$$

where  $r_{N_\lambda}$  = rate of change in number of organisms exposed to light of wavelength  $\lambda$

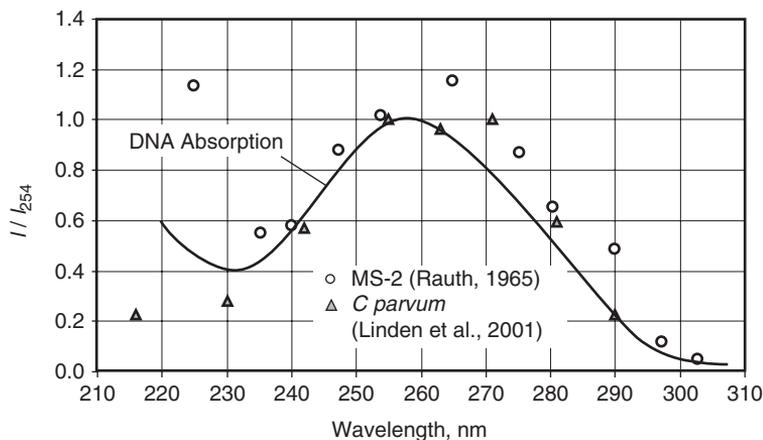

$N$  = number of organisms exposed to light, organisms/100 mL

$\Lambda_\lambda$  = coefficient of specific lethality for light of wavelength  $\lambda$ ,  $m^2/J$

$I_\lambda$  = intensity of light at wavelength  $\lambda$ ,  $W/m^2$

The action spectrum is a representation of  $\Lambda_\lambda$  over a range of wavelengths.

Often it is displayed as a plot of the ratio  $\Lambda_\lambda/\Lambda_{254\text{ nm}}$  versus wavelength. The action spectra for *C. parvum* (Linden et al., 2001) and MS2 (Rauth, 1965) are compared with the absorption spectrum for DNA on Fig. 13-36. A close correlation between  $\Lambda_\lambda$  and DNA absorption is observed. The action spectra of a number of organisms have been determined and are similar to the results shown on Fig. 13-36. As a result, many scientists believe that the germicidal efficiency determined for one species of microorganism to medium-pressure UV may be used to represent the relative response of other microorganisms as well (Giese and Darby, 2000).

**Figure 13-36**  
Comparing action spectra for *C. parvum* and MS-2 coliphage with absorption spectrum for DNA.

**Ultraviolet Light Dose**

The effectiveness of UV disinfection is based on the UV dose to which the microorganisms are exposed. The UV dose  $D$  is defined as

$$D = I_{\text{avg}} t \quad (13-56)$$

where  $D = UV$  dose,  $\text{mJ}/\text{cm}^2$  (note  $\text{mJ}/\text{cm}^2 = \text{mW} \cdot \text{s}/\text{cm}^2$ )  
 $I_{\text{avg}} =$  average UV intensity,  $\text{mW}/\text{cm}^2$   
 $t =$  exposure time, s

Note that the UV dose term is analogous to the dose term used for chemical disinfectants (i.e.,  $Ct$ ). As given by Eq. 13-56, the UV dose can be varied by changing either the average UV intensity or the exposure time. Determination of the average UV intensity, as a function of the distance from the light source, was illustrated previously in Example 2-2 in Chap. 2. The impact of dissolved and suspended substances on average UV intensity, and ultimately dose, are discussed below (Linder and Rosen Feldt, 2011; U.S. EPA, 2006).

**Influence of Water Quality**

The quality of the water being treated can have an important influence on the performance of UV disinfection systems. The two most important impacts stem from the action of dissolved and suspended substances.

**DISSOLVED SUBSTANCES**

Pure water absorbs light in the lower UV wavelengths. A number of dissolved substances also have important influence on the absorption of UV radiation as it passes through the water on its way to the target organism. Among the more significant are iron, nitrate, and natural organic matter. Chlorine, hydrogen peroxide, and ozone can also have important effects.

The absorption of light in aqueous solution by dissolved substances is described by the Beer–Lambert law. This relationship, discussed in Chaps. 2 and 8, takes the form

$$\log \left( \frac{I}{I_0} \right) = -\varepsilon(\lambda) Cx \quad (13-57)$$

where  $I =$  light intensity at distance  $x$  from light source,  $\text{mW}/\text{cm}^2$   
 $I_0 =$  light intensity at light source,  $\text{mW}/\text{cm}^2$   
 $C =$  concentration of light-absorbing solute,  $\text{mol}/\text{L}$   
 $x =$  light path length,  $\text{cm}$   
 $\varepsilon(\lambda) =$  molar absorptivity of light-absorbing solute at wavelength  $\lambda$ ,  
 $\text{L}/\text{mol} \cdot \text{cm}$

The term on the right-hand side of Eq. 13-57 is defined as the absorbance  $A$ , which is unitless. As discussed in Chap. 2, the absorptivity is the absorbance

corresponding to a path length of 1 cm, or

$$k(\lambda) = \varepsilon(\lambda)C = \frac{A}{x} \quad (13-58)$$

where  $k(\lambda)$  = absorptivity,  $\text{cm}^{-1}$

The absorptivity of the water is an important aspect of UV reactor design. Waters with higher absorptivity absorb more UV light and need a higher energy input for an equivalent level of disinfection. Absorbance is measured using a spectrophotometer typically using a fixed sample path length of 1.0 cm. The absorbance of water is typically measured at a wavelength of 254 nm.

In the application of UV radiation for microorganism inactivation, transmittance, which reflects the amount of UV radiation that can pass through a specified length at a particular wavelength, is the water quality parameter used in the design and monitoring of UV systems. The transmittance of a solution is defined as

$$\text{Transmittance, } T, \% = \left( \frac{I}{I_0} \right) \times 100 \quad (13-59)$$

The transmittance at a given wavelength can also be derived from absorbance measurements using the following relationship:

$$T = 10^{-A(\lambda)} \quad (13-60)$$

Thus, for a perfectly transparent solution  $A(\lambda) = 0$ ,  $T = 1$  and for a perfectly opaque solution  $A(\lambda) \rightarrow \infty$ ,  $T = 0$ . At a UV radiation wavelength of 254 nm, Eq. 13-60 is written as follows:

$$\text{UVT}_{254} = 10^{-A_{254}} \quad (13-61)$$

The term percent transmittance, commonly used in the literature is

$$\text{UVT}_{254, \%} = 10^{-A_{254}} \times 100 \quad (13-62)$$

Typical absorbance and transmittance values for various waters are presented in Table 13-10.

#### **PARTICULATE MATTER**

Particulate matter can also interfere with the transmission of UV light. Particulates are an aspect of water quality that can be particularly important where UV disinfection is concerned. Two mechanisms of particular importance are shading and encasement, as shown on Fig. 13-37. Interference of this kind has been studied at great depth for the case of coliform organisms in secondary wastewater effluents, and models have been developed that do an excellent job of characterizing the situation (Loge et al., 2001). The effect of shading can be integrated into models for the absorption of

**Table 13-10**

Typical absorbance and transmittance values for various waters

Type of Water	UV <sub>254</sub> Absorbance, AU/CM	Transmittance UVT <sub>254</sub> , %
Groundwater	0.0706–0.0088	85–98
Surface water, untreated	0.3010–0.0269	50–94
Surface water, after coagulation, flocculation, and sedimentation	0.0969–0.0132	80–97
Surface water, after coagulation, flocculation, sedimentation, and filtration	0.0706–0.0088	85–98
Surface water after microfiltration	0.0706–0.0088	85–98
Surface water after reverse osmosis	0.0458–0.0044	90–99

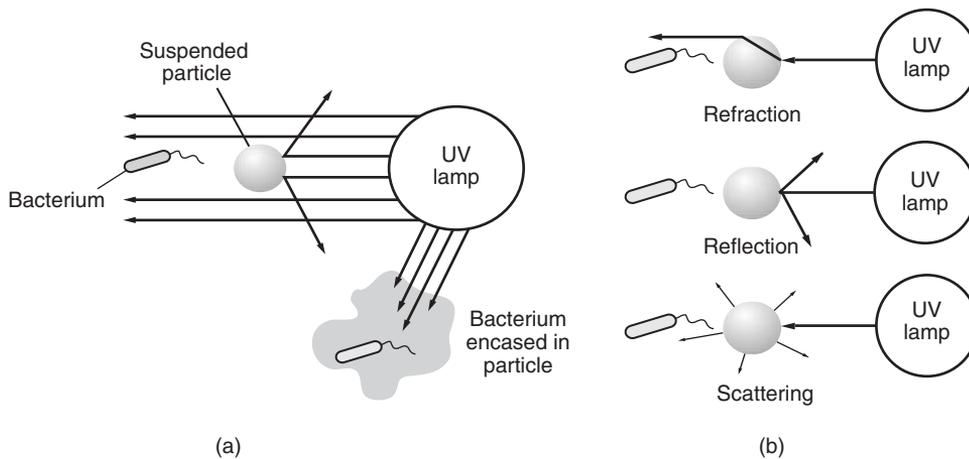

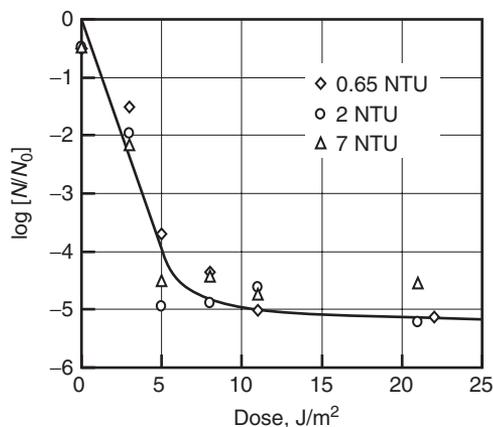

**Figure 13-37**

Illustration of mechanisms for interference in disinfection by particles: (a) overview of mechanisms for interference and (b) mechanisms of “shading.”

light. Beyond that, the number of organisms is dominated by the effect of organisms associated with particles. Particles can “shade” target organisms from UV light via three mechanisms: refraction, reflection, and scattering. Where filtration is used, these effects are not very important, but in the treatment of unfiltered water supplies and unfiltered wastewater effluents, these effects can be quite significant.

**Figure 13-38**  
Impact of low levels of turbidity on inactivation of *G. muris* with UV radiation. (Adapted from Oppenheimer et al., 2001).

The effects of particle shading are not particularly significant at low turbidities, as illustrated by the work of Oppenheimer et al. (2002), who examined the inactivation of *G. muris* added to waters with turbidities ranging from 0.65 to 7 NTU (see Fig. 13-38). A collimated beam apparatus (see Fig. 13-41) was used to study the inactivation of *G. muris* with waters at three different turbidity levels ranging from 0.65 to 7 NTU. After the UV dose was corrected for apparent absorbance (absorbance including the effects of particle shading), turbidities at these levels seemed to have little significance.

Ultraviolet disinfection systems, particularly medium-pressure systems, are characterized by overall residence times that are much shorter than other kinds of disinfection systems. In these systems short circuiting and dispersion are difficult design issues. Designing these systems to achieve good performance requires a greater appreciation of the factors that influence dispersion and short circuiting than is required for the design of most other disinfection systems. The issues are the same as those discussed earlier with contactors for disinfection with chlorine, chloramines, chlorine dioxide, and ozone; however, with UV disinfection contactors, the time spent in transition zones becomes much more important.

In chlorine contactors, for example, inlet conditions can have a big influence on performance. If the contactor is designed with a sufficiently long aspect ratio, good performance can be achieved in spite of nonideal inlet conditions. In many UV reactors, the zones of flow transition can dominate most of the contact time. Also because for the short contact time it is extremely difficult to conduct a meaningful tracer study. The outcome of a tracer study often depends on the UV reactor configuration and precisely where the tracer is introduced. A further complication in UV reactors is that the UV light intensity varies throughout the reactor. As a

### Influence of UV Reactor Hydraulics

result, the UV dose that an organism receives is not only a function of the length of time the organism spends in the reactor and the amount of light being emitted by the UV lamps but also of the specific path the organism takes as it makes its way through the reactor. Thus, the issue is not just the contact time the organism receives, but its cumulative exposure to UV.

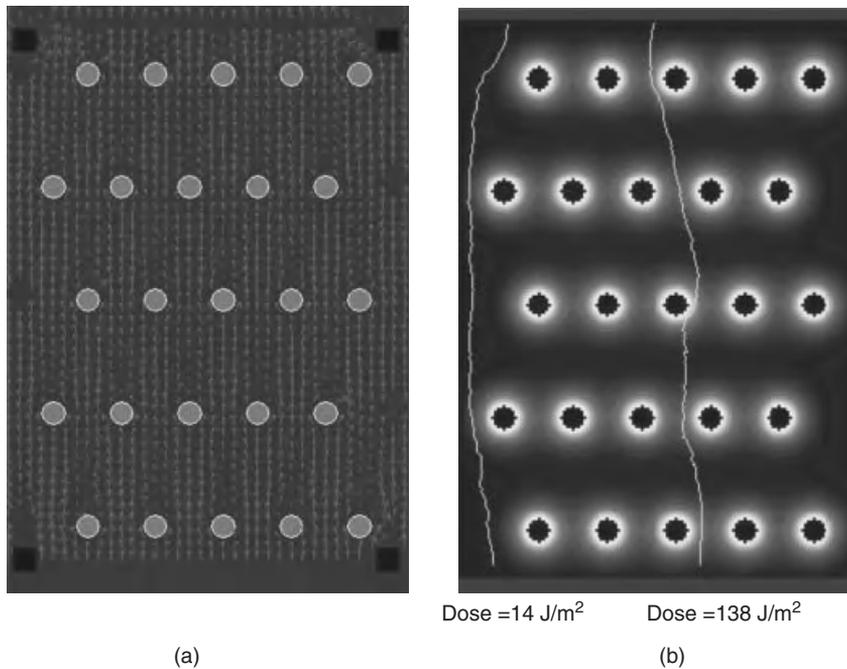

Because there are so many complications in determining the performance of a given full-scale UV reactor, it is increasingly common for regulators to require full-scale tests of each reactor design to establish, by actual disinfection measurements, how much of a UV dose a given reactor design will be credited with delivering. The use of a test microorganism to determine the performance of a UV reactor is known as *biodosimetry*. The principal limitation with biodosimetry, in light of the above discussion, is that it cannot be used to measure the dose distribution. Computational fluid dynamics (CFD) modeling and chemical actinometry, employing dyed microspheres, are also being used in conjunction with biodosimetry to assess the performance of UV reactors including the UV dose distribution. CFD modeling and chemical actinometry are discussed briefly below. Biodosimetry is considered subsequently in greater detail because it is the method now used most commonly for the assessment of UV reactor performance.

#### COMPUTATIONAL FLUID DYNAMICS

Because of the expense of conducting biodosimetry testing, CFD modeling is now used routinely to simulate mathematically the movement of particles (e.g., microorganisms) through a UV reactor. One of the earliest simulations of the movement of microorganisms through a hypothetical UV reactor was conducted by Chiu et al. (1999). Examples of their model simulation results are illustrated on Fig. 13-39. As shown on Fig. 13-39b, the dose a microorganism depends not only on the intensity of the lamps and the time the organism spends in the reactor but also on the specific path the organism takes through the reactor. The early CFD modeling studies have been extended by a number of researchers, including Lyn and Blatchley (2005) and Ducoste et al. (2005). Because so many different operating conditions can be modeled quickly, CFD modeling is now used essentially by all UV reactor manufacturers to develop new UV reactor configurations. When CFD modeling is coupled with chemical actinometry, and biodosimetry, the performance of UV reactors can be predicted with a greater degree of reliability as compared to the use of a single method.

#### CHEMICAL ACTINOMETRY

Determination of UV intensity from the measurement of the quantum yield of a chemical reaction induced by UV radiation is known as *chemical actinometry*. The quantum yield of a reaction, as given by Eq. 8-100, is a measure of the number of photolysis reactions (e.g., fluorescence) divided

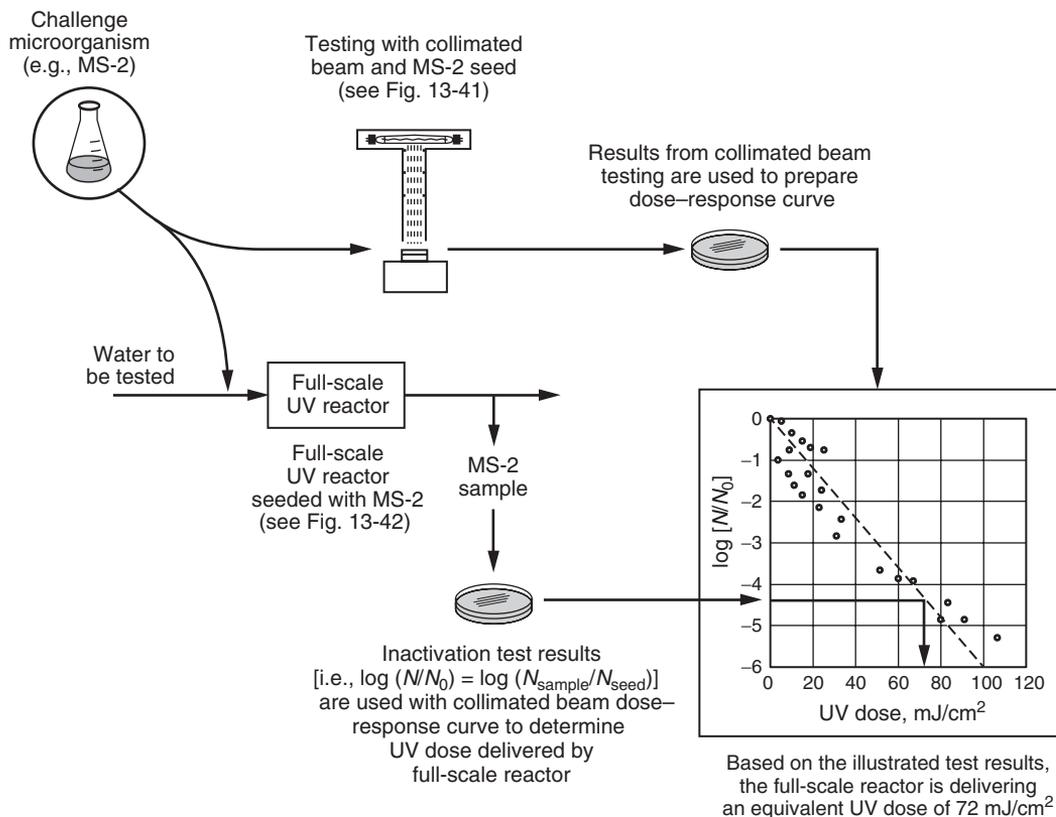

**Figure 13-39**  
Performance of UV reactor: (a) flow pattern and (b) UV dose based on two alternative microorganism travel tracks. The microorganism on the left was exposed to a UV dose of 14 J/m<sup>2</sup> whereas the microorganism on the right was exposed to a UV dose of 138 J/m<sup>2</sup>. (Adapted from Chiu et al., 1999.)

by the number of photons adsorbed. Ideally, chemical actinometry involves the use of a chemical that is easy to measure and has a known quantum yield. Microsphere chemical actinometry involves coating, imbedding, or attaching a chemical to polystyrene microspheres (specific gravity 1.05, mean diameter 5.6  $\mu\text{m}$ ) that will fluoresce when exposed to UV light (Bohrerova et al., 2005; Blatchley et al., 2008; Shen et al., 2009). If the fluorescence of the individual microsphere particles is measured, the increase in fluoresce intensity can be related to the UV dose received by an individual microsphere. If a sufficient number of microspheres are measured, the UV dose distribution can be assessed. This method has been demonstrated at full scale and the results have been compared with CFD modeling and biosimetry results (Blatchley et al., 2008; Shen et al., 2009). When all three techniques are used together to evaluate the performance of new UV reactor designs, a high degree of predictability can be achieved.

#### BIODOSIMETRY

Biosimetry, as illustrated on Fig. 13-40, involves conducting both bench-scale laboratory and field-scale tests with the same biological test organism. The laboratory study is conducted to establish the relationship between UV dose and the inactivation of a test organism. The field-scale test is conducted at design flow and under conditions designed to represent a conservative

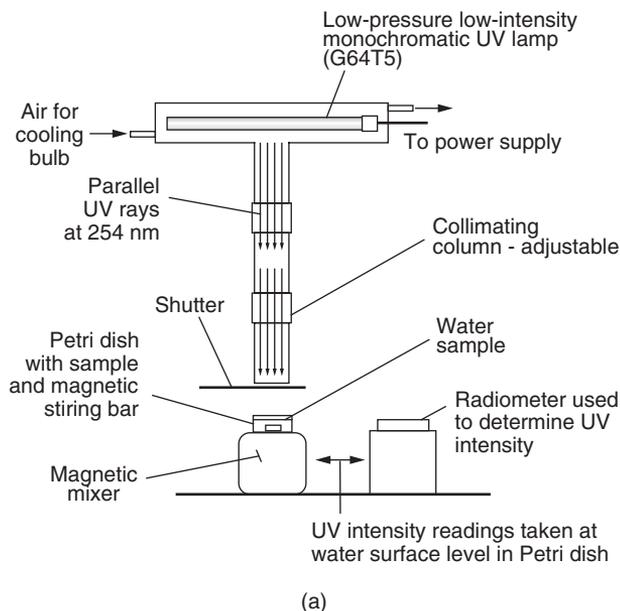

**Figure 13-40**

Schematic illustration of the application of biosimetry as used to determine the performance of a full-scale UV reactor.

simulation of full-scale operation. The specifics of the conduct of this test are outlined in the appropriate guidelines (see subsequent section). The disinfection dose that a UV reactor is credited with is determined by the dose that accomplishes the same level of inactivation under laboratory conditions. Biosimetry is most effective when it is conducted with an organism that shows approximately the same resistance to UV radiation as the target organism. The principal limitation of biosimetry, as discussed previously is that the test cannot be used to assess the UV dose distribution within the reactor. The elements of biosimetry are examined in what follows.

### Determination of UV Dose Using Collimated Beam

The most common procedure for determining the required UV dose for the inactivation of challenge microorganism involves the exposure of well-mixed water sample in a small batch reactor (i.e., a Petri dish) to collimated beam of UV light of known UV intensity for a specified period of time, as

**Figure 13-41**

Collimated beam devices used to develop dose–response curves for UV disinfection: (a) schematic of the key elements of a collimated beam setup and (b) view of two different types of collimated beam devices. The collimated beam on the left is of European design; the collimated beam on the right is of the type shown in the schematic on the left.

illustrated on Fig. 13-41. Use of a monochromatic low-pressure low-intensity lamp in the collimated beam apparatus allows for accurate characterization of the applied UV intensity. Use of a batch reactor allows for accurate determination of exposure time. The applied UV dose, as defined by Eq. 13-56, can be controlled either by varying the UV intensity or the exposure time. Because the geometry is fixed, the depth-average UV intensity within the Petri dish sample (i.e., the batch reactor) can be computed using the following relationship, which also takes into account other operational variables that may affect the UV dose:

$$D_{CB} = E_s t (1 - R) P_f \left[ \frac{1 - 10^{-k_{254} d}}{2.303 (k_{254} d)} \right] \left( \frac{L}{L + d} \right) \quad (13-63)$$

$$D_{CB} = E_s t (1 - R) P_f \left[ \frac{1 - e^{-2.303 k_{254} d}}{2.303 (k_{254} d)} \right] \left( \frac{L}{L + d} \right) \quad (13-64)$$

where  $D_{CB}$  = average collimated beam UV dose, mW/cm<sup>2</sup>  
 $E_s$  = incident UV intensity at the center of the surface of the sample, before and after sample exposure, mW/cm<sup>2</sup>

- $t$  = exposure time, s  
 $R$  = reflectance at the air–water interface at 254 nm  
 $P_f$  = Petri dish factor  
 $k_{254}$  = absorptivity, a.u./cm (base 10)  
 $d$  = depth of sample, cm  
 $L$  = distance from lamp centerline to liquid surface, cm

Without the other correction factors, the basic form of Eqs. 13-63 and 13-64 is the same as that derived in Example 2-2 in Chap. 2. The term  $(1 - R)$  on the right-hand side accounts for the reflectance at the air–water interface. The value of  $R$  is typically about 2.5 percent. The term  $P_f$  accounts for the fact that the UV intensity may not be uniform over the entire area of the Petri dish. The value of  $P_f$  is typically greater than 0.9. The term within the brackets is the depth averaged UV intensity within the Petri dish and is based on the Beer–Lambert law. The final term is a correction factor for the height of the UV light source above the sample. The application of Eqs. 13-63 illustrated in Example 13-11. The uncertainty of the computed UV dose at a given UV intensity can be estimated using the sum of the variances as given by either of the following expressions:

Maximum uncertainty:

$$U_D = \sum_{n=1}^N \left| U_{V_n} \frac{\partial D}{\partial V_n} \right| \quad (13-65)$$

Best estimate of uncertainty

$$U_D = \left[ \sum_{n=1}^N \left( U_{V_n} \frac{\partial D}{\partial V_n} \right)^2 \right]^{1/2} \quad (13-66)$$

- where  $U_D$  = uncertainty of UV dose value, %  
 $U_{V_n}$  = uncertainty or error in variable  $n$   
 $V_n$  = variable  $n$   
 $\partial D / \partial V_n$  = partial derivative of the expression with respect to the variable  $V_n$   
 $N$  = number of variables

The maximum estimate of uncertainty as given by Eq. 13-65 represents the condition where every error will be a maximum value. The best estimate of uncertainty, as given by Eq. 13-66, is used most commonly because it is unlikely that every error will be a maximum at the same time and the fact that some errors may cancel each other. The application of Eq. 13-66 is illustrated in Example 13-11.

### Example 13-11 Estimation of UV dose using collimated beam

A collimated beam, with the following characteristics, is to be used for biodosimetry testing. Using these data estimate the average UV dose delivered to the sample and best estimate of the uncertainty associated with the measurement.

$E_S = 15 \pm 0.75 \text{ mW/cm}^2$  (accuracy of meter  $\pm 5\%$ ),  $t = 10 \pm 0.2 \text{ s}$ ,  $R = 0.025$  (assumed to be the correct value),  $P_f = 0.94 \pm 0.02$ ,  $kA_{254} = 0.065 \pm 0.005 \text{ cm}^{-1}$ ,  $d = 1 \pm 0.05 \text{ cm}$ ,  $L = 40 \pm 0.5 \text{ cm}$ .

#### Solution

- Using Eq. 13-63 estimate the delivered dose:

$$D_{CB} = E_S t (1 - R) P_f \left[ \frac{1 - 10^{-k_{254} d}}{2.303(k_{254} d)} \right] \left( \frac{L}{L + d} \right)$$

$$D_{CB} = (15) \times (10)(1 - 0.025)(0.94) \left[ \frac{1 - 10^{-(0.065 \times 1)}}{(2.303)(0.065) \times (1)} \right] \left( \frac{40}{40 + 1} \right)$$

$$D_{CB} = (150)(0.975)(0.94)(0.928)(0.976) = 124.6 \text{ mJ/cm}^2$$

- Determine the best estimate of uncertainty for the computed UV dose. The uncertainty of the computed dose can be estimated using Eq. 13-66. The procedure is illustrated for one of the variables and summarized for the remaining variables.
  - Consider the variability in the measured time,  $t$ . The partial derivative of the expression used in step 1 with respect to  $t$  is

$$U_t = U_{t_e} \frac{\partial D}{\partial t} = t_e E_S (1 - R) P_f \left[ \frac{1 - 10^{-k_{254} d}}{2.303(k_{254} d)} \right] \left( \frac{L}{L + d} \right)$$

where  $t_e$  is the uncertainty of the measured value of (0.25). Substituting known values and solving for  $u_t$  the uncertainty with respect to  $t$ , yields

$$U_t = (0.2)(15)(1 - 0.025)(0.94) \left[ \frac{1 - 10^{-(0.065) \times 1}}{(2.303)(0.065) \times (1)} \right] \left( \frac{40}{40 + 1} \right)$$

$$U_t = 2.49 \text{ mJ/cm}^2$$

$$\text{Percent} = 100 U_t / D = (100) \times (2.49) / 124.6 = 2.0\%$$

- b. Similarly for the remaining variables, the corresponding uncertainty values are given below:

$$U_{ES} = 6.23 \text{ mJ/cm}^2 \text{ and } 5.0\%$$

$$U_{Pf} = 2.65 \text{ mJ/cm}^2 \text{ and } 2.13\%$$

$$U_a = -0.7 \text{ mJ/cm}^2 \text{ and } -0.56\%$$

$$U_d = -0.61 \text{ mJ/cm}^2 \text{ and } -0.49\%$$

$$U_L = 0.038 \text{ mJ/cm}^2 \text{ and } 0.03\%$$

- c. The best estimate of uncertainty using Eq. 13-66 is

$$U_D = \left[ (2.49)^2 + (6.23)^2 + (2.65)^2 + (-0.7)^2 + (-0.61)^2 + (0.038)^2 \right]^{1/2}$$

$$U_D = 7.27 \text{ mJ/cm}^2$$

$$\text{Percent} = (100) \times (7.27)/124.6 = 5.84\%$$

3. Based on the above uncertainty computation the most likely UV dose is  $124.6 \pm 7.27 \text{ mJ/cm}^2$

### Comment

Thus, the most conservative estimate of the UV dose that can be delivered consistently is  $117.3 \text{ mJ/cm}^2$  ( $124.6 - 7.27$ ). If a similar analysis is carried for each of the UV doses evaluated, a curve of the most likely UV dose can be drawn as a function of the microorganism inactivation achieved with each UV dose, as discussed below.

### DEVELOPMENT OF UV DOSE RESPONSE CURVE USING COLLIMATED BEAM

To assess the degree of inactivation that can be achieved at a given UV dose, the concentration of microorganism is determined before and after exposure in a collimate beam apparatus (see Fig. 13-41). Microorganism inactivation is measured using an most probable number (MPN) procedure for bacteria, a plaque count procedure for viruses, or an animal infectivity procedure for protozoa. To verify the accuracy of the laboratory collimated beam dose–response test data, the collimated beam test must be repeated to obtain statistical significance. To be assured that stock solution of the challenge microorganisms is monodispersed, the laboratory inactivation test data must fall within an accepted set of quality control limits. Quality control limits proposed by the National Water Research Institute (NWRI, 2003) and the U.S. EPA (2000) for bacteriophage MS2 spores are as follows:

NWRI:

$$\text{Upper bound: } -\log_{10}(N/N_0) = 0.040 \times D + 0.64 \quad (13-67)$$

$$\text{Lower bound: } -\log_{10}(N/N_0) = 0.033 \times D + 0.20 \quad (13-68)$$

U.S. EPA:

$$\text{Upper bound: } -\log_{10}(N/N_0) = -9.6 \times 10^{-5} \times D^2 + 4.5 \times 10^{-2} \times D \quad (13-69)$$

$$\text{Lower bound: } -\log_{10}(N/N_0) = -1.4 \times 10^{-4} \times D^2 + 7.6 \times 10^{-2} \times D \quad (13-70)$$

where  $D = \text{UV dose, mJ/cm}^2$

As illustrated in Example 13-12, the bounds proposed by the U.S. EPA are more lenient as compared to those used by NWRI. Similar bounding curves have been proposed for *B. subtilis* (U.S. EPA, 2006; AWWARF and NYSERDA, 2007). The NWRI guidelines are used for water reuse applications in California.

### Example 13-12 Develop dose response curve for bacteriophage MS2 using a collimated beam.

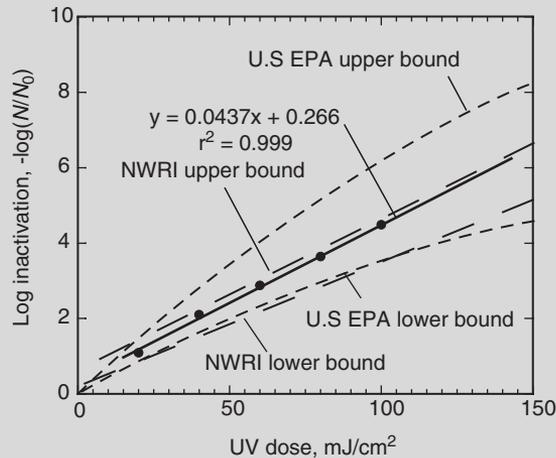

Bacteriophage MS2 (ATCC 15597) is to be used to validate the performance of a full-scale UV reactor. The following collimated beam test results were obtained for MS2 in a phosphate buffer solution with a  $\text{UVT}_{254}$  in the range from 95 to 99 percent (Data courtesy B. Cooper, BioVir Labs). Verify that the laboratory test results are acceptable and develop the dose–response curve for use in the full-scale validation. Also, estimate the UV dose required to achieve 2 log of inactivation.

Dose, $\text{mJ/cm}^2$	Surviving Concentration, phage/mL	Log Survival, Log (phage/mL)	Log Inactivation
0.	$5.00 \times 10^6$	6.70	
20	$4.00 \times 10^5$	5.60	1.10 <sup>a</sup>
40	$4.30 \times 10^4$	4.63	2.07
60	$6.31 \times 10^3$	3.80	2.9
80	$8.70 \times 10^2$	2.94	3.76
100	$1.20 \times 10^2$	2.08	4.62

<sup>a</sup>Sample calculation:  $\log \text{ inactivation} = 6.70 - 5.60 = 1.10$ .

#### Solution

1. Plot the collimated beam test results and compare to the quality control range expressions provided in the NWRI (Eqs. 13-67 and 13-68) and (Eqs. 13-69 and 13-70) U.S. EPA UV Guidelines. The results are plotted in the figure given below.

2. As shown in the above plot, all of the data points fall within the acceptable range.
3. Dose–response curve for bacteriophage MS2. The slope of the line, based on a linear fit, is

$$y = 0.0437x + 0.266$$

which corresponds to

$$-\log(N/N_0) = 0.266 + (0.0437 \text{ cm}^2/\text{mJ})(\text{UV dose, mJ/cm}^2)$$

4. UV dose required for 2 log of inactivation of MS2. Using the equation from step 3, the required UV dose is

$$\begin{aligned} \text{UVdose} &= \frac{-\log(N/N_0) - 0.266}{0.0437 \text{ cm}^2/\text{mJ}} = \frac{2 - 0.266}{0.0437 \text{ cm}^2/\text{mJ}} \\ &= 39.7 \text{ mJ/cm}^2 \end{aligned}$$

### Comment

As shown in the above plot, there is a considerable difference in the upper quality control limit between the NWRI and the U.S. EPA UV guidelines (U.S. EPA, 2006). Also note that the U.S. EPA guidelines are curvilinear, whereas the NWRI guidelines are linear. Clearly, the NWRI guidelines are more restrictive.

### UV DOSE REQUIRED FOR INACTIVATION OF *CRYPTOSPORIDIUM*, *GIARDIA*, AND VIRUSES

Using the biodosimetry approach, outlined above, the U.S. EPA has developed minimum UV dose requirements for various levels of inactivation for *Cryptosporidium*, *Giardia*, and virus (U.S. EPA, 2006). Adenovirus was utilized as the test virus because it is considered the most difficult to inactivate by UV radiation. It is important to note that the UV values reported in Table 13-11 are based on tests conducted using the specific organisms and take into account the uncertainty associated with dose–response relationships. Other sources of uncertainty associated with the full-scale installation such as the design of the UV reactors, the system hydraulics, the measured UV intensity, and monitoring approach are not included but are considered during the validation testing of UV reactors.

When a surrogate microorganism, such as MS2, is used, the values reported in Table 13-11 must be adjusted to reflect the differences in resistance between the target organism and the surrogate (see discussion under Validation of UV Reactors). The ideal surrogate should be

- Nonpathogenic
- Easy to culture at high titers (on the order of  $10^{11}$  to  $10^{12}$  org./mL)
- Stable over long periods
- Easy to enumerate

In the United States, the organism of choice is MS2 bacteriophage, whereas in Europe *B. subtilis* is the microorganism of choice. Other organisms such as the T1 and Q beta phage that more closely mirror the response of *Cryptosporidium* are also under investigation. Also, it is important to note that the host organism used for the culture of MS2 or other phage organisms must be specified if comparable results are to be obtained. Additional information on the types of microorganisms that have been examined may

**Table 13-11**

UV dose required for inactivation of *Cryptosporidium*, *Giardia*, and virus

Log Inactivation <sup>x</sup> Credit	UV Dose (mj/cm <sup>2</sup> )		
	<i>Cryptosporidium</i>	<i>Giardia</i>	Virus <sup>a</sup>
0.5	1.6	1.5	39

be found in an extensive report prepared by AWWARF and NYSERDA (2007).

### **Validation Testing of UV Reactors**

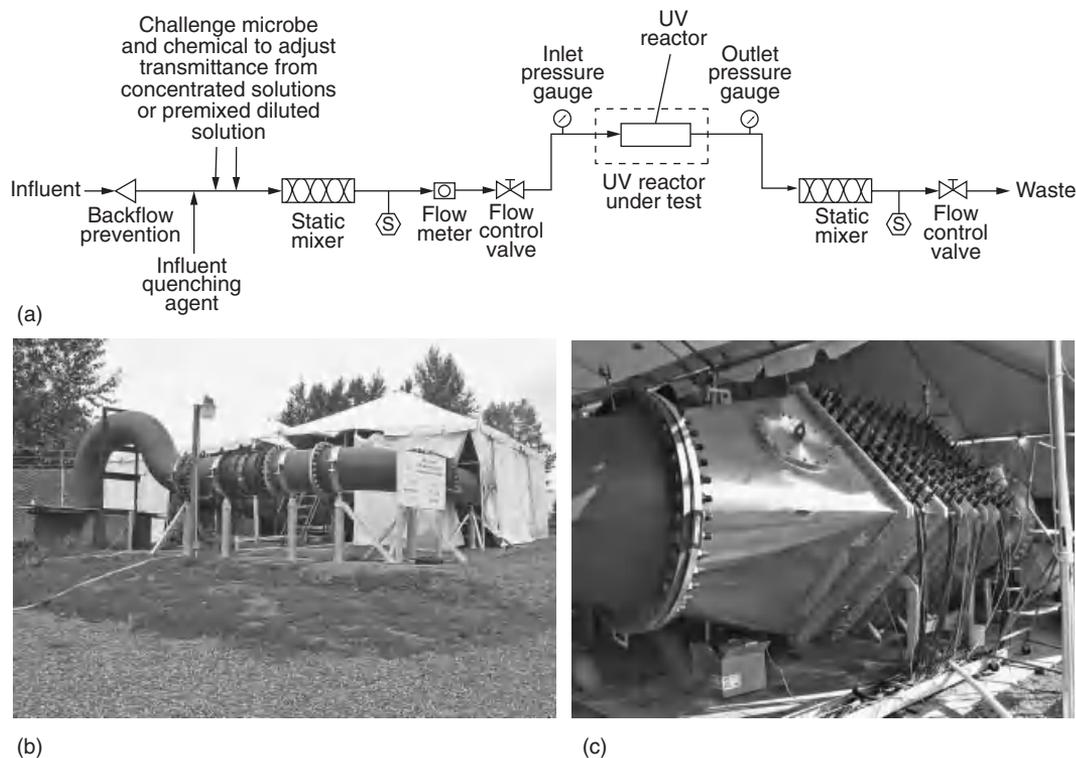

At the present time there are a number of UV manufacturers that produce UV reactors suitable for the inactivation of microorganisms. Unfortunately, the performance of the various UV reactors varies from unit to unit and manufacturer to manufacturer. Because of the interest in utilizing UV by the water industry to obtain partial inactivation credit for *Cryptosporidium*, *Giardia*, and viruses (in some cases) and the need to protect public health, the United States and many other countries have established regulations and guidelines for the use of UV radiation for water and wastewater treatment. The regulations typically involve validation testing of the UV reactors to verify minimum levels of performance (i.e., specifically the delivered UV dose) under varying the conditions of operation including:

1. High and low water transmittance
2. Varying flow rate
3. Varying power levels
4. Simulated lamp aging

Testing is also used to determine a set of operating conditions that can be monitored on a continuing basis to be assured that the UV dose needed for the inactivation credit is delivered at all times. Operationally, the method of controlling the UV dose, as discussed previously, is of critical importance. A number of prevalidated UV reactors, varying in size from 40 L/min (10 gal/min) to 225 ML/d (60 Mgal/d), are available from a number of manufacturers.

In general, validation testing must be done and certified by an independent third party. Typically, as illustrated in Fig. 13-40, validation testing involves:

1. Generation of a UV dose response curve for the challenge microorganism.
2. Determination of the inactivation achieved with the full-scale reactor, at the actual installation location or at an approved test site (see Fig. 13-42), using the challenge microorganism.
3. Determination of the UV dose corresponding to the measured inactivation achieved with the full-scale reactor using the dose–response curve developed with the collimated beam. The computed UV dose delivered by the reactor is known as the reduced equivalent dose (RED).
4. Determination of a validated UV dose by dividing the RED value by a validation factor VF. The VF is used to account for the fact that a challenge microorganism was used instead of the target organism and for the experimental uncertainty associated with the testing program.

**Figure 13-42**

Experimental setup for validation of UV reactors under controlled conditions: (a) schematic of setup requirements for testing full-scale UV reactor, (b) view of test facility at Portland, OR, and (3) large UV reactor instrumented for UV dose validation by dosimetry.

For most drinking water applications the target RED value is  $40 \text{ mJ}/\text{cm}^2$ . The principal validation guidelines now used for the validation of various UV reactors are summarized in Table 13-12. Validation test centers in the United States are located in Johnstown, New York, and Portland, Oregon. While the approach of using a prevalidated UV reactor is favored by most Public Water Systems because of simplicity, it tends to be more conservative as compared to the onsite validation.

As discussed previously in Chap. 4, the U.S. EPA developed the Long Term 2 Enhanced Surface Water Treatment Rule (LT2) to protect public health by further reducing the microbial contamination of drinking water. Based on the source water *Cryptosporidium* concentrations and current treatment practices, additional treatment may be required for some public water systems (PWS). Public water systems utilizing surface that must provide additional treatment under the LT2 rule can utilize UV radiation as one of the many different treatment options to meet the treatment requirements.

**Table 13-12**

UV reactor validation protocols used in the United States and Europe

Test Protocol	Discussion
German DVGW W294-3 (GAGW, 2003)	Use of reference sensor with multiple set points and a minimum number of monitoring ports. Although the protocol has a 10-year history, many feel the protocol is too prescriptive. UV validation based on a dose of 40 mJ/cm <sup>2</sup> . Test results guarantee a UV dose of 40 mJ/cm <sup>2</sup> or more.
Austrian ONORM M5873-1 Low pressure, and M5873-2 Medium pressure (Onorm, 2001, 2003)	Use of reference sensor with multiple set points. UV validation based on a dose of 40 mJ/cm <sup>2</sup> . Test results guarantee a UV dose of 40 mJ/cm <sup>2</sup> or more.
U.S. EPA UV Disinfection Guidance Manual (UVDGM) (U.S. EPA, 2006)	Greater flexibility as compared to German and Austrian guidelines, but more complex to understand. With proper testing, potential to reduce cost. Used for validation of community scale UV systems
ANSI/NSF Standard 55 (ANSI/NSF, 2004)	Unit must produce UV dose of 40 mJ/cm <sup>2</sup> at the alarm set point. A UV sensor to measure UV intensity continuously at 254 nm, a flow control device, and other related appurtenances are required. The challenge microorganism is MS2. Protocol is applied to residential point of use devices primarily.
National Water Research Institute (NWRI, 2003)	Developed primarily for wastewater reuse applications. Discussion of water applications is limited

Recognizing the desire of PWSs to use UV radiation to meet drinking water disinfection standards established under the Safe Drinking Water Act (SDWA), the U.S. EPA developed the UV Disinfection Guidance Manual (UVDGM) (U.S. EPA, 2006) to (1) delineate the design, operation, and maintenance needs for UV disinfection systems, which are quite different from those traditionally used in drinking water applications, (2) clarify the requirements for UV disinfection in the LT2 rule, and (3) familiarize states and PWSs with these distinctions, as well as associated regulatory requirements contained in the LT2 rules.

Two validation protocols are set forth in the UVDGM, the details of which are beyond the scope of this book. The two approaches are as follows:

1. PWS purchases a prevalidated UV reactor(s).

- a. If the UV reactor(s) are installed in accordance with specified hydraulic constraints, onsite validation is not necessary.
  - b. Onsite validation may be necessary if the full UVT range was not tested in the offsite validation, if the hydraulic constraints cannot be met, and/or if more information is needed to match current operation conditions.
2. PWS purchases a UV reactor that has not been prevalidated.
- a. In this case, the PWS can develop a plan for offsite validation and has the flexibility of using any hydraulic installation option.
  - b. PWS develops a validation plan and conducts an onsite validation, as outlined in the UVDGM.

## Problems and Discussion Topics

---

- 13-1 Based on your reading of this chapter, provide brief responses to the following questions:
- a. In waterworks practice, what two activities are described with the term disinfection?
  - b. What were the two principal means of controlling waterborne disease for the first five decades after John Snow did his work with cholera in the 1850s?
  - c. Why did chlorination encounter difficulties from the start?
  - d. What was the main discovery that caused concern about disinfection by-products?
  - e. What organism caused more stringent standards to be established for pathogen reduction?
  - f. What other organism was found to be so chlorine resistant that it began to raise questions about inactivation as a strategy for pathogen reduction?
- 13-2 Based on your reading of this chapter, discuss briefly two different ways in which the effect of concentration on the disinfection process can be handled. What are the advantages and disadvantages of each approach?
- 13-3 Describe how Watson proposed that the effect of concentration be handled in modeling disinfection.
- 13-4 Given below are some data from Wattie and Butterfield (1944) on the inactivation of *E. coli* with free chlorine at 2°C and pH 8. Fit the data to the Chick–Watson, Rennecker–Mariñas, and Collins–Selleck models and comment on the results.

C, mg/L	T, min	log(N/N <sub>0</sub> )
0.05	1.0	-0.02
0.05	3.0	-0.09
0.05	4.9	-0.15
0.05	9.6	-0.68
0.05	18	-2.52
0.07	1.0	-0.06
0.07	3.0	-0.22
0.07	4.9	-0.58
0.07	9.7	-2.28
0.14	1.0	-0.24
0.14	2.8	-0.95
0.14	4.5	-2.15

- 13-5 Fit the Rennecker–Mariñas model to the following disinfection data and determine the coefficient of lethality and the lag coefficient  $b$ :

C, mg/L	T, min	log(N/N <sub>0</sub> )
1.0	5	0.0
1.1	10	0.0
1.05	25	-1.0
1.03	30	-1.5
1.05	35	-2.1
2.05	20	-2.55
2.0	23	-3.1
2.03	25	-3.45
5.02	11	-4.1

- 13-6 Using data from Table 13-3, estimate the  $Ct$  required for a 3 log reduction of *C. parvum* and *B. subtilis* using combined chlorine and chlorine dioxide. Is either one practical? What about UV?
- 13-7 From an examination of Fig. 13-5, which organism varies the least in  $Ct$  or  $It$  between one disinfectant and the next? Which varies the most? Which disinfectant shows the smallest range of  $Ct$  or  $It$  values required for all organisms?
- 13-8 A treatment plant has been designed to achieve 99 percent inactivation of *C. parvum* using ozonation. The engineer used data on ozonation of *C. parvum* at 20°C for the design, but the plant operates in a northern climate and current estimates are that the low water temperature in some winters will be 0.5°C. Estimate how much inactivation the plant will actually achieve when the water is at that temperature. You may assume that the inactivation of *C.*

*parvum* follows the Chick–Watson relationship (Eq. 13-4). Use the  $E_a$  value of Rennecker et al. (1999) as reported in Table 13-4.

- 13-9 Use the Segregated Flow Model (SFM) to redo the dispersion estimate in Example 13-4 two times. In the first estimate, assume the contactor is operated so that the product  $C\tau$  is adequate to accomplish an 8 log reduction in the target organism, and in the second estimate assume the contactor is operated so that the product  $C\tau$  is adequate to accomplish a 0.5 log reduction in the target. Discuss the implications of the results.
- 13-10 A treatment plant with a design capacity of 80 ML/d has a pipeline between the plant and the clearwell that the operators would like to use as a contactor for disinfection. The pipeline was built with future expansions in mind and is 4 m in diameter and 80 m in length. What would be the dispersion in this pipeline when the plant is operating at design flow? Assume the Darcy–Weisbach friction factor is 0.02.
- 13-11 A water treatment plant with a capacity of 80 ML/d is being constructed. The plant includes a baffled chlorine contact chamber that has a length-to-width ratio of 40 : 1. Estimate both the dispersion and the  $t_{10}/\tau$  ratio for the chamber. Assume the coefficient of nonideality for the design,  $C_i$ , is 5. Other than baffling, what sort of provisions might have been made to improve the basin's performance? What might the design engineer have done to confirm this performance before going to construction?
- 13-12 Given below are data on the decay of ozone gathered by Gurol and Singer (1982). Fit the data to the first-order decay model and to the parallel first-order decay model and discuss.

<b>T, min</b>	<b>C, mg/L</b>
0.0	8.15
0.3	6.95
0.6	5.80
1.0	5.05
1.4	4.95
1.6	4.07
2.0	3.95
2.4	3.60

- 13-13 A treatment plant doing color removal by coagulation is using combined chlorine as a means of residual control. There have been complaints about chlorinous odors. The plant is operating with a chlorine-to-ammonia molar ratio of 5 : 1 and at a pH of 7. What precautions might be taken to reduce the odor complaints?

- 13-14 A water plant has influent ammonia levels of about 0.5 mg/L as N. The utility plans on installing a basin to remove the ammonia by breakpoint chlorination prior to using free chlorine for disinfection. What should the hydraulic detention time of that basin be to ensure that the ammonia is completely removed? The water is highly buffered at a pH of approximately 7.
- 13-15 What can the second plant in Example 13-7 do to improve performance of its residual control system?
- 13-16 A utility in south Florida has converted its plant to sodium hypochlorite because of community complaints about the safety of using chlorine gas. The hypochlorite is delivered at a concentration of 7 percent by weight and stored in a new fiberglass tank that was installed behind the maintenance building. The plant delivers an average of 8 ML/d of water with a chlorine dose of 4 mg/L. The storage tank is just large enough for one delivery, about 40,000 L. Recently, the local health department sampled the system and found high levels of chlorate ion. Also, periodically, especially during the summer, the utility finds that the strength of its bleach has dropped substantially. What precautions might be considered to improve the situation?
- 13-17 A gas chlorine system is being designed for residual control in the discharge line of a water treatment plant. The maximum and minimum design flows are 19 and 1.90 ML/d, respectively. The treated water discharge pipe is 2600 mm in diameter. The velocity of the chlorine gas in the vacuum line from the chlorinator to the injectors is 2 m/s, and the line is 20 m (66 ft) in length. The pipe from the injector to the application point is 152 m long, and the design velocity in the pipe is 1.5 m/s. The chlorine application point and the residual sampling point on the discharge line are 150 m apart. The sample runs for 100 m in a 6.35-mm sample line. The sample pump is designed for a flow of 200 mL/min. Sample analysis takes 20 s, and signal response times are assumed to be instantaneous. Prepare a sketch of the control loop similar to Fig. 13-13. Prepare a table analyzing the loop time and comment on the strengths and weaknesses of this design.
- 13-18 A continuous-flow pilot ozonation system was used to ozonate surface water at several different doses. The results are tabulated below. Assuming the pilot system successfully emulated the ozone dosing stage of the full-scale design, plot a curve of the ozone residual versus ozone dose and estimate the ozone demand and the ozone dose required to achieve a residual of 1 mg/L entering the disinfection section downstream.

Ozone Applied, mg/L	Residual, mg/L
1.30	0.04
2.45	0.28
2.74	0.43
3.05	0.56
3.39	0.56
4.01	0.90
4.49	1.12
6.01	1.50
6.05	1.74

- 13-19 The data below by Hermanowicz et al. (1999) show the decay of ozone residual in treated water from the upper Hackensack River. Estimate the  $Ct$  that can be achieved after 20 min of contact time.

T, min	C, mg/L	T, min	C, mg/L
0	0.97	12	0.155
1	1.02	13	0.135
2	0.85	14	0.12
3	0.71	15	0.115
4	0.58	16	0.11
5	0.49	17	0.105
6	0.41	18	0.1
7	0.35	19	0.1
8	0.295	20	0.095
9	0.25	21	0.09
10	0.22	22	0.09
11	0.185		

- 13-20 A full-scale UV reactor was tested with MS 2 bacteriophage and was rated to have an effective UV dose of  $25 \text{ mJ/cm}^2$ . Using an analogy to the thought experiment shown on Fig. 13-1, how much flow could have been bypassed around the reactor during the test without changing  $\log(N/N_0)$  for MS 2 by more than 10 percent? Assuming no short circuiting, how many logs of reduction should the reactor achieve with *C. parvum*? How many logs reduction in *C. parvum* would the reactor achieve if the bypass discussed earlier were to occur? Discuss the significance of these results.
- 13-21 Given the following UV disinfection data (courtesy B. Cooper, BoiVir Labs) determine for water sample number (to be selected by instructor) whether the results are consistent with the NWRI and U.S. EPA quality control limits and the expected log inactivation as a UV dose of  $50 \text{ mJ/cm}^2$ .

UV dose, mJ/cm <sup>2</sup>	Titer, Pfu/mL				
	Water sample number				
	1	2	3	4	5
0.00	5.30E+05	1.60E+05	2.80E+05	5.00E+06	2.60E+06
20.00	3.10E+04	1.30E+04	2.30E+04	4.00E+05	1.50E+05
40.00	5.30E+03	1.70E+03	1.90E+03	4.30E+04	1.70E+04
80.00	1.20E+02	6.00E+01	6.70E+01	8.70E+02	3.60E+02
100.00	2.20E+01	1.40E+01	1.30E+01	1.20E+02	7.00E+01

- 13-22 In Example 13-12, a linear relationship was used to define the UV dose response for MS2. What difference will it make with respect to the required UV dose if the linear relationship is replaced with a polynomial of the following form.

$$\log(N/N_0) = a + b(\text{UV dose}) + c(\text{UV dose})^2$$

where  $a$ ,  $b$ , and  $c$  are empirical constants.

- 13-23 Verify the results given in Example 13-11 for the error of the following variables are correct.

$$U_{ES} = 6.23 \text{ mJ/cm}^2 \text{ and } 5.0\%$$

$$U_{PF} = 2.65 \text{ mJ/cm}^2 \text{ and } 2.13\%$$

$$U_a = -0.7 \text{ mJ/cm}^2 \text{ and } -0.56\%$$

$$U_d = -0.61 \text{ mJ/cm}^2 \text{ and } -0.49\%$$

$$U_L = 0.038 \text{ mJ/cm}^2 \text{ and } 0.03\%$$

- 13-24 Review the current literature on the use of light emitting diode (LED) UV lamps for disinfection and prepare a brief assessment of their feasibility. A minimum of three articles, dating no further back than the year 2000, should be cited in your assessment.

## Terminology for Air Stripping and Aeration

---

<b>Term</b>	<b>Definition</b>
Absorption	Transfer of volatile substances from air to water.
Air Stripping	Process of removing or desorbing volatile and gaseous constituents from water into air by contacting fresh air with the contaminated water.
Aeration	Process of adding or absorbing gases (e.g., oxygen, ozone) from air into water by contacting the gaseous-laden air with the water.
Aspirator contactors	Devices that force pressurized water through a constriction, changing the pressure head of the water to velocity head, creating a low-pressure zone for atmospheric air or gas to be drawn into the water (e.g., Venturi tube).
Countercurrent packed tower	Tower in which water enters at the top and flows downward over a packing material while air is blown up from the bottom of the column and flows up through the voids of the column.
Desorption	Process for transfer of volatile substances from water to air.
Diffusion contactors	Devices that force compressed air into the water, forming bubbles and creating the surface area available for transfer of a constituent from one phase to another.
Droplet air–water contactors	Devices creating small water drops that are dispersed into fresh air for a given contact time to allow transfer of a constituent from one phase to the other depending on objective (e.g., absorption or desorption).

<b>Term</b>	<b>Definition</b>
Height of a transfer unit (HTU)	Parameter that is a measure of the effectiveness of a particular air–water contact device.
Mechanical contactors	Devices that agitate the water, creating renewed air–water surface for transfer of a constituent from one phase to the other.
Number of transfer units (NTUs)	Dimensionless number that is a measure of the effectiveness of stripping a constituent from water to air. As NTU increases, the maximum possible removal efficiency increases.
Packing factor	Parameter for a random packing material that is used in conjunction with the Eckert pressure drop correlation to estimate the gas pressure drop through the packing.
Random packing	Small geometrically designed irregularly-shaped pieces (typically plastic), randomly packed to a specified height in the tower to provide a high surface area and efficient air–water contact within the tower.
Stripping factor (S)	Dimensionless number defined as the slope of the equilibrium line to the slope of the operating line for countercurrent packed towers and that can be used to assess the ability of a constituent to be removed from water.
Thin-film contactors	Devices that allow water to flow over surfaces, creating a thin water film that is exposed to flowing air and allowing the constituent to be transferred from one phase to the other.

Air stripping and aeration are two water treatment unit processes that utilize the principles of mass transfer to accomplish specific water treatment objectives. Both of these water treatment unit processes bring air and water into intimate contact to transfer volatile substances from the water (e.g., hydrogen sulfide, carbon dioxide, volatile organic compounds) into the air or from the air (e.g., carbon dioxide, oxygen) into the water. The mass transfer process involving the removal of volatile substances from water into the air is known as *desorption*. Air stripping is one of the most common desorption processes used in water treatment. The addition of gases from air into water is the mass transfer process known as *absorption*. Aeration involving the addition of oxygen to water is a commonly used absorption process.

An understanding of the principles of the underlying mass transfer processes, including how to calculate diffusion coefficients and the basis for mass transfer correlations (discussed previously in Chap. 7), is necessary to design air strippers and aerators effectively. In this chapter, the focus is on the application of the aforementioned mass transfer principles to water treatment unit processes. Specific topics considered in this chapter include (1) an introduction to air stripping and aeration, (2) gas–liquid equilibria (Henry’s law), (3) the classification of air stripping and aeration systems, (4) the fundamentals of packed tower air stripping, (5) analysis and design for packed tower air stripping, (6) an analysis of low-profile air strippers, (7) an analysis of spray aerators, and (8) other air stripping and aeration processes. Other gas–liquid contacting systems are presented in other chapters, such as Chap. 13, where ozone contactors are discussed.

## 14-1 Introduction to Air Stripping and Aeration

Water treatment objectives that can be achieved through the gas–liquid mass transfer process are summarized in Table 14-1. In both air stripping and aeration, air–water contactors are used to increase the contact opportunities between the gas and liquid phases. By increasing the air–water contact opportunities, the desorption or absorption mass transfer process is accelerated above the rate that would occur naturally, meaning volatile

**Table 14-1**

Applications of air–water mass transfer in water treatment

Examples	Water Treatment Objectives
<b>Adsorption</b>	
O <sub>2</sub>	Oxidation of Fe <sup>2+</sup> , Mn <sup>2+</sup> , S <sup>2-</sup> ; lake destratification
O <sub>3</sub>	Disinfection, color removal, oxidation of selected organic compounds
Cl <sub>2</sub>	Disinfection; oxidation of Fe <sup>2+</sup> , Mn <sup>2+</sup> , H <sub>2</sub> S
ClO <sub>2</sub>	Disinfection
CO <sub>2</sub>	pH control
SO <sub>2</sub>	Dechlorination
NH <sub>3</sub>	Chloramine formation for disinfection
<b>Desorption</b>	
CO <sub>2</sub>	Corrosion control
O <sub>2</sub>	Corrosion control
H <sub>2</sub> S	Odor control
NH <sub>3</sub>	Nutrient removal
Volatile organics (e.g., CHCl <sub>3</sub> )	Taste and odor control, removal of potential carcinogens

substances move more rapidly from the water into the air or gases that are not as soluble move more rapidly from the air into the water. The increase in contact opportunities between the two phases occurs through increasing the air–water interface in the air–water contactor by increasing the air–water ratio.

Over the years, a number of methods have been developed to bring about effective air–water contact. Packed towers or slat countercurrent flow towers, known as gas-phase contactors, have a continuous gas phase and a discontinuous water phase and are typically used to remove (or strip) gases or volatile chemicals from water. Air–water contactors such as basins with diffused aeration, also called bubble columns, are known as flooded contactors. In flooded contactors the water phase is continuous and the gas phase is discontinuous because the air is present as discontinuous bubbles. Flooded contactors are typically used to add gases (e.g.,  $O_2$ ,  $CO_2$ ,  $O_3$ ) into water.

One confusing concept with air stripping and aeration is that aerators can be used to accomplish air–water contact in both air-stripping and aeration processes. In general, aerators are a relatively simple method for increasing the air–water ratio by (1) spraying water into the air or (2) introducing air into the water through surface turbines or submerged nozzles and diffusers (bubble columns). Thus, aerators allow both of the mass transfer processes, desorption and absorption, to occur in a relatively cost-effective manner. However, because backmixing can occur in aeration systems, a high degree of removal may be difficult to achieve.

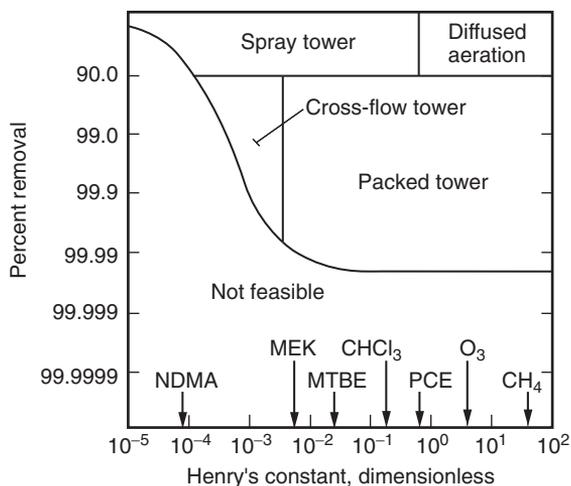

Two major types of air–water contactors are used for air stripping: (1) towers and (2) aerators. The two principal factors that control the selection of the type of air–water contactor for stripping are (1) the desired degree of removal of the compound and (2) the Henry's law constant of the compound. Towers are used when either a high degree of removal is desired or the compound has a high affinity for water (is not very volatile so it has a low Henry's law constant), as shown on Fig. 14-1. Aerators are used when either the desired degree of removal is not very high or the gas has a low affinity for water (is very volatile so it has a high Henry's law constant). When removals less than 90 percent are required, both spray and diffused aeration systems, including mechanical aeration, may be economically attractive. More information on the various types of air-stripping and aeration systems used in water treatment is presented in Sec. 14-3.

Aeration is used to increase the oxygen content in the water by adding air into water through (1) diffusers in a pipe, channel, or process basin; (2) cascading water over stacked trays; or (3) surface turbines and wheels that mix air into water at the top of basins. Oxygenation can also be

### **Bringing about Air–Water Contact**

### **Air Stripping**

### **Aeration**

**Figure 14-1**

Schematic diagram for selection of feasible aeration process for control of volatile compounds (Adapted from Kavanaugh and Trussell, 1981.)

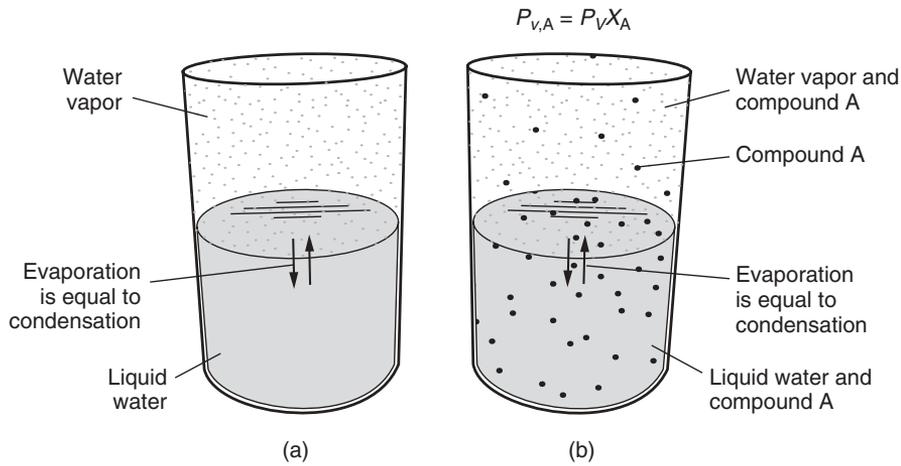

accomplished using pure oxygen. The various types of aeration systems are presented in Sec. 14-3 and the specific details of spray aerators are covered in Sec. 14-7.

## 14-2 Gas–Liquid Equilibrium

When gas-free water is exposed to air, compounds such as oxygen and nitrogen will diffuse from the air into the water until the concentration of these gases in the water reaches equilibrium with the gases in the air. Conversely, if water in deep wells is brought to the ground surface, dissolved gases such as methane or carbon dioxide will be released to the air because their concentrations in groundwater typically exceed equilibrium conditions with air. The eruption of a carbonated beverage after it is opened is a more familiar example of carbon dioxide release after a pressure change. In each case, the driving force for mass transfer is the difference between the existing and equilibrium concentrations in the two phases, as discussed in Chap. 7.

### Vapor Pressure and Raoult's Law

Consider water poured into a closed container that contains some headspace as shown on Fig. 14-2a. Some water molecules will have enough energy to overcome the attractive forces among the liquid water molecules and escape into the headspace above the liquid water, which is called evaporation. At the same time, some water molecules that have escaped into the gas phase above the liquid water may lose energy and move back into the liquid water, which is called condensation. When the rates of evaporation and condensation are equal, the system is at equilibrium. The partial pressure exerted by the water vapor above the liquid water in the

**Figure 14-2**

Schematic diagram for solution equilibrium description of vapor pressure with (a) vapor pressure of water and (b) partial pressure of compound A in the presence of water.

container at equilibrium is called the vapor pressure. Vapor pressure is dependent on temperature and increases with increasing temperature. For example, the vapor pressure of water is 1.23 kPa at 10°C and 3.17 kPa at 25°C. Other volatile liquids (e.g., acetone, benzene) behave the same way and also have a vapor pressure.

If a volatile compound (A) is placed in the same closed container containing water as shown on Fig. 14-2b, it too would come to equilibrium between the liquid and gas phases and exert a partial pressure above the liquid water. If the solution is assumed to behave ideally in which the molecular forces between the solute (A) and the solvent (water) are identical to the solvent-solvent forces, and the solute (or solvent) molecule behaves identically regardless of whether it is surrounded by solute or solvent molecules, then the partial pressure of the solute would be a function of its vapor pressure and the mole fraction of the solute. The partial pressure of solute A can be calculated from the following expression, known as Raoult's law:

$$P_A = P_{v,A} X_A \quad (14-1)$$

where  $P_A$  = partial pressure of solute A, Pa

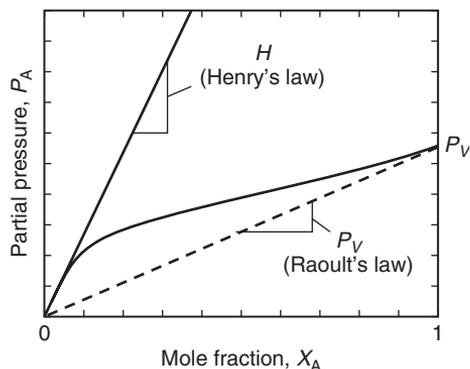

$P_{v,A}$  = vapor pressure of pure liquid A, Pa

$X_A$  = mole fraction of solute A in water, dimensionless

The mole fraction of A is defined as

$$X_A = \frac{n_A}{\sum_i n_i} = \frac{n_A}{n_A + n_{\text{H}_2\text{O}}} \quad (14-2)$$

where  $n$  = amount of A (solute) and water (solvent), mol

**Figure 14-3**

Relationship between partial pressure of a volatile compound and the mole fraction of the volatile compound in solution.

The relationship between partial pressure and mole fraction for solute A is illustrated on Fig. 14-3, and ideal solutions follow Raoult's law and the slope is  $P_{v,A}$ . For nonideal solutions the molecular forces between the solute and solvent are not identical to the solvent-solute forces because the molecular forces between water molecules are very strong, so the solute-solvent attractions are smaller than the solvent-solvent attractions. Since there are smaller attractive forces holding the solute in solution, it is pushed out of solution and into the gas phase. Consequently, as shown, the partial pressure of the solute is higher than predicted by Raoult's law (a positive deviation from Raoult's law).

### Henry's Law

For very dilute solutions most often found in environmental applications, the molecular interactions do not change significantly as additional solute is added, so partial pressure is proportional to mole fraction as shown in Figure 14-3, and this relationship is known as Henry's law. The equilibrium partitioning of a chemical solute between a liquid and gas phase is governed by Henry's law when the solute is very dilute in the mixture. Henry's law in equation form is

$$P_A = H_{PX}X_A \quad (14-3)$$

where  $H_{PX,A}$  = Henry's law constant for solute A in solvent (water), atm

Henry's law is valid and constant up to mole fractions of 0.01 and has been shown to be valid for concentrations up to 0.1 mol/L (Rogers, 1994). Solvent-solvent forces are unaffected by small amounts of solute and the solvent follows Raoult's law for dilute solutions. Henry's law constants are valid for binary systems (e.g., component A in water). For systems where there are several solutes in a solvent (water) and the solution is still considered dilute, Henry's law will be valid for each solute. The presence of air does not affect the Henry's law constant for volatile organic chemicals (VOCs) or gases because the constituents of interest have low concentrations in air.

### Other Units for Henry's Law Constants

The units of Henry's law constant,  $H_{PX}$ , in Eq. 14-3 are in atm because the standard conditions for pressure in the gas phase and concentration in the liquid phase were given in atmospheres and mole fractions, respectively. Henry's law constants can also be expressed in terms of concentration or partial pressure of A for the gas phase and mole fraction or concentration for the liquid or water phase. The gas-phase concentration expressed as either partial pressure (atm) or concentration in mol/L is related through the ideal gas law as shown below:

$$P_A V = n_A R T \quad \text{or} \quad Y_A = \frac{n_A}{V} = \frac{P_A}{RT} \quad (14-4)$$

where  $R$  = universal gas constant,  $0.082057 \text{ atm} \cdot \text{L/mol} \cdot \text{K}$   
 $Y_A = n_A/V$  = gas-phase concentration (mol/L)  
 $V$  = volume of the gas phase,  $\text{m}^3$

The liquid-phase concentration can be expressed as either mole fraction (mol/mol) or concentration (mol/L) as

$$X_A = \frac{n_A}{n_A + n_W} \approx \frac{n_A}{n_W} = \frac{C_A}{C_W} \quad (14-5)$$

where  $n_W$  = amount of water in solution, mol  
 $C_W = \frac{\text{density of water}}{\text{molecular weight of water}} = \frac{1000 \text{ g/L}}{18 \text{ g/mol}} = 55.56 \text{ mol/L}$   
 $C_A = X_A C_W = X_A (55.56 \text{ mol/L})$

Applying these relationships results in three common forms of expressing Henry's law, which are summarized in Table 14-2. A particularly useful set of units is when the solute is expressed as concentration (either mass or molar) in both the gas and liquid phases. These units are known as

**Table 14-2**

Unit conversions for Henry's law constants

$$\begin{aligned} H_{YC} \left( \frac{\text{L}_{\text{H}_2\text{O}}}{\text{L}_{\text{Air}}} \right) &= \frac{H_{PC} [\text{atm}/(\text{mol/L})]}{RT} \\ &= \frac{H_{PX} (\text{atm})}{RT \times (55.6 \text{ mol H}_2\text{O/L H}_2\text{O})} \\ H_{PC} [\text{atm}/(\text{mol/L})] &= \frac{H_{PX} (\text{atm})}{55.6 \text{ mol H}_2\text{O/L H}_2\text{O}} \\ H_{PX} (\text{atm}) &= H_{YC} \left( \frac{\text{L}_{\text{H}_2\text{O}}}{\text{L}_{\text{Air}}} \right) \times RT \times (55.6 \text{ mol H}_2\text{O/L H}_2\text{O}) \end{aligned}$$

Note: subscripts on  $H$  correspond to units as follows:

$Y$  = gas phase concentration,  $C$  = liquid-phase concentration,  $P$  = partial pressure,  $X$  = mole fraction

“dimensionless” forms of Henry’s law and are widely used in environmental engineering. Use of the relationships displayed in Table 14-2 is illustrated in Example 14-1.

### Example 14-1 Henry’s law constants

What is the dimensionless Henry’s law constant for a compound that has a value of 250 atm? What is the Henry’s law constant in atmospheres and atm/(mol/L) for a compound that has a dimensionless Henry’s law constant of 0.0545? Assume the temperature is 25°C.

#### Solution

1. Determine the dimensionless Henry’s law constant. Inserting Henry’s law constant of 250 atm into the relationship shown in Table 14-2 for converting  $H_{PC}$  to  $H_{YC}$  results in the expression

$$\begin{aligned} H_{YC} &= \frac{H_{PX}}{RT(55.6)} \\ &= \frac{250 \text{ atm}}{[0.082057 \text{ atm} \cdot \text{L/mol} \cdot \text{K}][(273 + 25) \text{ K}](55.6 \text{ mol/L})} \\ &= 0.183 \end{aligned}$$

2. Determine Henry’s law constant in atmospheres. Rearranging the expression for  $H_{PX}$  in terms of  $H_{YC}$  and solving for  $H_{PX}$  for an  $H_{YC}$  of 0.0545, the following result is obtained:

$$\begin{aligned} H_{PX} &= RT \times 55.6 H_{YC} \\ &= [0.082057 \text{ atm} \cdot \text{L/mol} \cdot \text{K}][(273 + 25) \text{ K}](55.6 \text{ mol/L})(0.0545) \\ &= 74.1 \text{ atm} \end{aligned}$$

3. Determine Henry’s law constant in atm/(mol/L) for an  $H_{YC}$  equal to 0.0545. Inserting Henry’s law constant of 0.0545 dimensionless into the relationship shown in Table 14-2 for converting  $H_{PC}$  to  $H_{YC}$  and solving for  $H_{PC}$  results in the expression

$$\begin{aligned} H_{PC} &= RTH_{YC} = [0.082057 \text{ atm} \cdot \text{L/mol} \cdot \text{K}][(273 + 25) \text{ K}](0.0545) \\ &= 1.33 \text{ atm/(mol/L)} \end{aligned}$$

#### Sources of Henry’s Law Constants

Methods have been developed to determine Henry’s law constants for volatile compounds. In the early 1980s methods that included measuring the compound’s vapor pressure and solubility, direct measurement of a compound’s vapor pressure and aqueous concentrations in an equilibrium

system, and using batch air stripping techniques to determine Henry's law constants were evaluated and compared (Mackay and Shiu, 1981). However, these techniques can be unreliable, and a more suitable method was developed called the equilibrium partitioning in closed systems (EPICS) technique (Lincoff and Gossett, 1984). This method consists of the addition of equal masses of a volatile solute to two sealed serum bottles that are identical in all respects except they possess different water volumes. The gas-phase concentrations are measured, and the following equation is used to determine Henry's law constant (Gossett, 1987):

$$H_{YC} = \frac{V_{W2} - [(C_{g1}/M_1) / (C_{g2}/M_2)] V_{W1}}{[(C_{g1}/M_1) / (C_{g2}/M_2)] V_{g1} - V_{g2}} \quad (14-6)$$

where  $V_{W1}$  = volume of water in bottle 1, L

$V_{W2}$  = volume of water in bottle 2, L

$V_{g1}$  = volume of headspace in bottle 1, L

$V_{g2}$  = volume of headspace in bottle 2, L

$M_1$  = total mass of of solute added to bottle 1, mol

$M_2$  = total mass of of solute added to bottle 2, mol

$C_{g1}$  = concentration of solute in the gas in bottle 1, mol/L

$C_{g2}$  = concentration of solute in the gas in bottle 2, mol/L

In the evaluation of  $H_{YC}$  using Eq. 14-6 the actual masses  $M_1$  and  $M_2$  do not need to be known but only their ratio. This means that if the same stock solution of a solute is used and injected into the two serum bottles, the actual concentration of the stock required need not be known because a gravimetric measure of the relative quantity of the stock added to the bottles is all that is needed (Gossett, 1987). The reported precision or coefficient of variation of this method is within 2 to 5 percent. This technique has become widely used to experimentally determine Henry's constants for VOCs (Gossett, 1987; Ashworth et al., 1988; Robbins et al., 1993; Dewulf et al., 1995; Heron et al., 1998; Ayuttya et al., 2001).

Henry's law constants are readily available in the published literature (Yaws et al., 1976; Mckay et al., 1979; Nicholson et al., 1984; U.S. EPA, 1986; Ashworth et al., 1988; Sander, 1999). Values can also be found in Internet databases, including at sites maintained by NIST (2011) and SRC (2011). Table 14-3 displays Henry's constants for several VOCs encountered in water supplies. Note their values change with temperature, and a discussion of the impact of temperature on Henry's constants is presented below. Most Henry's constants reported in the literature are performed using organic-free laboratory water. Natural waters used for drinking supply may contain concentrations of dissolved solids (50 to 600 mg/L TDS) and natural organic matter (0.5 to 15 mg/L as DOC). The value of Henry's constants is not impacted by the range of these dissolved constituents in

**Table 14-3**

Dimensionless Henry's law constants for selected volatile organic chemicals

Component	Henry's Law Constants, H				
	10°C	15°C	20°C	25°C	30°C

natural waters (Nicholson et al., 1984). The impact of high dissolved constituent concentrations on Henry's constants is discussed below. For water supplies that contain multiple VOCs in low concentrations, their Henry's constant values are not impacted by the other VOCs present in the water.

When experimental values of Henry's constant are not available, they can be estimated using software that incorporates molecular group or bond contribution calculations or from solubility and vapor pressure data as discussed in the following section.

### Estimation of Henry's Constant Using Molecular Techniques or Using Vapor Pressure and Solubility

#### ESTIMATION OF HENRY'S CONSTANTS USING MOLECULAR TECHNIQUES

Molecular methods have been developed to estimate Henry's constants for solutes that lack reliable experimental data. Methods involving group contributions are widely used to estimate Henry's constants for solutes in water. Group contribution methods separate a molecular structure of a molecule into smaller parts, known as functional groups or fragments such that the molecule property is obtained from summing its functional groups. The small functional groups or segments are determined by fitting to a set of experimental data containing many solutes, while assuming the interaction parameter values for a functional group or fragment are

independent of the molecules in which they make up and can be used to estimate Henry's constants of more complex solutes (Lin and Sandler, 2002). Group and bond contribution methods to predict Henry's constants of solutes in water have been developed and presented in the literature (Hine and Mookerjee, 1975; Nirmalakhandan and Speece, 1988; Meylan and Howard, 1991; Suzuki et al., 1992; Meylan, 1999; Lin and Sandler, 2000, 2002). Many of these methods are incorporated into user-friendly programs that can be used to estimate Henry's constants for solutes in water. The most widely known software program is HENRYWIN, which is a part of EPI (Estimation Programs Interface) Suite. EPI Suite is a Windows-based suite of physical/chemical property and environmental fate estimation programs developed by the EPA's Office of Pollution Prevention Toxics and Syracuse Research Corporation (Meylan, 1999). EPI Suite is available for free download on the EPA's website. Another commonly used software package is the System to Estimate Physical Properties (StEPP). StEPP contains a database of over 600 compounds and their physical properties including experimentally determined values of Henry constants as well as estimation methods using a group contribution method (Hokanson, 1996).

#### ESTIMATION OF HENRY'S CONSTANTS FROM VAPOR PRESSURE AND SOLUBILITY DATA

Compounds with strong repulsive interactions with water molecules have low aqueous solubilities. These compounds usually have large deviations between Henry's constant and vapor pressure. The ratio of vapor pressure to Henry's constant is approximately equal to the aqueous solubility of the compound as shown in the expression

$$C_{S,A} \approx \frac{P_{V,A}}{H_{PC,A}} \quad (14-7)$$

where  $C_{S,A}$  = aqueous solubility of compound A, mol/L  
 $P_{V,A}$  = vapor pressure of compound A, atm

Consequently, Henry's constant for a slightly soluble compound A can be estimated from vapor pressure and aqueous solubility as

$$H_{PC,A} \approx \frac{P_{V,A}}{C_{S,A}} \quad (14-8)$$

For completely miscible compounds, the Henry law constant approaches the value of the vapor pressure:

$$H_{PX,A} \approx P_{V,A} \quad (14-9)$$

Using this approach, the estimated values are typically within  $\pm 50$  to 100 percent of the experimentally reported values and should, therefore, only be used when measured values of the constants are not available. This approach is valid for compounds that are liquid at standard conditions.

### Factors Influencing Henry's Constant

Temperature, pressure, ionic strength, surfactants, and solution pH (for ionizable species such as  $\text{NH}_3$  and  $\text{CO}_2$ ) can influence the equilibrium partitioning between air and water. The impact of total system pressure on  $H_{YC}$  is negligible because other components in air have limited solubility in water.

#### EFFECT OF TEMPERATURE

Henry's constants for several compounds (at different temperatures) and gases (at  $20^\circ\text{C}$ ) are listed in Table 14-4. Assuming that the standard enthalpy change ( $\Delta H_{\text{dis}}^\circ$ ) for the dissolution of a component in water is constant over the temperature range of interest, the change in  $H_{YC}$  with temperature can be estimated using the van't Hoff equation (see Chap. 5):

$$H_{YC,T_2} = H_{YC,T_1} \exp \left[ \frac{-\Delta H_{\text{dis}}^\circ}{R} \left( \frac{1}{T_2} - \frac{1}{T_1} \right) \right] \quad (14-10)$$

where  $H_{YC,T_2}$  = dimensionless Henry's law constant at temperature  $T_2$

$H_{YC,T_1}$  = dimensionless Henry's law constant at temperature  $T_1$

$\Delta H_{\text{dis}}^\circ$  = standard enthalpy change of dissolution in water, J/mol

$R$  = universal gas constant,  $8.314 \text{ J/mol} \cdot \text{K}$

$T_1, T_2$  = absolute temperature, K ( $273 + ^\circ\text{C}$ )

Equation 14-10 can be simplified to the following expression, and  $K_C$  and  $\Delta H_{\text{dis}}^\circ$  values for selected compounds are reported in Table 14-4:

$$H_{YC} = K_C \exp \left( -\frac{\Delta H_{\text{dis}}^\circ}{RT} \right) \quad (14-11)$$

**Table 14-4**

Dimensionless Henry's law constants at  $20^\circ\text{C}$  and temperature dependence for gases in water

Compound	$\Delta H_{\text{dis}}^\circ$ <sup>a</sup>	$K_C$	$H_{YC}$
Air	10.28	3,368	49.58
Ammonia	36.12	1,526	0.0006
Carbon dioxide	19.97	4,013	1.1
Chlorine	16.80	420	0.43
Chlorine dioxide	28.26	4,300	0.04
Hydrogen sulfide	17.84	567	0.38
Methane	14.86	12,402	28.41
Nitrogen	7.94	1,563	60.01
Oxygen	13.40	7,537	30.75
Ozone	24.28	83,848	3.92
Sulfur dioxide	23.15	358	0.03

<sup>a</sup> $\Delta H_{\text{dis}}^\circ$  in units of kJ/mol.

The application of Eq. 14-11 to calculate  $H_{YC}$  as a function of temperature is illustrated in Example 14-2. Another common method of expressing the temperature dependence of  $H_{YC}$  is to define  $K_C$  and  $\Delta H_{\text{dis}}^\circ/R$  as fitting parameters  $K_A$  and  $K_B$ , respectively, using the equation

$$H_{YC} = \exp\left(K_A - \frac{K_B}{T}\right) \quad (14-12)$$

Values of  $K_A$  and  $K_B$  for several compounds valid for temperatures ranging from 283 to 303 K are presented in Ashworth et al. (1988).

The relationship between  $H_{YC}$  and temperature over a wide temperature range is displayed in Fig. 14-4 for benzene and hexane. For most

### Example 14-2 Henry's law constant and temperature effect

Calculate Henry's law constant at 5 and 20°C for ozone using Eq. 14-11 and Table 14-4.

#### Solution

- At 5°C: Using Eq. 14-11 and the constants provided in Table 14-4, Henry's law constant for ozone at 20°C can be estimated as follows:

$$K_C = 83,848$$

$$\Delta H_{\text{dis}}^\circ = 24.28 \times 10^3 \text{ J/mol}$$

$$H_{YC} = K_C \exp\left(-\frac{\Delta H_{\text{dis}}^\circ}{RT}\right)$$

$$= 83,848 \exp\left\{-\frac{24.28 \times 10^3 \text{ J/mol}}{(8.314 \text{ J/mol} \cdot \text{K})(273 + 5) \text{ K}}\right\}$$

$$= 2.3$$

- At 20°C:

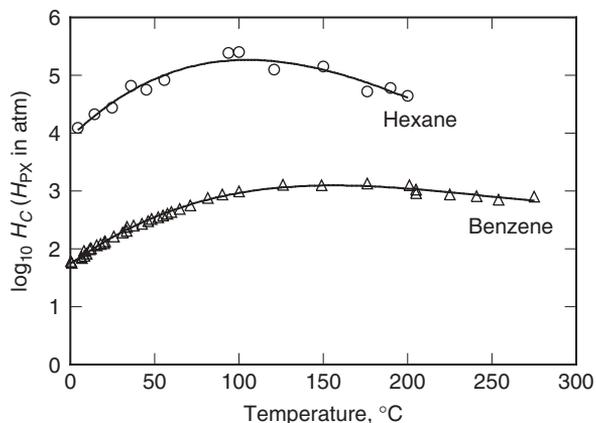

$$H_{YC} = K_C \exp\left(-\frac{\Delta H_{\text{dis}}^\circ}{RT}\right)$$

$$= 83,848 \exp\left\{-\frac{24.28 \times 10^3 \text{ J/mol}}{(8.314 \text{ J/mol} \cdot \text{K})(273 + 20) \text{ K}}\right\}$$

$$= 3.93$$

#### Comment

From the above computations, it is clear that temperature has an effect on the dimensionless form of Henry's law.

**Figure 14-4**

Relationship between Henry's law constant and temperature for benzene and heptane. (Adapted from Lan, 2009).

environmental applications where the temperature is less than 30°C, the relationship is nearly linear and can be approximated by the van't Hoff and related equations (Eqs. 14-11 and 14-12). Depending on the volatility of the compound, for temperatures greater than 30°C,  $H_{YC}$  increases nonlinearly with temperature reaching a maximum and then decreasing as temperature continues to increase (Miller and Hawthorne, 2000; Lau 2009). For benzene,  $H_{YC}$  reaches a maximum at 100°C followed by a decrease as temperature continues to increase. While this may not be important for air stripping at ambient temperatures, it may be important for other applications such as steam stripping of VOCs from industrial wastes.

#### IONIC STRENGTH

Gases or synthetic organic chemicals (SOCs) have a higher apparent Henry's law constant ( $H_{YC,app}$ ) when the dissolved solids are high because equilibrium depends on activity, not concentration. Thus, the apparent Henry's law constant takes activity into account:

$$Y_A = H_{YC} \{A\} = H_{YC} \gamma_A C_A = H_{YC,app} C_A \quad (14-13)$$

where  $H_{YC,app} = H_{YC} \gamma_A =$  apparent Henry's law constant,  
dimensionless

$Y_A =$  gas-phase concentration, mol/L

$\gamma_A =$  activity coefficient of A

$C_A =$  concentration of A, mol/L

$H_{YC} =$  dimensionless Henry's constant

The activity coefficient  $\gamma_A$  is a function of ionic strength and can be calculated using the following empirical equation for neutral species:

$$\log \gamma_A = K_s \times I \quad (14-14)$$

where  $K_s$  = Setschenow, or “salting-out,” constant, L/mol  
 $I$  = ionic strength of water, mol/L

Values of  $K_s$  need to be determined experimentally because there is no general theory for predicting them. Salting-out coefficients for several compounds in seawater are available in the literature (Gossett, 1987; Schwarzenbach et al., 1993). Significant increases in volatility and the apparent Henry constant are observed only for high-ionic-strength waters such as seawater.

#### EFFECT OF SURFACTANTS

Surfactants can impact the volatility of compounds. In most natural waters, surfactant concentrations are relatively low; consequently, surfactants do not affect the design of most aeration devices. However, when surfactants are present in relatively high concentrations, the volatility of other compounds may decrease by several mechanisms. The dominant mechanism is collection of surfactants at the air-water interface, decreasing the mole fraction of the volatile compound at the interfacial area, thereby lowering the apparent Henry law constant. For example, the solubility of oxygen in water can decrease by 30 to 50 percent due to the presence of surfactants.

Another surfactant effect for hydrophobic organic compounds is the incorporation of dissolved organic compounds into micelles in solution. Above the critical micelle concentration, the formation of additional micelles will decrease the concentration of the organic compound at the air-water interface and decrease the compound's volatility.

#### IMPACT OF PH

The pH does not affect the Henry's constant directly, but it does affect the distribution of species between ionized and un-ionized forms, which influences the overall gas-liquid distribution of the compound because only the un-ionized species are volatile.

Uncharged weak acids such as  $\text{H}_2\text{CO}_3$ , HCN, or  $\text{H}_2\text{S}$  cannot be stripped at pH values significantly above their  $\text{p}K_a$  value. For example, if hydrogen sulfide is a weak acid with the following equilibrium (note, the second ionization constant can be neglected because  $\text{p}K_{a2} > 14$ ):

Ionization constants for weak acids were described in Chap. 5. The equilibrium constant ( $K_a$ ) for the reaction in Eq. 14-15 is  $7.94 \times 10^{-8}$  ( $\text{p}K_a = 7.1$ ). Since only the un-ionized species is volatile, Henry's law can be written as

$$Y_A = H_{YC} [\text{H}_2\text{S}] = H_{YC}\alpha_0 C_{T,S} = H_{YC,\text{app}} C_{T,S} \quad (14-16)$$

$$\alpha_0 = \frac{[\text{H}^+]}{[\text{H}^+] + K_a} \quad (14-17)$$

where  $[H_2S]$  = hydrogen sulfide concentration, mol/L  
 $C_{T,S}$  = total sulfide concentration, mol/L  
 $\alpha_0$  = fraction of total sulfide present as hydrogen sulfide  
 $H_{YC,app}$  = apparent Henry's law constant, dimensionless  
 $K_a$  = acid dissociation constant

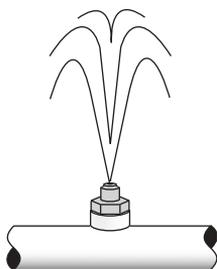

If the pH is equal to 5.1, two pH units lower than the  $pK_a$ , then sulfide is only 1 percent ionized and the apparent Henry's constant is essentially the same as the  $H$  value. If the pH is two units higher than the  $pK_a$  value, then sulfide is 99 percent ionized and the apparent Henry's constant is 1 percent of the  $H$  value.

### 14-3 Classification of Air-Stripping and Aeration Systems

Gas-liquid contactors are classified as either gas phase contactors or flooded contactors and then further classified into four subgroups based on the method that is used to either remove gas from water or add gas to water. The four basic types of air-water contact systems that are discussed in this section are (1) droplet or thin-film air-water contactors, (2) diffusion or bubble aerators, (3) aspirator-type aerators, and (4) mechanical aerators. Characteristics and typical applications of air-water contact systems that fall into one of these four groups are summarized in Table 14-5. Some of these systems may be used to contact water with gases other than air, and while these uses are listed in Table 14-5, they are discussed in other chapters such as Chap. 13.

#### Droplet or Thin-Film Air-Water Contactors

Droplet or thin-film air-water contactors are gas-phase contactors designed to produce small droplets of water or thin films, which promote rapid mass transfer.

**Figure 14-5**  
Schematic of fountain spray aerator.

#### DROPLET AIR-WATER CONTACTORS

Contactors that use droplets are spray devices, such as towers and the fountain spray aerator shown on Fig. 14-5. Spray devices are designed to provide the desired droplet size for the desired contact time with the gas phase, which is typically air. Spray aerators are an efficient method of gas transfer; however, for efficient operation spray aerators should be placed in large basins or reservoirs in favorable climatic conditions.

#### THIN-FILM AIR-WATER CONTACTORS

Thin films of water are created in cascade and multiple-tray aerators and packed columns and towers. Air-water contact occurs when water flows by gravity over the surfaces of packing materials that are placed in

**Table 14-5**  
Characteristics of gas–liquid contacting systems

Type of Contacting Device	Process Description	Method of Gas Introduction	Typical Applications	Oxygen Transfer Rate, kg O <sub>2</sub> /kW · h	Number of Transfer Units (NTU)	Hydraulic Head Required, m (ft)	Loading Factor
Spray aerator	Water to be treated is sprayed through nozzles to form disperse droplets; typically, a fountain configuration. Nozzle diameters usually range from 2.5 to 4 cm (1–1.6 in.) to minimize clogging.	Natural aeration through convection	H <sub>2</sub> S, CO <sub>2</sub> , and marginal VOC removal; taste and odor control, oxygenation	—	0.5–0.7	1.5–7.6 (5–25)	Surface area of 0.10–0.30 m <sup>2</sup> · s/L
Spray tower	Water to be treated is sprayed downward through nozzles to form disperse droplets in a tower configuration; air–water ratio is controlled; typically countercurrent flow.	Forced-draft aeration	H <sub>2</sub> S, CO <sub>2</sub> , and VOC removal; taste and odor control	—	1–1.5	1.5–7.6 (5–25)	Surface area of 0.10–0.30 m <sup>2</sup> · s/L
Packed tower	Water to be treated is sprayed onto high-surface-area packing to produce a thin-film flow; process configuration typically countercurrent.	Forced-draft aeration	H <sub>2</sub> S, CO <sub>2</sub> , and VOC removal; taste and odor control	—	1–4	3–12 (10–40)	

(continued)

Table 14-5 (Continued)

Type of Contacting Device	Process Description	Method of Gas Introduction	Typical Applications	Oxygen Transfer Rate, kg O <sub>2</sub> /kW · h	Number of Transfer Units (NTU)	Hydraulic Head Required, m (ft)	Loading Factor
Cascade	Water to be treated flows over the side of sequential pans, creating a waterfall effect to promote droplet-type aeration.	Aeration primarily by natural convection	CO <sub>2</sub> removal, taste and odor control, aesthetic value, oxygenation	—	0.5–0.7	0.9–3 (3–10)	
Multiple tray	Water to be treated trickles by gravity through trays containing media [layers 0.1–0.15 m (4–6 in.) deep] to produce thin-film flow. Typical media used include coarse stone or coke [50–150 mm (2–6 in.) in diameter] or wood slats.	Natural or forced-draft aeration	H <sub>2</sub> S, CO <sub>2</sub> removal, taste and odor control	—	<1	1.5–3 (5–10)	0.007–0.014 m/s (10–20 gpm/ft <sup>2</sup> )
Low profile (sieve tray)	Water flows from entry at the top of the tower horizontally across series of perforated trays. Large air flow rates are used, causing frothing upon air–water contact, which provides large surface area for mass transfer. Units are typically less than 3 m (10 ft) high.	Air introduced at bottom of tower	VOC removal	—	—	—	Water flow rates less than 0.065 m <sup>3</sup> /s (1000 gpm)

Diffuser	Fine bubbles are supplied through porous diffusers submerged in the water to be treated; tank depth is typically restricted to 4.5 m (15 ft).	Compressed air or ozone	Fe and Mn removal, CO <sub>2</sub> removal, taste and odor control, oxygenation, ozonation	0.5	0.5–1.5	—	0.1–1 L air/L water
Dispersed air	Compressed air is created through a stationary sparger orifice-type dispersion apparatus located directly below a submerged high-speed turbine.	Compressed air or ozone	Ozonation, especially when high concentrations of Fe and Mn are present. Used due to clogging of porous diffusers	1.5	1–2		
Hydraulic aspirator	A gas stream is educted into the liquid stream with a venturi-type device.	Compressed ozone, CO <sub>2</sub> , Cl <sub>2</sub>	Ozonation, CO <sub>2</sub> addition, Cl <sub>2</sub> disinfection	1.5–3.5	—	3–6 (10–20)	
Mechanical aspirator	A hollow-blade impeller rotates at a speed sufficient to aspirate and discharge a gas stream into the water.	Compressed air or ozone	Ozonation, CO <sub>2</sub> addition	0.7			
Mechanical aerator	Surface aerators (brush or turbine types) sweep air into the water and fling water into the air. Aeration pumps pull air into the water.	Mechanical agitation of water into surrounding air	O <sub>2</sub> absorption, VOC removal when <90% removal required	1.5–4.5 (turbine) 2.5 (brush)			

trays, columns, or towers and between trays. The thin liquid film that forms as water flows downward is disrupted continuously by the irregular surfaces of the packing material, maximizing the exposure of the water to the atmosphere and encouraging air–water mixing.

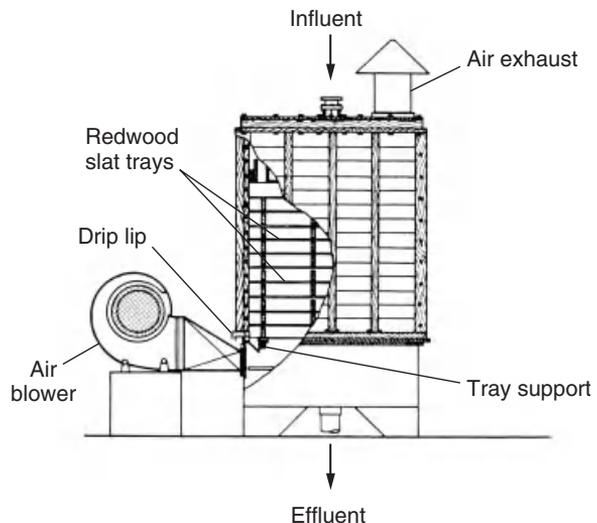

#### *Cascade aerators*

Cascade aerators are commonly used for treating groundwater and may be located at the groundwater source or reservoir. Cascade aerators are also called step aerators as water flows downward in a thin film over a series of steps or baffles, sometimes constructed of concrete. Cascade aerators are generally less efficient than other types of thin-film aerators because water flow is less turbulent, resulting in less air–water mixing.

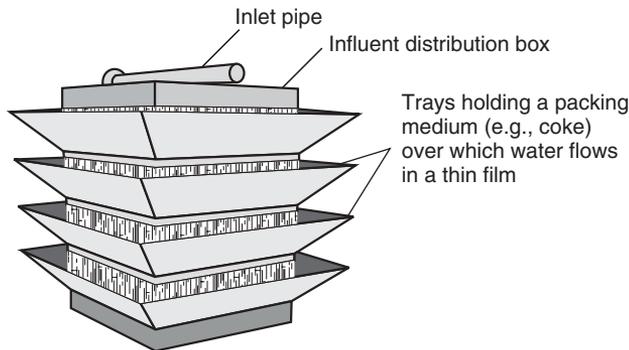

#### *Multiple-tray aerators*

There are several types of multiple-tray aerators, all based on the same design concept of stacked trays, where water is distributed over the top tray with a spray nozzle or special distribution trough and then flows from the upper tray over the tray sides into lower trays. Tray-type aerators may be either natural draft type such as coke tray aerators or forced draft type such as wood slat aerators.

Of all the types of multiple-tray aerators, wood slat towers are the most efficient. The slat towers are either forced or induced draft and are enclosed in a wood, fiberglass, or metal shell, as shown on Fig. 14-6. The slats are generally stacked and centered vertically and the horizontal spaces between the slats are staggered so that the water trickling down one tray strikes the middle of the slat of the next tray.

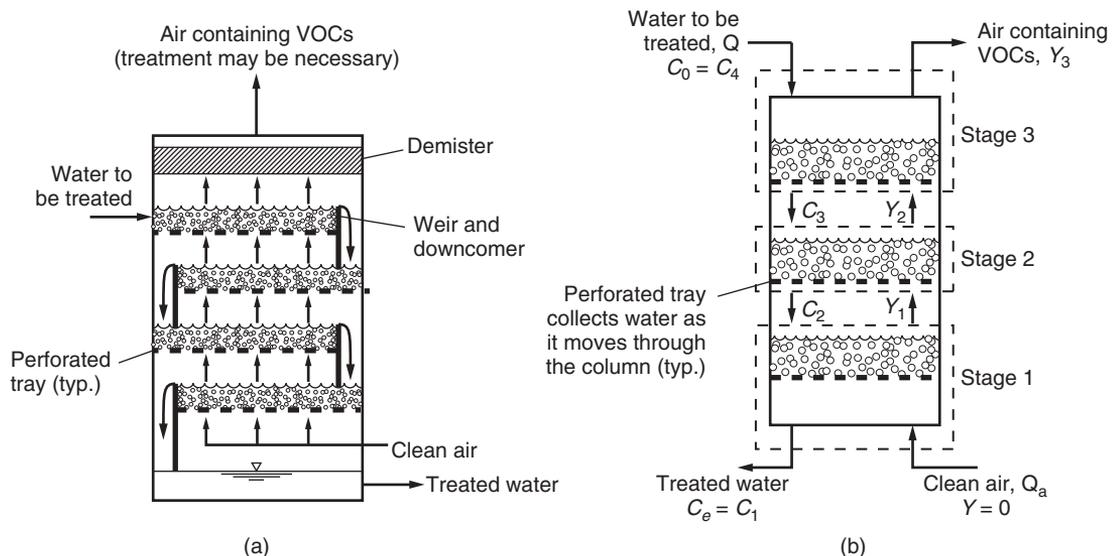

**Figure 14-6**  
Forced-draft multiple-slat tower cascade aerator.

**Figure 14-7**  
Natural draft coke tray aerator.

Tray aerators are typically designed for natural draft, as shown on Fig. 14-7, and typically the tray is filled with packing material such as coke. Coke tray aerators provide somewhat more turbulence in air–water contact because the large surface area of the coke provides a large air–water contact area. Tray aerators are built with splash skirts to reduce the water loss and icing of the protective retaining screens.

A type of multiple-tray aerator that has recently grown in use for removal of VOCs from contaminated waters is the low-profile air stripper, also called the sieve tray column, as shown on Fig. 14-8a. Because the water flows horizontally across each tray, the desired removal efficiency can be obtained by increasing the length or width of the trays instead of the height.

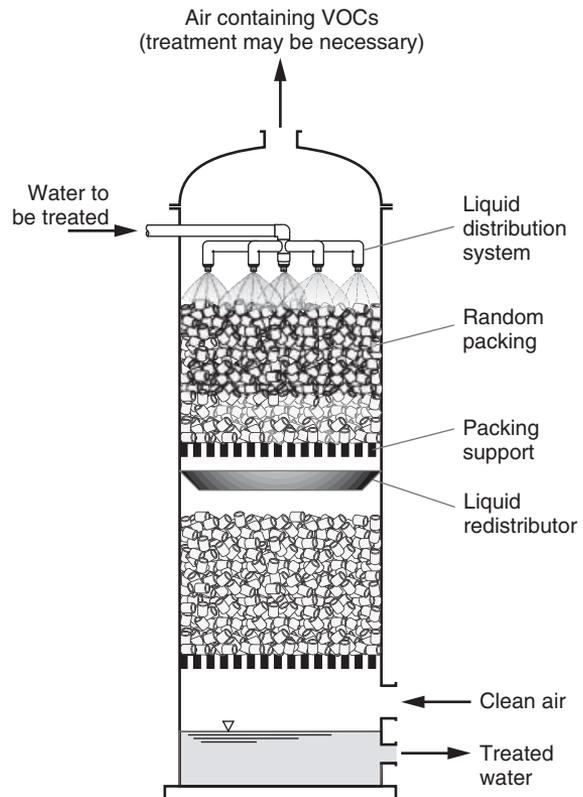

**Figure 14-8**  
Low-profile air stripping: (a) schematic (adapted from U.S. ACE, 2001) and (b) diagram of low-profile air stripping as multistage, countercurrent process.

*Packed towers*

Packed towers are circular or square towers that are filled with an irregular shaped inert packing material, as shown on Fig. 14-9. Packing material is available in a wide variety of sizes and shapes depending on the manufacturer. Operationally, water is pumped to the top of the tower and into a liquid distributor where it is dispersed as uniformly as possible across the packing surface, and then it flows by gravity through the packing material and is collected at the bottom of the tower. Airflow may be in the same direction as the water (co-current), in the opposite direction as the water (countercurrent), or across the water (cross flow). For countercurrent operation, a blower is used to introduce fresh air into the bottom of the tower and the air flows countercurrent to the water up through the void spaces between the wetted packing material, as shown on Fig. 14-9.

An important part of the packed tower system that is not shown on Fig 14-9 is a demistor, which eliminates entrained water drops and aerosols in the off-gas of a packed tower. Aerosols must be eliminated because they can be displeasing to local communities from an aesthetic point of view and they can freeze in cold climates, causing icing problems.

**Figure 14-9**  
Schematic of a countercurrent packed tower.

Diffusion-type aeration systems (either diffused-air or dispersed-air systems) force air into the water using compressed air. Blowers used for aerating systems are either multiple-stage or single-stage centrifugal or rotary positive displacement. Rotary blowers are often used for small installations, where water depth varies significantly.

## Diffusion and Dispersion Aerators

### DIFFUSED AIR

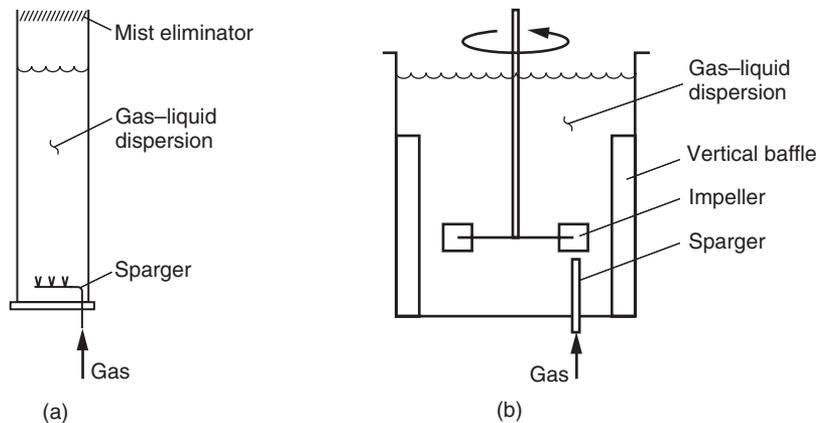

Compressed air is generally introduced through porous membranes, porous plates or tubes, or wound fiber or metallic filaments at the bottom of a basin or tank, as illustrated by the bubble column on Fig. 14-10a. Diffused-air systems generally require filters to screen out particulates in the air because the air is forced to flow through very fine pores, which can easily plug.

### DISPERSED AIR

Mechanical mixers and a stationary orifice-type sparger air dispersion system are used to force air into water in dispersed-air systems, as shown on Fig. 14-10b. The mechanical mixer in the contactor aids in the air–water mixing and, therefore, the gas transfer efficiencies are generally much better than in simple diffused-air systems. The air dispersion outlet is generally located a small distance above the tank bottom to reduce the pressure requirements of the air compressor. Dispersed-air systems usually do not require air filtration as the orifice-type spargers do not readily plug.

Air aspiration is commonly accomplished with either hydraulic aspirators or mechanical devices. A typical hydraulic aspirator is a type of hydraulic eductor or injector in which pressurized water flows through a throat similar to a venturi tube to create a low-pressure condition that in turn draws atmospheric air or gas into the water. A second type of aspirator is a mechanical aspirator that consists of a hollow-blade impeller that rotates at a speed sufficient to aspirate and discharge atmospheric air into the

## Aspirators

**Figure 14-10**  
Common diffused aeration systems: (a) bubble column and (b) agitated vessel.

water. Hydraulic aspirators are mostly small in size, but a single unit under favorable conditions and operating with atmospheric air produces twice the oxygen transfer rate of ordinary mechanical aspirators.

### Mechanical Aerators

Surface aerators and aeration pumps are the two basic types of mechanical aerators. Surface aerators may be of the turbine type or the brush type, as shown on Fig. 14-11. Aeration pumps consist of a turbine mixer with a draft tube. A number of patented mechanical aerators can be purchased from manufacturers.

### Advantages and Disadvantages of Various Air-Stripping and Aeration Systems

Each type of air-stripping and aeration system offers process and cost advantages for a specific mass transfer problem. Low-profile air strippers versus packed towers and diffusion-type aerators versus droplet and thin-film aerators are compared in the following discussion.

#### LOW-PROFILE AIR STRIPPERS VERSUS PACKED TOWERS

The advantages of using a low-profile air stripper over a conventional packed tower stripper are that (1) the low-profile air stripper is smaller and more compact and (2) periodic maintenance is easier to perform on the low-profile air stripper. The disadvantage is that for a given removal the low-profile air stripper requires a significantly higher airflow than a conventional countercurrent packed tower. Consequently, the operational costs can be greater for the low-profile air stripper. In addition, low-profile air strippers are limited to lower water flow rates than countercurrent packed towers.

#### DIFFUSION-TYPE AERATORS VERSUS DROPLET AND THIN-FILM AERATORS

The advantages of diffusion-type aerators include (1) negligible head loss for the process water system and (2) less space requirements than for

**Figure 14-11**  
Typical examples of surface aeration devices: (a) brush type and (b) turbine type.

(a)

(b)

the droplet and thin-film aerators. Diffused-air systems may be extremely effective for reservoir management. Many successful diffused-air applications for reservoir destratification have been reported in the literature (AWWA, 1978a,b; Biederman and Fulton, 1971; Garton, 1978; Laverty and Nielsen, 1970; Steichen et al., 1979; Symons et al., 1970).

Selection of the appropriate equipment is based on relative transfer efficiencies, available hydraulic head, ease of maintenance, and cost considerations (capital and operating costs). Transfer efficiency and some cost considerations are considered below.

### **Selection of Appropriate Equipment**

#### **TRANSFER EFFICIENCY**

An important consideration in selecting a process for a specific application is the upper limit of transfer efficiency that can be economically achieved by the process. Many of the processes described in Table 14-5 have limited transfer efficiency. Commercially available cascade aerators cannot achieve greater than 50 or 60 percent removal of chloroform, a relatively volatile organic contaminant. In contrast, packed towers can achieve >99% removal of chloroform. Cascade and multiple-tray aerators encounter corrosion and algae and slime growth problems, particularly if the process water contains hydrogen sulfide. Chlorination and copper sulfate treatment of the process water may help control these problems, but that is an additional operational issue with which to contend.

#### **COST CONSIDERATIONS**

For many applications of air–water mass transfer in water treatment, such as stripping of volatile contaminants or addition of a reactant gas, one or more of the four types of air–water contacting systems described above may be used. When more than one system may be appropriate to address the air–water mass transfer issue, capital and operating costs generally are the deciding factors.

##### *Capital cost*

The capital cost of each of the processes discussed is closely related to the mass transfer efficiency of the process. In general, the lower the transfer efficiency, the larger the facility required for achieving a certain removal.

##### *Operating cost*

Operating cost is primarily a function of the hydraulics of the process and the method of gas dispersion. Equipment complexity or heavy maintenance is typically not a major consideration because most mass transfer equipment is relatively simple, although it should be noted that fouling by chemical precipitation and/or biological growth must be controlled.

When adding a reactive gas such as oxygen, the operating cost must also include chemical costs. The principal cost may be the chemical itself

and/or generation of the compound and to a lesser degree the feeding equipment and gas transfer contact tank (if any).

## 14-4 Fundamentals of Packed-Tower Air Stripping

Packed towers are either cylindrical columns or rectangular towers containing packing that disrupts the flow of liquid, thus producing and renewing the air–water interface. A schematic of a countercurrent cylindrical packed tower is shown on Fig 14-9, and the operation was described in Sec. 14-3. Packed towers have high liquid interfacial areas and void volumes greater than 90 percent, which minimizes air pressure drop through the tower.

The random packing material is important to the efficient transfer of volatile contaminants from the water to the air because it provides a large air–water interfacial area. Various types of packing shapes, sizes, and their physical properties are available commercially, as shown on Fig. 14-12. The packing can be structured packing or individual pieces that are randomly placed in the tower.

### Mass Balance Analysis for a Countercurrent Packed Tower

The model for countercurrent packed towers requires the relationship that relates the bulk water-phase concentration to the bulk air-phase concentration. To obtain a relationship between the bulk air and water concentrations that are shown on Fig. 14-13, a mass balance is written around the lower half of the tower as follows:

1. The general statement of mass balance in words is

$$\begin{aligned} & \text{Mass of chemical entering in liquid phase per unit time} \\ & + \text{mass of chemical entering in gas phase per unit time} \\ & = \text{mass of chemical exiting in liquid phase per unit time} \\ & + \text{mass of chemical exiting in gas phase per unit time} \quad (14-18) \end{aligned}$$

2. The mass balance representation using symbols on Fig. 14-13 is

$$QC_b(z) + Q_a Y_0 = QC_e + Q_a Y_b(z) \quad (14-19)$$

where  $Q$  = liquid flow rate,  $\text{m}^3/\text{s}$

$C_b(z)$  = bulk liquid-phase concentration at axial position  $z$  along tower,  $\text{mg}/\text{L}$

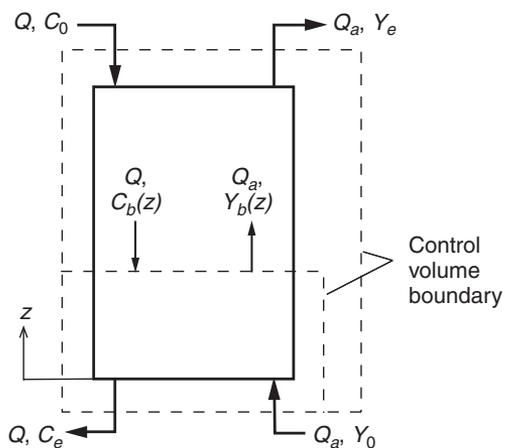

$Q_a$  = gas flow rate,  $\text{m}^3/\text{s}$

$Y_0$  = gas-phase concentration entering tower,  $\text{mg}/\text{L}$

$C_e$  = effluent liquid-phase concentration,  $\text{mg}/\text{L}$

$Y_b(z)$  = bulk gas-phase concentration at axial position  $z$  along tower,  $\text{mg}/\text{L}$

**Figure 14-13**  
Definition drawing for mass balances on a packed tower.

Combining terms, Eq. 14-21 can be written as

$$Y_e - Y_0 = \left( \frac{Q}{Q_a} \right) (C_0 - C_e) \quad (14-22)$$

where  $C_0$  = influent liquid-phase concentration to tower, mg/L

$Y_e$  = effluent gas-phase concentration from tower, mg/L

Assuming clean air entering the bottom of the tower ( $Y_0 = 0$ ), Eq. 14-20 becomes

$$Y_b(z) = \left( \frac{Q}{Q_a} \right) [C_b(z) - C_e] \quad (14-23)$$

Under the same assumption, Eq. 14-22 can be written as

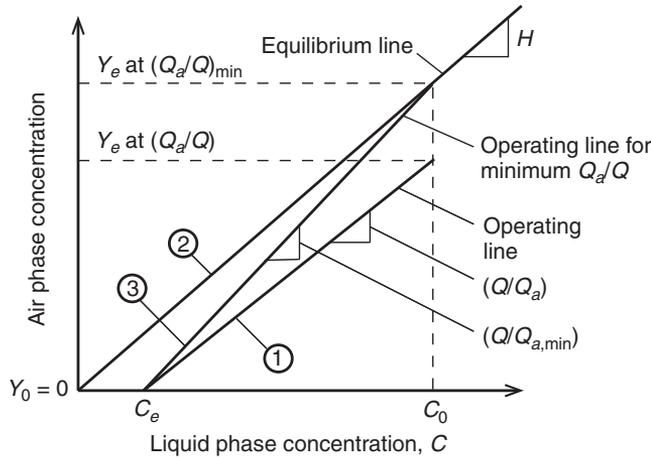

$$Y_e = \left( \frac{Q}{Q_a} \right) (C_0 - C_e) \quad (14-24)$$

Equations 14-23 and 14-24 represent the operating line equation for packed-tower aeration (see Chap. 7 for an introduction to operating lines). The operating and equilibrium lines for packed-tower aeration are presented on Fig. 14-14, which is known as a McCabe–Thiele diagram (McCabe and Thiele, 1925). The operating line is labeled 1 on Fig. 14-14, and the equilibrium line is labeled 2. Equilibrium is described by a straight line known as Henry's law (see Sec. 14-2):

$$Y = H_{YC}C \quad (14-25)$$

where  $Y$  = gas-phase concentration, mg/L

$C$  = liquid-phase concentration in equilibrium with gas-phase concentration  $Y$ , mg/L

**Figure 14-14**  
Operating line diagram for packed tower.

As discussed in Chap. 7, the operating and equilibrium lines are an important concept in separation processes, such as air stripping, because they can be used to determine the minimum amount of extracting phase (e.g., air in packed-tower aeration), in terms of mass or volume required to remove a component (e.g., from water in packed-tower aeration) to a desired removal efficiency.

#### STRIPPING FACTOR

A parameter commonly used in the evaluation of packed towers is the stripping factor ( $S$ );  $S$  is defined as the ratio of the slope of the equilibrium line to the operating line slope. As shown in Fig. 14-14, the equilibrium line divided by the operating line yields the following expression for the  $S$ :

$$S = \frac{\text{slope of equilibrium line}}{\text{slope of operating line}} = \frac{H_{YC}}{Q/Q_a} = \left(\frac{Q_a}{Q}\right) H_{YC} \quad (14-26)$$

where  $S$  = stripping factor, dimensionless

$Q_a/Q$  = operating air-to-water ratio of tower

$Q_a$  = air flow rate,  $\text{m}^3/\text{s}$

$Q$  = water flow rate,  $\text{m}^3/\text{s}$

When  $S = 1$ , the slopes of the equilibrium and operating lines are parallel to one another and removal to the treatment objective is possible but will require a very long or infinite tower length. When  $S < 1$ , the slope of the operating line is greater than the slope of the equilibrium line, the desired removal will be equilibrium limited and the treatment objective will not be obtained if a very low effluent concentration is needed. When  $S > 1$ , the slope of the operating line is less than the slope of the equilibrium line and the treatment objective can be met using stripping.

**MINIMUM AIR-TO-WATER RATIO**

A special case of the operating line shown in Fig. 14-14 is line number 3. This line intersects the equilibrium line where the influent concentration,  $C_0$ , is in equilibrium with the exiting gas-phase concentration (i.e.,  $Y_e = H_{YC}C_0$ ). The slope of this line represents the inverse of the minimum air-to-water ratio that can meet the treatment objective if the packed-tower length is infinite. If it is assumed the influent gas-phase concentration,  $Y_0$ , is equal to zero, and the influent liquid-phase concentration is in equilibrium with the exiting air according to Eq. 14-25, then Eq. 14-22 can be rearranged to yield the following expression for the minimum air-to-water ratio:

$$\left(\frac{Q_a}{Q}\right)_{\min} = \frac{C_0 - C_e}{H_{YC}C_0} \quad (14-27)$$

where  $(Q_a/Q)_{\min}$  = minimum air-to-water ratio, dimensionless

$C_0$  = influent liquid-phase concentration, mg/L

$C_e$  = treatment objective, mg/L

The minimum air-to-water ratio  $(Q_a/Q)_{\min}$  represents the minimum air-to-water ratio that can be applied for a packed tower to meet its treatment objective  $C_e$ . If the air-to-water ratio applied is less than the minimum air-to-water ratio, it will not be possible to design a packed tower capable of meeting the treatment objective because equilibrium will be established in the tower before the treatment objective is reached.

With respect to the selection of the optimum air-to-water ratio, it has been demonstrated that minimum tower volume and power requirements are achieved using approximately 3.5 times the minimum air-to-water ratio for contaminants with Henry's law constants greater than 0.05 for high percentage removals, corresponding to a stripping factor of 3.5 (Hand et al., 1986).

**RELATIONSHIP BETWEEN  $S$  AND  $(Q_a/Q)_{\min}$** 

The stripping factor can be related to the minimum air-to-water ratio when the treatment efficiency is very high, and Eq. 14-27 can be approximated as

$$\left(\frac{Q_a}{Q}\right)_{\min} = \frac{C_0 - C_e}{H_{YC}C_0} \approx \frac{1}{H_{YC}} \quad (C_e \ll C_0) \quad (14-28)$$

Substitution of Eq. 14-28 into Eq. 14-26 yields a relationship for stripping factor in terms of minimum air to water ratio

$$S = \frac{Q_a/Q}{(Q_a/Q)_{\min}} \quad (14-29)$$

When  $C_e \ll C_0$ , the stripping factor is approximately equal to the ratio of the actual air flow rate to the minimum air flow rate for treating a given flow of water.

### Example 14-3 Calculation of minimum air-to-water ratio and stripping factor

Calculate the minimum air-to-water ratio and operating air-to-water ratio for 1,2-dichloropropane (DCP) and tetrachloroethylene (PCE) with 90 percent removal at 10°C for a countercurrent packed tower. Calculate the operating air-to-water ratio for a packed tower that minimizes the tower volume and power requirements, and the stripping factor for each compound at the operating air-to-water ratio.

#### Solution

- Determine  $H_{PC}$  for each compound using data in Table 14-3.

a. DCP:

$$H_{YC,DCP} = 0.0525 \text{ (dimensionless)}$$

b. PCE:

$$H_{YC,PCE} = 0.364 \text{ (dimensionless)}$$

- Calculate the minimum air-to-water ratio for each compound using Eq. 14-28.

a. DCP:

$$\left(\frac{Q_a}{Q}\right)_{\min,DCP} = \frac{C_0 - C_e}{H_{YC,DCP}C_0} = \frac{C_0 - 0.1C_0}{0.0525C_0} = 17.14$$

b. PCE:

$$\left(\frac{Q_a}{Q}\right)_{\min,PCE} = \frac{C_0 - C_e}{H_{YC,PCE}C_0} = \frac{C_0 - 0.1C_0}{0.364C_0} = 2.47$$

- To calculate the operating air-to-water ratio that minimizes tower volume and power consumption, multiply the minimum air-to-water ratio by 3.5.

a. DCP:

$$\left(\frac{Q_a}{Q}\right)_{DCP} = 3.5 \left(\frac{Q_a}{Q}\right)_{DCP,\min} = (3.5)(17.14) = 60$$

b. PCE:

$$\left(\frac{Q_a}{Q}\right)_{PCE} = 3.5 \left(\frac{Q_a}{Q}\right)_{PCE,\min} = (3.5)(2.47) = 8.65$$

4. Calculate the stripping factor for each compound using Eq. 14-26. Note that the largest air-to-water ratio from step 3 applies to all compounds being stripped in the tower.

a. DCP:

$$S_{\text{DCP}} = \left( \frac{Q_a}{Q} \right) H_{Y_{C,\text{DCP}}} = (60) (0.0525) = 3.15$$

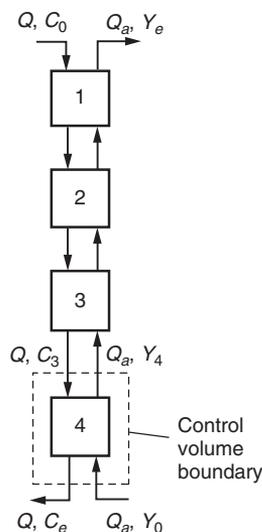

b. PCE:

$$S_{\text{PCE}} = \left( \frac{Q_a}{Q} \right) H_{Y_{C,\text{PCE}}} = (60) (0.364) = 21.8$$

### Comment

The compound with the lower Henry's law constant (DCP) requires much larger minimum and operating air-to-water ratios to achieve the desired removal. This is expected because a smaller Henry's constant indicates lower volatility, i. that is, a greater preference of the compound for the water phase and a lower tendency for stripping from the water phase to the air phase.

### Mass Balance for Multistage Stripping Tower

**Figure 14-15**  
Definition drawing for mass balances on multistage stripping tower.

In the design of air-stripping towers, the number of equilibrium stages required for stripping is often determined. Determining the number of equilibrium stages is analogous to representing plug flow as a series of completely mixed flow reactors (CMFRs), as described in Chap. 6. It is assumed that equilibrium conditions prevail within each stage.

A mass balance on the lower section of a staged countercurrent tower shown in Fig. 14-15 is

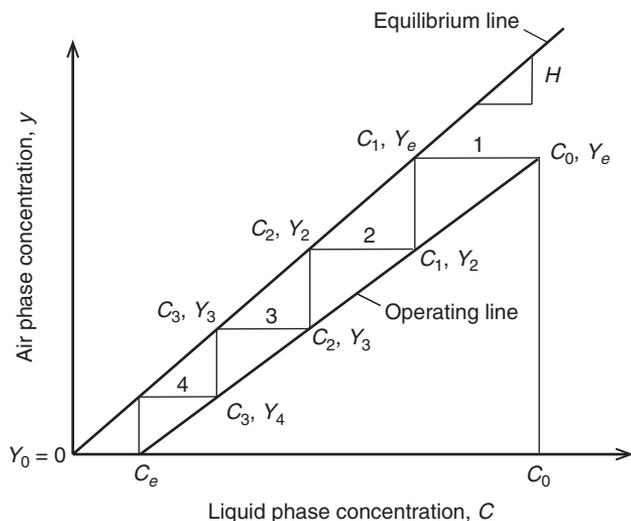

$$QC_3 + Q_a Y_0 = QC_e + Q_a Y_4 \quad (14-30)$$

Assuming clean air enters the tower ( $Y_0 = 0$ ) and rearranging Eq. 14-30,

$$Y_4 = \left( \frac{Q}{Q_a} \right) (C_3 - C_e) \quad (14-31)$$

The McCabe–Thiele (1925) graphical method for determining the number of equilibrium stages is demonstrated on Fig. 14-16 for a four-stage stripping tower. Both the operating line and the equilibrium line are shown on Fig. 14-16. The method for constructing the McCabe–Thiele diagram for finding the number of equilibrium stages or number of transfer units is described as follows:

1. The point  $(C_0, Y_e)$  represents the influent water-phase concentration and exiting air-phase concentration of the contaminant of interest at the top of the tower. Draw a horizontal line from the point  $(C_0, Y_e)$  to the point  $(C_1, Y_e)$ , which represents the

**Figure 14-16**  
Operating line diagram for multistage stripping tower.

location where the water-phase concentration of the constituent is in equilibrium with the exiting air, as shown on Fig. 14-16.

2. Draw a vertical line from the point  $(C_1, Y_e)$  to the point  $(C_1, Y_2)$  on the operating line. The numerical value of  $Y_2$  can be determined based on a mass balance around stage 1 shown on Fig. 14-16:

$$Y_2 = \left( \frac{Q}{Q_a} \right) C_1 + Y_e - \left( \frac{Q}{Q_a} \right) C_0 \quad (14-32)$$

3. Draw a horizontal line from the point  $(C_1, Y_2)$  on the operating line to the point  $(C_2, Y_2)$  on the equilibrium line.
4. Draw a vertical line from the point  $(C_2, Y_2)$  on the equilibrium line to the point  $(C_2, Y_3)$  on the operating line.
5. Draw a horizontal line from the point  $(C_2, Y_3)$  on the operating line to the point  $(C_3, Y_3)$  on the equilibrium line.
6. Draw a vertical line from the point  $(C_3, Y_3)$  on the equilibrium line to the point  $(C_3, Y_4)$  on the operating line.
7. Continue until point  $(C_n, Y_{n+1})$  is reached and the effluent concentration  $C_e$  is surpassed.

If the final stage does not intersect the effluent concentration, then the minimum number of stages would include the stage that overshoots the effluent concentration. This procedure is used to estimate the minimum number of stages or transfer units, because equilibrium is not usually attained and additional stages are required beyond the minimum number.

The McCabe–Thiele method described above can also be used to determine the minimum number of trays required in low-profile air stripping, which is a countercurrent, staged process and is discussed in Sec. 14-6.

### Design Equation for Determining Packed-Tower Height

Predicting the required height of a packed tower to meet a given air-stripping treatment objective is one of the goals of packed-tower design. The design equation for tower height can be derived using these assumptions: (1) steady-state conditions prevail in the tower, (2) air flow rate and water flow rate are constant through the column, (3) no chemical reactions occur, and (4) plug flow conditions prevail for both the air and water.

#### LIQUID-PHASE MASS BALANCE AROUND A DIFFERENTIAL ELEMENT

A liquid-phase mass balance around the differential element surrounded by a dashed box on Fig. 14-17a serves as the basis for the design equation. A schematic of the differential element applicable to the case of a liquid-side mass balance is presented on Fig. 14-17b.

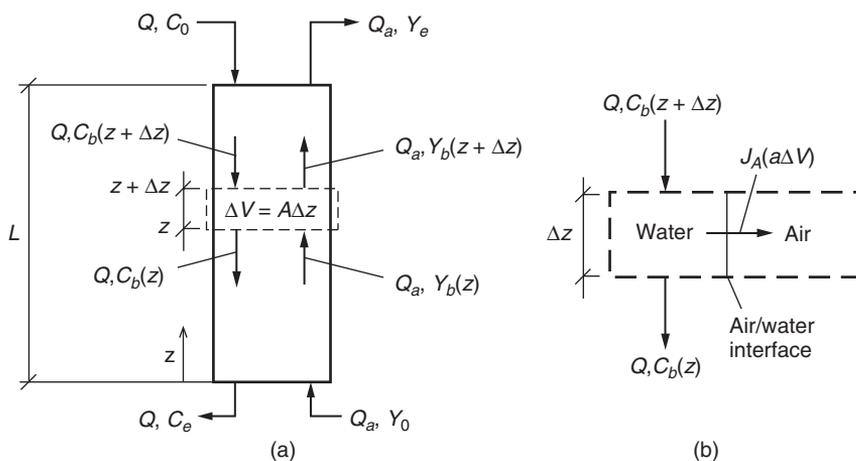

The liquid-phase mass balance around the differential element is written in words as

$$\begin{aligned} & \text{Mass of organic entering per unit time} \\ & - \text{mass of organic leaving per unit time} \\ & + \text{mass of organic generated per unit time} \\ & = \text{mass of organic accumulated per unit time} \end{aligned} \quad (14-33)$$

Equation 14-33 can be written symbolically as

$$[QC_b(z + \Delta z)] - [QC_b(z)] + 0 - [J_A(a\Delta V)] = 0 \quad (14-34)$$

where  $Q$  = water flow rate,  $\text{m}^3/\text{s}$   
 $C_b$  = bulk liquid-phase concentration,  $\text{mg}/\text{L}$   
 $z$  = axial position along tower,  $\text{m}$   
 $\Delta z$  = height of differential element,  $\text{m}$   
 $J_A$  = flux across air–water interface,  $\text{mg}/\text{m}^2 \cdot \text{s}$

**Figure 14-17**  
 Packed-tower design equation definition drawing: (a) schematic of packed tower showing differential element and (b) schematic of differential element used in liquid-side mass balance.

$a$  = area available for mass transfer divided by vessel volume,  
 $\text{m}^2/\text{m}^3$

$\Delta V$  = volume of differential element,  $\text{m}^3$

As shown in Chap. 7, the term  $J_A$  in Eq. 14-34 is obtained from the two-film theory:

$$J_A = K_L [C_b(z) - C_s^*(z)] \quad (14-35)$$

where  $K_L$  = overall liquid-phase mass transfer coefficient,  $\text{m/s}$

$C_s^*(z)$  = liquid-phase concentration at air–water interface in equilibrium with the bulk gas-phase concentration,  $\text{mg/L}$

Inserting Eq. 14-35 and  $\Delta V = A \Delta z$  into Eq. 14-34 yields

$$[QC_b(z + \Delta z)] - [QC_b(z)] - \{K_L [C_b(z) - C_s^*(z)](aA \Delta z)\} = 0 \quad (14-36)$$

where  $A$  = cross-sectional area of packed tower,  $\text{m}^2$

Rearranging Eq. 14-36 and dividing by  $A \Delta z$  yields the equation

$$\frac{Q}{AK_L a} \left[ \frac{C_b(z + \Delta z) - C_b(z)}{\Delta z} \right] = C_b(z) - C_s^*(z) \quad (14-37)$$

where  $K_L a$  = overall mass transfer rate constant,  $\text{s}^{-1}$

Taking the limit as  $\Delta z$  approaches zero results in

$$\frac{Q}{AK_L a} \lim_{\Delta z \rightarrow 0} \left[ \frac{C_b(z + \Delta z) - C_b(z)}{\Delta z} \right] = \frac{Q}{AK_L a} \frac{dC_b}{dz} = [C_b(z) - C_s^*(z)] \quad (14-38)$$

Separating variables in Eq. 14-39 results in

$$\frac{Q}{AK_L a} \int_{C_e}^{C_0} \frac{dC_b}{C_b - C_s^*} = \int_0^L dz = L \quad (14-39)$$

where  $L$  = height of packed tower,  $\text{m}$

$C_0$  = influent liquid-phase concentration,  $\text{mg/L}$

$C_e$  = treatment objective,  $\text{mg/L}$

#### RELATING CONCENTRATION AT AIR–WATER INTERFACE TO CONCENTRATION IN BULK LIQUID

To solve Eq. 14-39,  $C_s^*$  needs to be expressed in terms of  $C_b$ . The following relationship, obtained by using the definition of  $C_s^*$  and the operating line, can be used:

$$C_s^* = \frac{Y_b}{H_{YC}} = \frac{Y_b(z)}{H_{YC}} \quad (14-40)$$

where  $Y_b$  = bulk gas-phase concentration,  $Y_b(z)$ ,  $\text{mg/L}$

Substituting Eq. 14-25 into Eq. 14-40 yields the desired result:

$$C_s^* = \frac{Y_b}{H_{YC}} = \frac{(Q/Q_a)(C_b - C_e)}{H_{YC}} \quad (14-41)$$

where  $Q_a$  = air flow rate, m<sup>3</sup>/s

#### DETERMINATION OF TOWER HEIGHT

Substituting Eq. 14-41 into Eq. 14-39 results in the following:

$$L = \frac{Q}{AK_L a} \int_{C_e}^{C_0} \frac{dC_b}{C_b [1 - (Q/Q_a)/H_{YC}] + C_e (Q/Q_a)/H_{YC}} \quad (14-42)$$

$$= \frac{Q}{AK_L a} \left[ \frac{1}{1 - (Q/Q_a)/H_{YC}} \right] \ln \left[ C_b \left( 1 - \frac{Q/Q_a}{H_{YC}} \right) + C_e \left( \frac{Q}{Q_a} \right) / H_{YC} \right] \Big|_{C_e}^{C_0} \quad (14-43)$$

$$= \frac{Q}{AK_L a} \left[ \frac{1}{1 - (Q/Q_a)/H_{YC}} \right] \ln \left[ \frac{C_0 + (C_e - C_0)(Q/Q_a)/H_{YC}}{C_e} \right] \quad (14-44)$$

Additional details on the development of the design equation for countercurrent packed-tower aeration may be found in the literature (Ball and Edwards, 1992; Ball et al., 1984; Cummins and Westrick, 1983; Dzombak et al., 1993; Gross and TerMaath, 1985; Hand et al., 1986; Kavanaugh and Trussell, 1980, 1981; McKinnon and Dyksen, 1984; Roberts and Levy, 1985; Roberts et al., 1985; Sherwood and Hollaway, 1940; Singley et al., 1980, 1981; Treybal, 1980; Umphres et al., 1983).

#### *Expressing tower height in terms of stripping factor*

Equation 14-44 can be further simplified using the definition of the stripping factor,  $S = (Q_a/Q)H_{YC}$  (see Eq. 14-26):

$$L = \frac{Q}{AK_L a} \left[ \frac{1}{1 - (1/S)} \right] \ln \left[ \frac{(1/S)(C_e - C_0) + (C_0)}{C_e} \right] \quad (14-45)$$

$$= \frac{Q}{AK_L a} \left( \frac{S}{S - 1} \right) \ln \left[ \frac{(C_e - C_0) + S(C_0)}{SC_e} \right] \quad (14-46)$$

The design equation for packed-tower aeration is given by

$$L = \frac{Q}{AK_L a} \left[ \frac{S}{(S - 1)} \right] \ln \left[ \frac{1 + (C_0/C_e)(S - 1)}{S} \right] \quad (14-47)$$

where  $L$  = packed-tower height, m

$A$  = cross-sectional area of packed tower, m<sup>2</sup>

$K_L a$  = overall liquid-phase mass transfer rate constant, 1/s

$S$  = stripping factor, dimensionless

$C_0$  = influent liquid-phase concentration, mg/L

$C_e$  = treatment objective, mg/L

*Expressing tower height in terms of transfer units*

In packed-tower aeration, the tower length is often defined as

$$L = \text{HTU} \times \text{NTU} \quad (14-48)$$

where HTU = height of transfer unit, m

NTU = number of transfer units or number of equilibrium stages

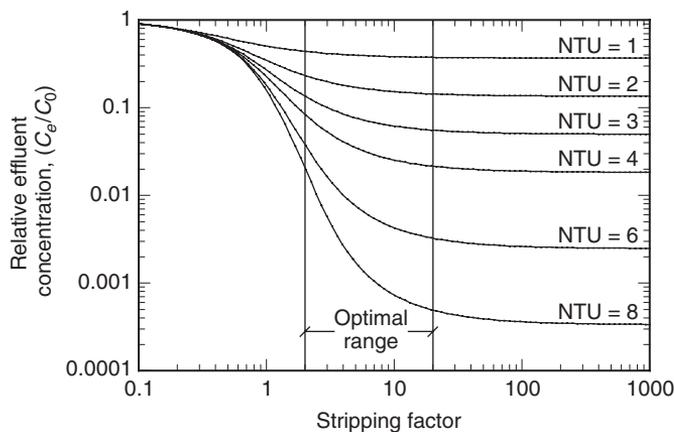

With additional algebraic rearranging, the HTU and NTU are defined as

$$\text{HTU} = \frac{Q}{AK_L a} \quad (14-49)$$

$$\text{NTU} = \frac{S}{S-1} \ln \left[ \frac{1 + (C_0/C_e)(S-1)}{S} \right] \quad (14-50)$$

The height of a transfer unit is determined by the superficial velocity ( $Q/A$ ) divided by the overall mass transfer rate constant. For packed towers, the height of a transfer unit is a measure of the stripping effectiveness of particular packings for a given stripping process. Packing that is typically smaller in size has higher specific surface area causing more efficient transfer of solute from one phase to another, thereby increasing  $K_L a$  and decreasing the HTU. The HTU and tower length will decrease as the superficial velocity decreases or the rate of mass transfer increases.

The number of transfer units can be thought of as a measure of the difficulty of stripping a solute from the liquid to the gas phase. The more difficult it is to strip the solute, the more NTUs needed to achieve a given removal efficiency. The number of transfer units in a packed column can be determined from Fig. 14-18, which is a plot of numerous solutions of Eq. 14-50. For a given  $S$ , the removal efficiency increases with increasing

**Figure 14-18**  
Dependence of relative effluent concentration on NTU and stripping factor.

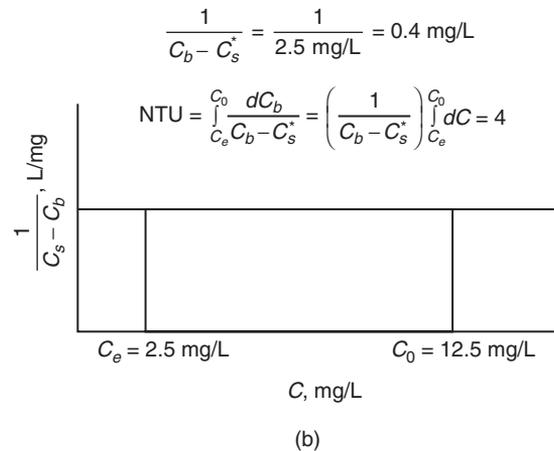

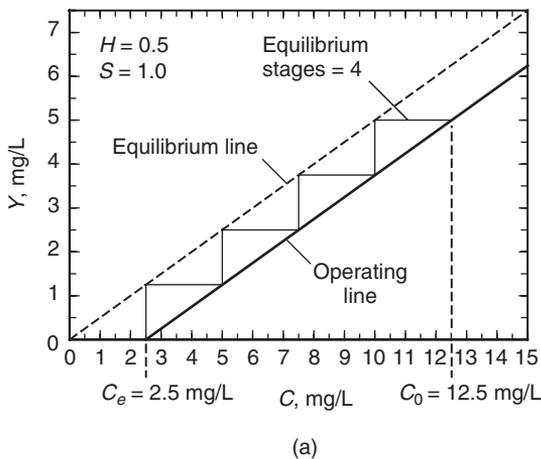

NTU (or number of hypothetical completely mixed tanks). In addition, for a given removal efficiency, increasing  $S$  or the air-to-water ratio will decrease the NTU required. As shown on Fig. 14-18, the optimal range for the stripping factor might be considered between 2 and 20 because high removal efficiency is not possible at  $S$  less than 1, and no additional improvements in removal occurs at values of  $S$  greater than about 20. The best efficiency point for minimum power requirements and tower volume tends to occur at an air-to-water ratio of 3.5 times the minimum air-to-water ratio required for stripping, which would correspond to a low value of the stripping factor (Hand et al., 1986).

The NTU concept bridges the gap between continuous fluid contact and stage operation (see discussion in Chap. 7). For the hypothetical driving force shown on Fig. 14-19a, four equilibrium countercurrent stages would be required to meet an effluent concentration of 2.5 mg/L for an influent concentration of 12.5 mg/L. The stripping factor and Henry's constant for this situation are 1.0 and 0.5, respectively.

The operating and equilibrium lines are parallel, and  $C_b - C_s^*$  differs by exactly 2.5 mg/L, resulting in exactly four equilibrium stages. The NTU for continuous contact can be determined from this equation and the integration of  $1/(C_b - C_s^*)$ , which is shown on Fig. 14-19b:

$$NTU = \int_{C_e}^{C_0} \frac{dC_b}{C_b - C_s^*} \tag{14-51}$$

where  $C_s^* = C_s^*(z)$  represents the liquid-phase concentration at the air-water interface in equilibrium with  $Y_b(z)$  (see Eq. 14-41) in milligrams per liter and  $C_b = C_b(z)$ , which is defined above.

**Figure 14-19**

(a) Determination of the number of equilibrium stages (NTU) using an operating line diagram for a packed tower. (b) Sample integration to determine the number of transfer units (NTU).

In this case, the NTU for equilibrium stages and continuous contact are equal. In general, this will not be true, but this does establish the relationship between NTU and the number of equilibrium tanks in series. The HTU is the height of one equivalent stage at equilibrium.

## 14-5 Analysis and Design of Packed-Tower Air Stripping

---

The two main design categories for packed-tower air stripping are (1) modifications to existing towers (rating analysis) and (2) designing new towers (design analysis). Modifications are made to existing towers to either treat greater volumes of water or modify constituent removal (e.g., lower levels, different constituents). Process efficiency may be improved by increasing the air flow rate, decreasing the water flow rate, replacing the packing with a more efficient packing type, or increasing the packed-tower height. Designing new towers includes the selection of packing type, air-to-water ratio, gas pressure drop, and operational flexibility.

Because packed-tower analysis involves repetitive calculations and the opportunity for introducing errors, commercially available software is commonly used to evaluate the impact of process variables on process performance. Software design tools typically contain the design equations, Henry's constants, mass transfer correlations, databases for many commercially available packing types, and physical properties of many VOCs that have been encountered in water supplies. In addition, graphical user interfaces make the software user friendly (Dzombak et al., 1993; Hokanson, 1996).

Packed-tower air stripping is analyzed in this section including (1) determination of properties required to calculate packed-tower height, (2) description of process variables, and (3) representation of the equations applicable to design versus rating analysis of packed towers. The following design considerations for packed-tower air stripping are also discussed: (1) design variables, (2) design approach, and (3) factors influencing packed-tower performance.

To determine the packed-tower height as described above, the following properties are needed: (1) gas pressure drop, (2) cross-sectional area of the tower, and (3) mass transfer rate constant. Determination of the properties required to calculate packed-tower height is discussed below.

### **GAS PRESSURE DROP**

The gas pressure drop in packed columns is an important design and operational parameter because the electrical costs of the blower account for a significant fraction of the operational costs. Consequently, it is important to operate at a low gas pressure drop to minimize the blower costs. Methods used to determine the gas pressure drop through the packing includes: pilot

**Properties  
Needed to  
Determine  
Packed-Tower  
Height**

and full-scale data collection, manufacturer's pressure drop specifications, and generalized Eckert pressure drop curves. Pressure drop data obtained from pilot and full-scale testing is the best way to determine the operating gas pressure drop. However, in many instances engineers use software programs and spreadsheets to design these systems because much of the design information is known or can be easily calculated.

Manufacturers provide gas pressure drop information on most all of their packing materials, which can be used to determine the pressure drop through the packing. The pressure drop of gas rising countercurrent to liquid flowing through a packed tower typically follows the pattern illustrated on Fig. 14-20. This pressure drop data is for Jaeger 3.5-in. nominal diameter Tripack plastic packing. The pressure drop per unit depth of packing is typically plotted in terms of a C factor, which is defined by the following equation:

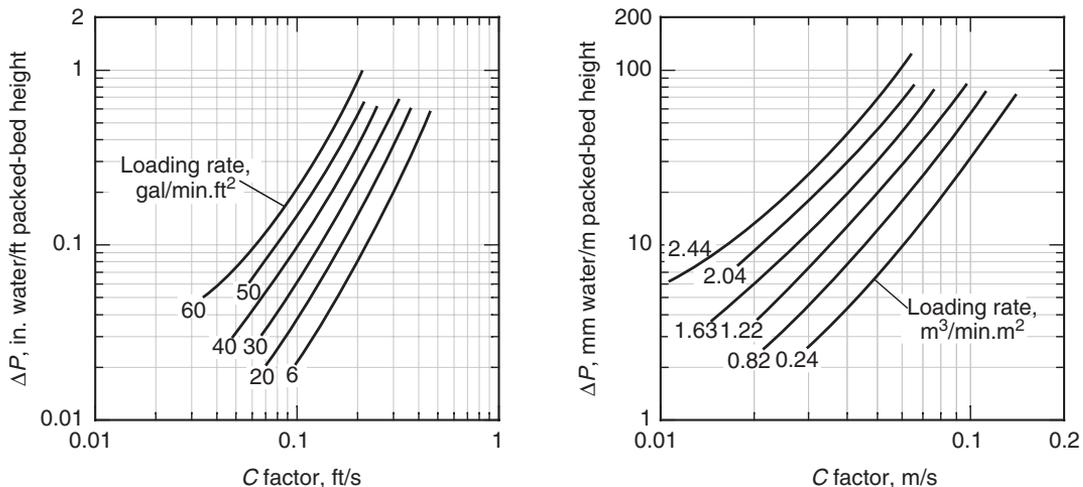

$$C \text{ factor} = V_S \left( (\rho_L - \rho_g) / (\rho_g) \right)^{0.5} \quad (14-52)$$

where  $V_S$  = superficial gas velocity, m/s

$\rho_g$  = gas density, kg/m<sup>3</sup>

$\rho_L$  = liquid density, kg/m<sup>3</sup>

C factor is the density-corrected superficial gas velocity through the column packing and describes the balance between the gas momentum force, which acts to entrain bundles of liquid droplets, and the gravity force, which resists the upward entrainment of water (Kister et al., 2007). Given

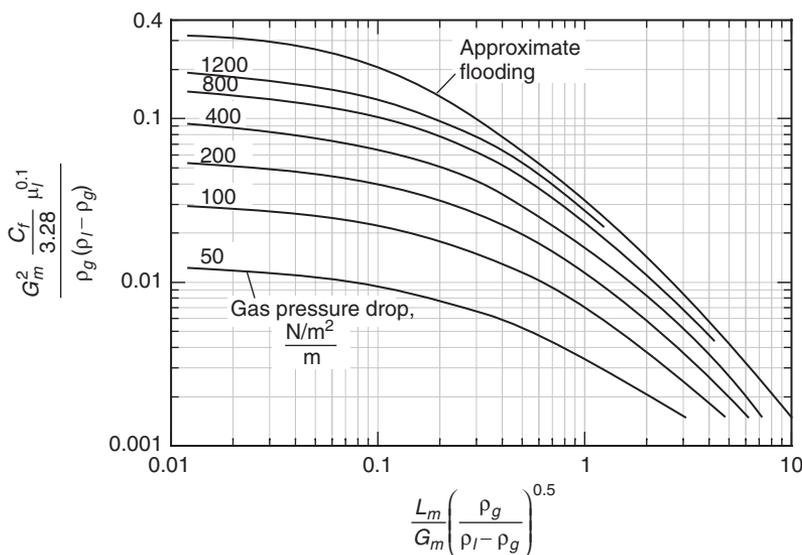

**Figure 14-20**

Gas pressure drop curves as a function of C factor for 3.5-in. nominal diameter plastic tripacks (Adapted from Jaeger Products, Brochure 600).

the temperature, packed-tower area, packing height, gas and liquid loading rates, Fig. 14-20 can be used to determine the pressure drop across the packing material. Manufacturers typically supply pressure drop information on their various packing materials.

When manufacturers data is not available, a common method of estimating the gas pressure drop through random packing in towers is the use of the generalized Eckert pressure drop correlation (see Fig. 14-21). The Eckert correlation relates the gas pressure drop to the capacity parameter on the ordinate ( $y$  axis) as a function of the flow parameter on the abscissa ( $x$  axis). For high gas loading rates, entrainment of the liquid by the rising gas can occur, characterized by a sudden rapid increase in the gas pressure drop, and eventually the column will become a flooded contactor because of the back pressure caused by the rising gas. However, as discussed above, most all air-stripping applications operate at low gas pressure drops to minimize energy costs associated with the blower operation and flooding is never a problem.

The Eckert correlation shown in Fig. 14-21 was developed based on data for packings such as small intalox saddles, rashig, and pall rings. Incorporated in the capacity parameter on the ordinate scale is an empirical parameter characteristic of the shape, size, and material property of the packing type and is called the packing factor ( $C_f$ ).  $C_f$  has units of inverse length and is used to relate the packing type to the relative gas pressure drop through the packing in the tower. Figure 14-12 displays  $C_f$  values for several commonly used plastic packing types. Since  $C_f$  is incorporated in the numerator of the capacity parameter on the ordinate scale, packing

**Figure 14-21** Generalized Eckert gas pressure drop and liquid and gas loading correlation in SI units for random packed tower. The coefficient 3.28 is a conversion factor when the packing factor in SI units ( $\text{m}^{-1}$ ) is used because the Eckert diagram was originally drawn in English units. (Adapted from Eckert, 1961; Treybal, 1980).

materials with a higher  $C_f$  value will have a higher gas pressure drop than packing materials with a lower  $C_f$  value. In general, the gas pressure drop will increase with increasing packing factor.

The practical operating range for packed towers is between abscissa ( $x$  axis) values of 0.02 and 4.0 on the generalized Eckert pressure drop curves (see Fig. 14-21). For abscissa values greater than 4, large water loading rates can reduce the water–air contact area provided by the packing surface and inhibit proper airflow through the column, causing a decrease in removal efficiency. Similarly, high air flow rates (abscissa values less than about 0.02) can cause entrained water in the tower as well as channeling of the air through the tower. For situations where high air flow rates are required for high removal efficiencies (>95 percent), it is important to provide an even air inlet distribution at the bottom of the tower (Thom and Byers, 1993). Towers operating in the regions described above may require additional packing depth to compensate for efficiency reductions.

For an air–water system at 20°C and 1 atm and  $S$  value of 3, the dimensionless Henry's constants can only range from about 0.0021 to 0.42, corresponding to an abscissa between 0.02 and 4 on the Eckert curves. Thus, use of Fig. 14-21 for stripping tower design is restricted, and pilot studies are recommended for tower design when the abscissa values are greater than 4, unless manufacturer's data on gas pressure drop applies in that higher range. Nonvolatile compounds with Henry's constants below 0.0021 should not be used as the basis for a packed-tower aeration design given the difficulty of their removal in the air-stripping process.

In summary, the best method for evaluating gas pressure drop for a given design is from pilot or full-scale studies. If these studies are not available, the next best way would be to use manufacturer's data for gas pressure drop, followed by the use of the Eckert curves. The Eckert curves could be applied initially to estimate the tower diameter followed by the use of the manufacturer's data to determine the actual pressure drop for the given tower diameter.

#### CROSS-SECTIONAL AREA

The cross-sectional area of a packed tower can be estimated from the generalized Eckert pressure drop curves shown on Fig. 14-21 (see above discussion of gas pressure drop). The gas loading rate, liquid loading rate, and tower area may be determined from Fig. 14-21 using the following procedure:

1. Specify the following design parameters:
  - a. Packing factor for the media (see Fig. 14-12)
  - b. Air-to-water ratio [typically 3.5 times  $(Q_a/Q)_{\min}$ ]
  - c. Gas pressure drop (typically 50 N/m<sup>2</sup>/m)

2. Determine the value on the  $x$  axis on the Eckert curve shown on Fig. 14-21:

$$x = \left( \frac{1}{G_m/L_m} \right) \left( \frac{\rho_g}{\rho_l - \rho_g} \right)^{0.5} \quad (14-53)$$

where  $x$  = value on  $x$  axis on Eckert curve

$G_m$  = air mass loading rate,  $\text{kg}/\text{m}^2 \cdot \text{s}$

$L_m$  = water mass loading rate,  $\text{kg}/\text{m}^2 \cdot \text{s}$

$\rho_g$  = air density,  $\text{kg}/\text{m}^3$

$\rho_l$  = water density,  $\text{kg}/\text{m}^3$

The value of  $G_m/L_m$  can be determined knowing the air-to-water ratio, water density, and air density:

$$\frac{G_m}{L_m} = \left( \frac{Q_a}{Q} \right) \left( \frac{\rho_g}{\rho_l} \right) \quad (14-54)$$

3. Graphically determine the numerical value  $y$  on the  $y$  axis on the Eckert curve shown on Fig. 14-21 knowing the gas pressure drop and  $x$ .
4. Determine the gas loading rate based on the following relationship for the  $y$ -axis value on the Eckert curve shown on Fig. 14-21:

$$y = \frac{G_m^2 (C_f/3.28) \mu_l^{0.1}}{\rho_g (\rho_l - \rho_g)} \quad (14-55)$$

Rearrange Eq. 14-55 and solve for  $G_m$ :

$$G_m = \left[ \frac{y \rho_g (\rho_l - \rho_g)}{(C_f/3.28) \mu_l^{0.1}} \right]^{0.5} \quad (14-56)$$

where  $y$  = numerical value on  $y$  axis of Eckert curve determined in step 3

$C_f$  = packing factor,  $\text{m}^{-1}$

$\mu_l$  = dynamic viscosity of water,  $\text{kg}/\text{m} \cdot \text{s}$

5. Determine the water mass loading rate based on the following relationship:

$$L_m = \frac{G_m}{(Q_a/Q) (\rho_g/\rho_l)} \quad (14-57)$$

6. Determine the cross-sectional area of the packed tower based on the following relationship:

$$A = \frac{Q \rho_l}{L_m} \quad (14-58)$$

where  $A$  = cross-sectional area of packed tower,  $\text{m}^2$

$Q$  = water flow rate,  $\text{m}^3/\text{s}$

Correlations describing the Eckert pressure drop curves to predict gas loading rate and tower area were fit by Cummins and Westrick (1983). The Eckert pressure drop correlations are useful for performing packed-tower aeration design calculations using spreadsheets or computer programs, but the correlations are beyond the scope of this book.

### Example 14-4 Diameter, area, and pressure drop of a packed tower

Determine the cross-sectional area and tower diameter for a packed-tower design based on 1,2-dichloropropane (DCP) at 10°C for a water flow rate  $Q$  of 0.1 m<sup>3</sup>/s (1585 gal/min). The basis for design is given by the operating air-to-water ratio of 60 (see Example 14-3), gas pressure drop  $\Delta P/L = 50 \text{ N/m}^2 \cdot \text{m}$ , and the 8.9-cm (3.5-in.) plastic tripacks. The physical properties of air and water at 10°C are as follows: water density  $\rho_l = 999.7 \text{ kg/m}^3$ , water viscosity  $\mu_l = 1.307 \times 10^{-3} \text{ kg/m} \cdot \text{s}$ , and air density,  $\rho_g = 1.247 \text{ kg/m}^3$  (see Apps. B and C). The packing factor from Fig. 14-12,  $C_f$ , for 8.9-cm (3.5-in.) plastic tripacks is 39.0 m<sup>-1</sup>. The dimensionless Henry's law constant of DCP is  $H_{Y_C,DCP} = 0.0525$  (see Table 14-3).

#### Solution

- Specify the packing factor, air-to-water ratio, and gas pressure drop.
  - Packing factor*: Given in problem statement:

$$C_f = 39 \text{ m}^{-1}$$

- Air-to-water ratio*: Determined in Example 14-3 for 90 percent removal:

$$\left(\frac{Q_a}{Q}\right)_{\text{DCP}} = 60$$

- Gas pressure drop*: Given in problem statement:

$$\frac{\Delta P}{L} = 50 \text{ N/m}^2 \cdot \text{m}$$

- Determine the value on the  $x$  axis on the Eckert curve shown on Fig. 14-21:
  - Determine  $G_m/L_m$  using Eq. 14-54:

$$\begin{aligned} \frac{G_m}{L_m} &= \left(\frac{Q_a}{Q}\right) \left(\frac{\rho_g}{\rho_l}\right) = 60 \left(\frac{1.247}{999.7}\right) \\ &= 0.075 \text{ kg air/kg water} \end{aligned}$$

b. Determine  $x$  using Eq. 14-53:

$$x = \left[ \frac{1}{(G_m/L_m)} \right] \left( \frac{\rho_g}{\rho_l - \rho_g} \right)^{0.5} = \left( \frac{1}{0.075} \right) \left( \frac{1.247}{999.7 - 1.247} \right)^{0.5}$$

$$= 0.47$$

3. Graphically determine the numerical value  $y$  on the  $y$  axis on the Eckert curve shown on Fig. 14-21 knowing the gas pressure drop and  $x$ . At the location on Fig. 14-21 where  $x = 1.13$  and  $\Delta P/L = 50 \text{ N/m}^2 \cdot \text{m}$ ,

$$y = 0.005$$

4. Determine the gas loading rate based on the relationship for the  $y$ -axis value on the Eckert curve shown on Fig. 14-21. Solve for  $G_m$  using Eq. 14-56:

$$G_m = \left[ \frac{y \rho_g (\rho_l - \rho_g)}{(C_f/3.28) \mu_l^{0.1}} \right]^{0.5} = \left[ \frac{0.005(1.247)(999.7 - 1.247)}{(39.0/3.28)(1.307 \times 10^{-3})^{0.1}} \right]^{0.5}$$

$$= 1.01 \text{ kg/m}^2 \cdot \text{s}$$

5. Determine the water mass loading rate using Eq. 14-57:

$$L_m = \frac{G_m}{(Q_a/Q)(\rho_g/\rho_l)} = \frac{1.01 \text{ kg/m}^2 \cdot \text{s}}{(60)(1.247 \text{ kg/m}^3/999.7 \text{ kg/m}^3)}$$

$$= 13.5 \text{ kg/m}^2 \cdot \text{s}$$

6. Determine the cross-sectional area of the packed tower using Eq. 14-58:

$$A = \frac{Q}{L_m} = \frac{(0.1 \text{ m}^3/\text{s})(999.7 \text{ kg/m}^3)}{13.5 \text{ kg/m}^2 \cdot \text{s}}$$

$$= 7.4 \text{ m}^2$$

7. Determine the tower diameter assuming a circular tower area.

$$D = \sqrt{\frac{4A^2}{\pi}} = \sqrt{\frac{4(7.4 \text{ m}^2)}{\pi}} = 3.07 \text{ m}$$

Standard tower sizes of 1.22 m (4 ft), 1.83 m (6 ft), 2.44 m (8 ft), 3.048 m (10 ft), 3.66 m (12 ft), and sometimes 4.27 m (14 ft) in diameter are usually the norm for most packed-tower equipment manufacturers. For this case we will use a 3.048-m (10-ft) diameter tower. For a tower diameter of 3.048 m, the operating values of  $G_m$  and  $L_m$  are  $1.02 \text{ kg/m}^2 \cdot \text{s}$  and  $13.7 \text{ kg/m}^2 \cdot \text{s}$ , respectively.

8. Determine the tower gas pressure drop based on the manufacturer's data presented in Fig. 14-20.

a. Calculate the C-factor from Eq. 14-52,

$$\begin{aligned} \text{C factor} &= V_S ((\rho_L - \rho_g)/(\rho_g))^{0.5} \\ &= \left( \frac{1.02 \text{ kg/m}^2 \cdot \text{s}}{1.247 \text{ kg/m}^3} \right) (999.7 - 1.247/1.247)^{0.5} \\ &= 0.03 \text{ m/s} \end{aligned}$$

b. Calculate the liquid loading rate in  $\text{L/m}^2 \cdot \text{min}$  for a tower diameter of 3.048 m (10 ft):

$$\frac{Q}{A} = \frac{0.1 \text{ m}^3/\text{s}}{\pi (3.048 \text{ m})^2/4} \frac{1000 \text{ L}}{\text{m}^3} \frac{60 \text{ s}}{\text{min}} = 822 \frac{\text{L}}{\text{m}^2 \cdot \text{min}}$$

c. Determine the relative head loss through the packing using Fig. 14-20.

For a C factor of 0.03 m/s and a volumetric liquid loading of  $822 \text{ L/m}^2 \cdot \text{min}$ , the head loss per unit length of packing is about 4.5 mm water per m of packing height or  $44 \text{ N/m}^2 \cdot \text{m}$ . In this case the gas pressure drop determined from the Eckert correlation is in close agreement with the manufacturer's gas pressure drop data.

### Comment

If multiple compounds are to be removed, the compound with the lower Henry's law constant in the water to be treated is used as the basis for determining the cross-sectional area of the tower, because it will require the highest air-to-water ratio to have a stripping factor in the optimal range.

### MASS TRANSFER RATE CONSTANT

The general equation for calculating the overall mass transfer rate constant  $K_L a$  in aeration processes was derived earlier based on the two-film theory of mass transfer in Chap. 7:

$$\frac{1}{K_L a} = \frac{1}{k_l a} + \frac{1}{H_{YC} k_g a} \quad (7-88)$$

where  $K_L a$  = overall mass transfer rate constant,  $\text{s}^{-1}$

$k_l$  = liquid-phase mass transfer coefficient,  $\text{m/s}$

$k_g$  = gas-phase mass transfer coefficient,  $\text{m/s}$

$a$  = area available for mass transfer divided by vessel volume,  $\text{m}^2/\text{m}^3$

The  $K_La$  values for packed towers can be determined by performing pilot plant studies or from packing manufacturers and previously reported field studies. They can also be estimated from mass transfer correlations.

*Determination by pilot plant studies*

A pilot plant study is the preferred way to determine  $K_La$  for a given VOC in water, but, as discussed below, fairly accurate estimates can be made from the correlations. Pilot-scale packed towers range in size from 2 to 6 m (6.5 to 20 ft) in height and 0.3 to 0.6 m (1 to 2 ft) in diameter. The column diameter used will depend upon the desired packing size. It is generally recommended that ratios of column diameter to nominal packing diameter be greater than 10:1 (>15:1 desired) to minimize error caused by channeling of the water down the walls of the column (Treybal, 1980). It is also recommended that the packed-column height-to-diameter ratio be greater than 1:1 to provide for proper liquid distribution (Treybal, 1980; Roberts et al., 1985).

Equation 14-48 is used in conjunction with pilot plant data to determine  $K_La$  for a given VOC. The value of  $K_La$  is based on VOC removal due to the packed height portion of the tower. However, VOC removal also occurs as the water contacts the air above the packing at the top of the tower and at the bottom as the water falls into the clearwell below the packing. This incidental additional removal is sometimes referred to as “end effects” (Umphres et al., 1983). To determine the  $K_La$ ,  $NTU_{\text{measured}}$  is plotted versus the packing height and the  $NTU$  value corresponding to zero packing depth is referred to as  $NTU_{\text{end effects}}$  (dimensionless):

$$NTU_{\text{measured}} = \left( \frac{1}{HTU} \right) \times Z + NTU_{\text{end effects}} \quad (14-59)$$

where  $Z$  = distance from top of packing to sample port location  
along packed portion of tower, L

For a given water and air loading rate, aqueous-phase concentration measurements are evaluated at the influent, effluent, and various sample port locations along the packed column and  $NTU_{\text{measured}}$  is calculated from Eq. 14-50. The plot of  $NTU_{\text{measured}}$  versus  $Z$  should result in a straight line (Eq. 14-59), and  $K_La$  is determined from the slope ( $1/HTU$ ). Experimentally determined  $K_La$  values can be correlated as a function of water loading rate for several air-to-water ratios that would be expected during operation of the full-scale column. The full-scale packed-tower height can be determined from  $K_La$  and the design equations.

A full-scale packed-tower height calculated using a  $K_La$  value determined from a pilot study is generally conservative. For a given packing size,  $K_La$  values generally increase as the tower diameter increases (Roberts et al., 1985). The increase is caused by minimizing channeling of the water down the inside of the column walls (wall effects), which occurs to a greater degree in small columns. The VOC removal rate is lower along the walls

**Table 14-6**Packed-tower air-stripping pilot plant studies that determined  $K_L a$  values for several VOCs

Water Matrix	VOCs	Reference
Sacramento–San Joaquin Delta water in northern California	Chloroform, dibromochloromethane, bromodichloromethane, bromoform	Umphres et al. (1983)
Potomac tidal fresh estuary water mixed with nitrified effluent wastewater	Carbon tetrachloride, tetrachloroethene, trichloroethene, chloroform, bromoform	Ball et al. (1984)
City of Tacoma, WA, groundwater	1,1,2,2-Tetrachloroethane, trans-1,2-dichloroethene, trichloroethene, tetrachloroethene	Byers and Morton (1985)
Laboratory-grade organic free water	Oxygen, tetrachloroethene, Freon-12, 1,1,1-trichloroethane, trichloroethene, carbon tetrachloride	Roberts et al. (1985)
North Miami Beach, FL, groundwater and City of Gainesville, FL, groundwater	Chloroform	Bilello and Singley (1986)
Village of Brewster, NY, groundwater	cis-1,2-Dichloroethene, trichloroethene, tetrachloroethene	Wallman and Cummins (1986)
Gloucester, Ottawa, Ontario, groundwater	Chloroform, toluene, 1,2-dichloroethane, 1,1-dichloroethane, trichloroethene, diethyl ether	Lamarche and Droste (1989)
Miami, FL, tap water	Bromoform, bromodichloromethane, chloroform, dibromochloromethane, carbontetrachloride, tetrachloroethene, trichloroethene, 1,1,1-trichloroethane, chlorobenzene, <i>m</i> -dichlorobenzene, <i>m</i> -xylene, toluene	Narbaitz et al. (2002)

of the column than within the packing because the air/water contact time, surface area, and mixing are smaller. As the tower diameter increases, the percentage of flow down the walls of the column decreases, minimizing the wall effects.

Based on the results from several packed-tower field studies (see Table 14-6), experimentally determined  $K_L a$  values for several VOCs and various contaminated water sources can be obtained. The  $K_L a$  values reported in these studies can be used to design towers if the operating conditions (temperature, water and air loading rate) and packing type and size are identical.

#### *Estimation with empirical correlations*

From an evaluation of available mass transfer models for packed-tower aeration (Onda et al., 1968; Sherwood and Hollaway, 1940; Shulman et al., 1955), it has been found that the Onda model or a modification of it provides the best predictions of mass transfer coefficients (Lamarche and Droste, 1989; Djebbar and Narbaitz, 1995, 1998). For several VOCs, it has been demonstrated that  $K_L a$  values obtained from the Onda correlations compare favorably to pilot plant data using smaller packing sizes (Cummins

and Westrick, 1983; Roberts et al., 1985). The Onda correlations for determination of the liquid-phase mass transfer coefficient ( $k_l$ ), gas-phase mass transfer coefficient ( $k_g$ ), and specific interfacial area ( $a$ ) are presented in Chap. 7. The packing properties needed for the Onda correlations are shown in Fig. 14-12. The Onda correlations were developed for nominal packing sizes up to 5.1 cm (2 in.).

Studies have found that the Onda correlations for mass transfer coefficients overestimate the  $K_L a$  values for larger packing sizes [greater than 2.5 cm (1 in.) nominal diameter] (Djebbar and Narbaitz, 1995; Lenzo et al., 1990; Thom and Byers, 1993; Dvorak et al., 1996). Djebbar and Narbaitz (1998) modified the Onda model in an effort to improve its predictive capabilities. The modified Onda model included recalibration to a new extensive set of mass transfer data that included adjustments to the constants and exponents in the model, incorporation of an additional dimensionless parameter ( $L/d_p$ ) into the liquid-phase mass transfer correlation  $k_l$ , and incorporation of the gas-phase Reynolds number ( $RE_g$ ) and the packing efficiency number ( $a_i d_p$ ) into the interfacial area equation. As compared to the Onda model, the modified Onda model reduced the average absolute error to 21 percent as compared to 30 percent for the Onda model, which is about a 30 percent reduction in the error. The modified Onda model requires a trial-and-error method for design because an initial guess of the tower length is needed to calculate the  $k_l$ . More recently Djebbar and Narbaitz (2002) used neural network nonparametric approach to analyze gas and liquid mass transfer data from packed tower technology to predict  $K_L a$  values. They were able to improve upon the predictions for  $K_L a$  with an average absolute error of less than 19 percent, which is perhaps the best prediction to date. Unfortunately, it would be too time consuming for design engineers to use this technique to obtain  $K_L a$  values.

At present, there is no correlation that can be used to predict  $K_L a$  within  $\pm 10$  percent for larger packing sizes. Thus, based on the literature cited above, it is recommended that a safety factor of 0.70 (design  $K_L a$ /Onda  $K_L a$ ) be applied for packing diameters greater than 2.5 cm (1 in.) as a conservative estimate of packing height required.

### Example 14-5 Mass transfer coefficients in packed-tower aeration

Determine the mass transfer coefficients for DCP and PCE at 10°C in packed-tower aeration for the air mass loading rate and water mass loading rate determined in Example 14-4 using the Onda correlations and a safety factor of 0.70 (design  $K_L a$ /Onda  $K_L a$ ) for 8.9 cm (3.5 in.) plastic tripacks. The water flow rate,  $Q$ , is 0.1 m<sup>3</sup>/s (1585 gal/min). The physical properties of air and water from Apps. B and C at 10°C are water density  $\rho_l = 999.7$

kg/m<sup>3</sup>, the dynamic viscosity of water  $\mu_l = 1.307 \times 10^{-3}$  kg/m · s, water surface tension  $\sigma = 0.0742$  N/m, air density  $\rho_g = 1.247$  kg/m<sup>3</sup>, and air viscosity  $\mu_g = 1.79 \times 10^{-5}$  kg/m · s. The properties of the packing material from Fig. 14-12 are nominal diameter of packing  $d_p = 0.0889$  m, packing factor  $C_f = 39.0$  m<sup>-1</sup>, specific surface area of packing  $a_t = 125.0$  m<sup>2</sup>/m<sup>3</sup>, and critical surface tension of packing  $\sigma_c = 0.033$  N/m. The liquid diffusivity  $D_l$  and gas diffusivity  $D_g$  for DCP and PCE were determined from the Hayduk–Laudie correlation and the Wilke–Lee modification of the Hirschfelder–Bird–Spotz method, respectively, to be equal to  $D_{l,DCP} = 6.08 \times 10^{-10}$  m<sup>2</sup>/s,  $D_{l,PCE} = 5.86 \times 10^{-10}$  m<sup>2</sup>/s,  $D_{g,DCP} = 7.65 \times 10^{-6}$  m<sup>2</sup>/s, and  $D_{g,PCE} = 7.13 \times 10^{-6}$  m<sup>2</sup>/s (see Chap. 7). From Example 14-4, the air loading rate  $G_m$  and water loading rate  $L_m$  are equal to 1.02 and 13.7 kg/m<sup>2</sup> · s, respectively. As obtained in Table 14-3 at 10°C, the dimensionless Henry's law constants of DCP and PCE are  $H_{Y,DCP} = 0.0525$  and  $H_{Y,DCE} = 0.364$ .

### Solution

1. Calculate the specific surface area available for mass transfer  $a_w$ , which is determined from the Onda correlations (see Table 7-5):

$$a_w = a_t \left\{ 1 - \exp \left[ -1.45 \left( \frac{\sigma_c}{\sigma} \right)^{0.75} \left( \frac{L_m}{a_t \mu_l} \right)^{0.1} \left( \frac{L_m^2 a_t}{\rho_l^2 g} \right)^{-0.05} \left( \frac{L_m^2}{\rho_l a_t \sigma} \right)^{0.2} \right] \right\}$$

$$= 125 \left\{ 1 - \exp \left[ \begin{array}{l} -1.45 \left( \frac{0.0330}{0.0742} \right)^{0.75} \left( \frac{13.7}{125.0 \times 1.307 \times 10^{-3}} \right)^{0.1} \\ \times \left( \frac{13.7^2 \times 125.0}{999.7^2 \times 9.81} \right)^{-0.05} \\ \times \left( \frac{13.7^2}{999.7 \times 125.0 \times 0.0742} \right)^{0.2} \end{array} \right] \right\}$$

$$= 67 \text{ m}^2/\text{m}^3$$

2. Calculate the liquid-phase mass transfer coefficient  $k_\ell$  using the Onda correlations (see Table 7-5).
  - a. DCP:

$$k_\ell = 0.0051 \left( \frac{L_m}{a_w \mu_l} \right)^{2/3} \left( \frac{\mu_l}{\rho_l D_l} \right)^{-0.5} (a_t d_p)^{0.4} \left( \frac{\rho_l}{\mu_l g} \right)^{-1/3}$$

$$= 0.0051 \left\{ \left[ \frac{13.7}{67 \times (1.307 \times 10^{-3})} \right]^{2/3} \left[ \frac{1.307 \times 10^{-3}}{999.7 \times (6.08 \times 10^{-10})} \right]^{-0.5} \right. \\ \left. \times (125.0 \times 0.0889)^{0.4} \left[ \frac{999.7}{(1.307 \times 10^{-3}) \times 9.81} \right]^{-1/3} \right\}$$

$$= 1.95 \times 10^{-4} \text{ m/s}$$

b. PCE:

$$k_\ell = 0.0051 \left( \frac{L_m}{a_w \mu_l} \right)^{2/3} \left( \frac{\mu_l}{\rho_l D_l} \right)^{-0.5} (a_t d_p)^{0.4} \left( \frac{\rho_l}{\mu_l g} \right)^{-1/3}$$

$$= 0.0051 \left\{ \left[ \frac{13.7}{67 \times (1.307 \times 10^{-3})} \right]^{2/3} \left[ \frac{1.307 \times 10^{-3}}{999.7 \times (5.87 \times 10^{-10})} \right]^{-0.5} \right. \\ \left. \times (125.0 \times 0.0889)^{0.4} \left[ \frac{999.7}{(1.307 \times 10^{-3}) \times 9.81} \right]^{-1/3} \right\}$$

$$= 1.92 \times 10^{-4} \text{ m/s}$$

3. Calculate the gas-phase mass transfer coefficient  $k_g$  using the Onda correlations (see Table 7-5).

a. DCP:

$$k_g = 5.23 (a_t D_g) \left( \frac{G_m}{a_t \mu_g} \right)^{0.7} \left( \frac{\mu_g}{\rho_g D_g} \right)^{1/3} (a_t d_p)^{-2}$$

$$= 5.23 \left\{ \left[ 125.0 \times (7.65 \times 10^{-6}) \right] \left[ \frac{1.02}{125.0 \times (1.79 \times 10^{-5})} \right]^{0.7} \right. \\ \left. \times \left[ \frac{1.79 \times 10^{-5}}{1.247 \times (7.65 \times 10^{-6})} \right]^{1/3} (125.0 \times 0.0889 \text{ m})^{-2} \right\}$$

$$= 3.63 \times 10^{-3} \text{ m/s}$$

b. PCE:

$$k_g = 5.23 (a_t D_g) \left( \frac{G_m}{a_t \mu_g} \right)^{0.7} \left( \frac{\mu_g}{\rho_g D_g} \right)^{1/3} (a_t d_p)^{-2}$$

$$= 5.23 \left\{ \left[ 125.0 \times (7.13 \times 10^{-6}) \right] \left[ \frac{1.02}{125.0 \times (1.79 \times 10^{-5})} \right]^{0.7} \right. \\ \left. \times \left[ \frac{1.79 \times 10^{-5}}{1.247 \times (7.13 \times 10^{-6})} \right]^{1/3} (125.0 \times 0.0889 \text{ m})^{-2} \right\}$$

$$= 3.46 \times 10^{-3} \text{ m/s}$$

4. Calculate the overall mass transfer rate constant  $K_L a$  based on  $a_w$ ,  $k_l$ , and  $k_g$  from the Onda correlations using Eq. 7–88.

a. DCP:

$$\begin{aligned}\frac{1}{K_L a} &= \frac{1}{k_l a_w} + \frac{1}{k_g a_w H_{YC}} \\ &= \frac{1}{(1.95 \times 10^{-4}) \times 67} + \frac{1}{(3.63 \times 10^{-3}) \times 67 \times 0.0525} \\ \Rightarrow K_L a &= 0.00645 \text{ s}^{-1} \quad (\text{based on Onda correlations})\end{aligned}$$

b. PCE:

$$\begin{aligned}\frac{1}{K_L a} &= \frac{1}{k_l a_w} + \frac{1}{k_g a_w H_{YC}} \\ &= \frac{1}{(1.92 \times 10^{-4}) \times 67} + \frac{1}{(3.46 \times 10^{-3}) \times 67 \times 0.364} \\ \Rightarrow K_L a &= 0.011 \text{ s}^{-1} \quad (\text{based on Onda correlations})\end{aligned}$$

5. Calculate actual  $K_L a$  applying a safety factor (SF) of 0.70 on the Onda  $K_L a$ .

a. DCP:

$$\begin{aligned}K_L a &= K_L a(\text{Onda}) \times (\text{SF}) = (0.00645 \text{ s}^{-1}) \times 0.70 \\ &= 0.00452 \text{ s}^{-1}\end{aligned}$$

b. PCE:

$$\begin{aligned}K_L a &= K_L a(\text{Onda}) \times (\text{SF})_{K_L a} = (0.011 \text{ s}^{-1}) \times 0.70 \\ &= 0.0077 \text{ s}^{-1}\end{aligned}$$

## Power Requirements

The total operating power for a single air-stripping packed-tower system is the sum of the blower and pump brake power requirements. The blower brake power  $P_{\text{blower}}$  can be determined from the following relationship (Tchobanoglous et al., 2003):

$$P_{\text{blower}} = \left( \frac{G_{\text{me}} R T_{\text{air}}}{\text{MW } n_a \text{ Eff}_b} \right) \left[ \left( \frac{P_{\text{in}}}{P_{\text{out}}} \right)^{0.283} - 1 \right] \quad (14-60)$$

where  $P_{\text{blower}}$  = blower brake power, kW

$\text{Eff}_b$  = blower net efficiency, expressed as decimal fraction, which accounts for both fan and motor on blower

- $G_{me}$  = mass flow rate of air, kg/s  
 $n_a$  = constant used in determining blower brake power,  
 = 0.283 for air  
 $P_{in}$  = inlet air pressure in packed tower (bottom of tower),  
 atm or N/m<sup>2</sup>  
 $P_{out}$  = outlet air pressure in packed tower (top of the tower),  
 usually equal to ambient pressure, atm or N/m<sup>2</sup>  
 $R$  = universal gas constant, 8.314 J/mol · K  
 $T_{air}$  = absolute air temperature, typically assumed equal to  
 $T$ , K (273 + °C)  
 $T$  = absolute water temperature, K (273 + °C)  
 MW = molecular weight of air, 28.97 g/mol

The term  $P_{in}$  refers to the pressure at the bottom of the tower, which is the inlet for the airstream:

$$P_{in} = P_{ambient} + [(\Delta P/L) \times L] + \Delta P_{losses} \quad (14-61)$$

- where  $P_{ambient}$  = ambient pressure, atm or N/m<sup>2</sup>  
 $\Delta P$  = pressure drop caused by packing media, atm or N/m<sup>2</sup>  
 $L$  = packing height, m  
 $\Delta P_{losses}$  = pressure drop by demister, packing support plate,  
 duct work, inlet and outlet of tower, atm or N/m<sup>2</sup>

The pressure drop  $\Delta P_{losses}$  may be estimated by using the empirical constant  $k_p$ , which was determined by fitting full-scale tower data (Hand et al., 1986):

$$\Delta P_{losses} = \left( \frac{Q_a}{A} \right)^2 k_p \quad (14-62)$$

- where  $Q_a$  = volumetric air flow rate, m<sup>3</sup>/s  
 $A$  = tower cross-sectional area, m<sup>2</sup>  
 $k_p$  = empirical constant, 275 N · s<sup>2</sup>/m<sup>4</sup>

The air pressure drop through the demister, packing support plate, duct work, and inlet and outlet of the tower is accounted for in Eq. 14-62. It is assumed that turbulent-flow conditions prevail and most of the losses occur in the tower (i.e., in the packing support plate and the demister).

The pump power requirement can be determined from the equation

$$P_{pump} = \frac{\rho_l Q H g}{Eff_p} \quad (14-63)$$

- where  $P_{pump}$  = power required to pump water to top of tower, W  
 $\rho_l$  = water density, kg/m<sup>3</sup>

$Q$  = water flow rate,  $\text{m}^3/\text{s}$

$H$  = vertical distance from pump to liquid distributor at top of tower, m

$g$  = acceleration due to gravity,  $9.81 \text{ m/s}^2$

$\text{Eff}_p$  = pump efficiency, expressed as fraction

Equation 14-63 only accounts for the additional head required to pump the water to the top of the tower.

### Example 14-6 Power requirements for packed-tower aeration

Determine the total power requirement (blower and pump brake power) and specific energy per unit volume of water treated for a packed tower aeration design removing DCP at  $10^\circ\text{C}$  and 1 atm ( $101,325 \text{ N/m}^2$ ) for a water flow rate of  $0.1 \text{ m}^3/\text{s}$ , a stripping factor of 3.5, and a gas pressure drop of  $50 \text{ (N/m}^2\text{)/m}$ . Assume the blower efficiency is 35 percent ( $\text{Eff}_b = 0.35$ ) and the pump efficiency is 80 percent ( $\text{Eff}_p = 0.80$ ).

From Example 14-4, the air-to-water ratio  $Q_a/Q = 60$  and the tower area  $A = 7.3 \text{ m}^2$  (based on a 3.048-m (10-ft) tower diameter). From Example 14-7, the tower length  $L = 7.8 \text{ m}$ . The water density and air density at  $10^\circ\text{C}$  are  $\rho_l = 999.7 \text{ kg/m}^3$  and  $\rho_g = 1.247 \text{ kg/m}^3$ .

#### Solution

1. Calculate blower power requirements.
  - a. Calculate the air mass flow rate from the volumetric air flow rate.
    - i. Calculate volumetric air flow rate  $Q_a$ :

$$\begin{aligned} Q_a &= \left(\frac{Q_a}{Q}\right) Q = (60)(0.1 \text{ m}^3/\text{s}) \\ &= 6.0 \text{ m}^3/\text{s} \end{aligned}$$

- ii. Calculate the air mass flow rate  $G_{me}$ :

$$\begin{aligned} G_{me} &= Q_a \rho_g = (6.0 \text{ m}^3/\text{s})(1.247 \text{ kg/m}^3) \\ &= 7.48 \text{ kg/s} \end{aligned}$$

- b. Calculate the pressure drop through the demister, the packing support plate, duct work, and inlet and outlet ( $\Delta P_{\text{losses}}$ ) using Eq. 14-62:

$$\begin{aligned} \Delta P_{\text{losses}} &= \left(\frac{Q_a}{A}\right)^2 k_p = \left(\frac{6.0 \text{ m}^3/\text{s}}{7.3 \text{ m}^2}\right)^2 (275 \text{ N} \cdot \text{s}^2/\text{m}^4) \\ &= 186 \text{ N/m}^2 \end{aligned}$$

- c. Calculate the inlet pressure to the packed tower,  $P_{in}$ , using Eq. 14-61:

$$\begin{aligned} P_{in} &= P_{ambient} + \left(\frac{\Delta P}{L}\right)L + \Delta P_{losses} = 101,325 \text{ N/m}^2 \\ &+ \left\{[(50 \text{ N/m}^2)/\text{m}] \times 7.66 \text{ m}\right\} + 186 \text{ N/m}^2 \\ &= 101,894 \text{ N/m}^2 \end{aligned}$$

- d. Calculate the blower brake power  $P_{blower}$  using Eq. 14-60:

$$\begin{aligned} P_{blower} &= \left(\frac{G_{me}RT_{air}}{MW n_a \text{Eff}_b}\right) \left[\left(\frac{P_{in}}{P_{out}}\right)^{n_a} - 1\right] \\ &= \left[\frac{(7.48)(8.314) \times (273 + 10)}{(28.97)(0.283)(0.35)}\right] \left[\left(\frac{101,894}{101,325}\right)^{0.283} - 1\right] \\ &= 9.73 \text{ kW} \end{aligned}$$

2. Calculate pump power requirements  $P_{pump}$  to move the water to the top of the tower using Eq. 14-63:

$$\begin{aligned} P_{pump} &= \frac{\rho_l Q L g}{\text{Eff}_p} \\ &= \left[\frac{(999.7 \text{ kg/m}^3)(0.1 \text{ m}^3/\text{s})(7.8 \text{ m})(9.81 \text{ m/s}^2)}{0.80}\right] \left(\frac{1 \text{ W}}{1 \text{ kg} \cdot \text{m}^2/\text{s}^3}\right) \\ &= 9,561 \text{ W} = 9.56 \text{ kW} \end{aligned}$$

3. Calculate total power requirements  $P_{total}$ :

$$P_{total} = P_{blower} + P_{pump} = 9.56 \text{ kW} + 9.73 \text{ kW} = 19.3 \text{ kW}$$

4. Calculate the specific energy:

$$E = \frac{19.3 \text{ kW}}{(0.1 \text{ m}^3/\text{s})(3600 \text{ s/h})} = 0.0536 \frac{\text{kWh}}{\text{m}^3}$$

There are two types of analyses commonly performed for packed-tower air stripping, termed *design analysis* and *rating analysis*. In a design analysis, it is desired to *size a new packed tower* to exactly meet the treatment objective  $C_{TO}$ . Substituting  $C_{TO} = C_e$  into Eq. 14-47 results in the design equation for packed tower aeration:

$$L = \frac{Q}{AK_L a} \left(\frac{S}{S-1}\right) \ln \left[\frac{1 + (C_0/C_{TO})(S-1)}{S}\right] \quad (14-64)$$

### Design versus Rating Analysis of Packed Towers

where

- $L$  = packed tower height, m
- $Q$  = water flow rate, m<sup>3</sup>/s
- $A$  = cross-sectional area of packed tower, m<sup>2</sup>
- $K_L a$  = overall liquid-phase mass transfer rate constant, s<sup>-1</sup>
- $S$  = stripping factor, dimensionless
- $C_0$  = influent liquid-phase concentration, mg/L
- $C_{TO}$  = treatment objective, mg/L

Estimation of mass transfer rate constant  $K_L a$  and cross-sectional area  $A$  for packed-tower air stripping is described above.

In a rating analysis, the effluent concentrations of various compounds *for an existing tower* can be determined. The following variables are known in a rating analysis: (1) tower height, (2) tower diameter, (3) type of packing, (4) water flow rate, (5) air flow rate, (6) pressure, (7) temperature, (8) influent concentration, and (9) mass transfer coefficient. Knowing these variables, it is possible to determine effluent concentration and gas pressure drop for the tower. The effluent concentration is found by rearranging Eq. 14-47 and solving for effluent concentration  $C_e$ :

$$C_e = \frac{C_0(S - 1)}{S \exp[LK_L a(S - 1)/(Q/A)S] - 1} \quad (14-65)$$

where  $C_e$  = effluent liquid-phase concentration, mg/L

In a rating analysis, the pressure drop for the tower can be calculated using an iterative method based on correlations for the Eckert curves.

## Design Variables

Design variables for packed-tower air stripping include (1) the air-to-water ratio, (2) the gas pressure drop, and (3) the type of packing material. Once the physical properties of the contaminant(s) of interest, the influent concentration(s), treatment objective(s), water, and air properties are known, design parameters can be selected to obtain the lowest capital and operation and maintenance costs.

### AIR-TO-WATER RATIO

It has been shown that air-to-water ratios of approximately 3.5 times the minimum air-to-water ratio provide the minimum tower volume and power requirement, which corresponds to a stripping factor of about 3.5 for a range of Henry's law constants from 0.003 to 0.3 (Hand et al., 1986).

### GAS PRESSURE DROP

A low gas pressure drop should be chosen to minimize the blower power consumption. Packed towers are usually designed to operate with a gas pressure drop well below flooding conditions. Many stripping towers are designed for gas pressure drops of 200 to 400 (N/m<sup>2</sup>)/m of packing depth (0.25 to 0.5 in. H<sub>2</sub>O/ft of packing) (Treybal, 1980). Based on detailed

cost analyses, it has been found that using a lower gas pressure drop between 50 and 100 (N/m<sup>2</sup>)/m and a stripping factor of 3.5 yields the lowest total annual treatment cost for removal of volatile compounds with dimensionless  $H_{YC}$  values greater than 0.05 (Cummins and Westrick, 1983; Dzombak et al., 1993; Hand et al., 1986). Towers have been constructed with gas pressure drops as low as 30 (N/m<sup>2</sup>)/m, but gas pressure drops that are too low may result in very low liquid loading and poor water distribution across the packing, which will reduce the area available for mass transfer and tower performance.

An additional advantage of operating at a low gas pressure drop is that, if the blower is sized conservatively, the air flow rate can be increased to improve removal efficiency without major changes in the process operation. However, the required tower height may sometimes be too large for a particular application (mostly for aesthetic reasons, the local community may object to tall towers). To obtain a smaller tower height for a given removal, the air-to-water ratio can be increased.

#### **TYPE AND SIZE OF PACKING MATERIAL**

The competing requirements of a low gas pressure drop and high surface area available for mass transfer per vessel volume must be weighed when selecting packing because the preferred packing characteristics work against each other as high surface area per volume causes higher gas pressure drop. The surface area per volume and packing factor for commonly available packing materials are reported on Fig. 14-12. For a given type of packing, the packing factor and surface area increase as the size of packing decreases. However, different types of packing can have lower packing factors for the same surface area per volume. For example, the 75-mm (3-in.) saddles and 50-mm (2-in.) tripacks have packing factors of 16 and 15, respectively, and yet the tripacks have 76 percent more surface area per volume because of their unique shape, which is shown on Fig. 14-12. A packing material with a low packing factor and a high specific surface area is desired for optimal tower performance.

Tower volume and power requirements have been compared for a number of packing types and sizes reported in Fig. 14-12. The comparisons show that the type of packing media does not have a large impact on the tower volume or the total operating power requirements. However, it has been shown for the same type of packing (e.g., plastic tripacks), smaller nominal diameters result in lower tower volume and power requirements (Hand et al., 1986).

A major concern with respect to choosing the type and size of packing is the possibility of calcium, iron, and manganese precipitates forming on the packing during extended periods of operation and causing reduced removals and higher gas pressure drops, which is discussed in this section. To alleviate precipitation problems, larger packing sizes, which have smaller specific surface area, may be preferable because there would be less

surface area upon which precipitate can form as well as larger spaces for airflow.

The criteria for choosing the type and size of packing will depend upon the water flow rate and the desired degree of operational flexibility of the design. For small water flow rates, it is recommended that nominal diameter packing of 50 mm (2 in.) or less be used to minimize channeling or short circuiting of the water down the wall of the tower. Minimizing the impact of channeling requires that the ratio of tower diameter to nominal packing diameter be greater than 10:1 (> 15:1 is desired).

### Design Approach

In most situations in water treatment, multiple contaminants are present in the water, and the packed tower must be designed to remove all the contaminants to some specified treatment level. At the design stage, the limiting contaminant that controls the design must first be determined. In general, the contaminant with the lowest Henry's constant is used to determine the required air-to-water ratio and the contaminant with the highest removal efficiency is used to determine the required packing height.

Once the influent concentration of the organic contaminant, treatment objective, flow rate, and design temperature are known, the following steps are followed for design:

1. Select an efficient packing material that is expected to give good mass transfer at low gas head loss. For the selected packing, determine head loss and mass transfer characteristics from commercially available data. Based on the data provided in Table 14-5, tripacks and lantec packing are among the best packing material.
2. Select a gas-phase pressure drop per unit tower length. A value of  $50 \text{ N/m}^2/\text{m}$  usually provides an economical choice and the largest flexibility.
3. Select an operating air-to-water ratio. For most situations, an operating air-to-water ratio that is 3.5 times the minimum air-to-water ratio required for stripping provides the most economical design. For multicomponent systems, the compound with the lowest Henry's constant is used to calculate the operating air-to-water ratio.
4. Given the packing type, stripping factor, and gas pressure drop, the gas loading rate, liquid loading rate, and tower diameter can be determined based on the Eckert curve.
5. Compare the liquid loading rate to allowable liquid loading rates in commercially available equipment. If the liquid loading rate exceeds recommended values, reduce the gas pressure drop and repeat the computation. If the liquid loading rate is less than recommended values, increase the gas pressure drop and repeat the computation.
6. Determine the  $K_L a$  from the Onda correlation using a safety factor of 0.70.

7. Determine the HTU from Eq. 14-49.
8. Determine the NTU from Eq. 14-50. For multicomponent systems, the contaminant with the highest degree of removal is used to determine the NTU.
9. Determine the height of the tower from Eq. 14-48. Typical packed-tower heights usually do not exceed about 9.0 m (30 ft). Should the calculated tower length exceed 9.0 m, the air-to-water ratio could be increased by increasing the air flow rate to achieve the same treatment objective but with a smaller tower height.
10. Repeat for various values of the stripping factor and the gas pressure drop and determine the optimum or least-cost design. The optimal design will usually be obtained with an operating air-to-water ratio equal to 3.5 times the minimum air-to-water ratio required for stripping and a gas pressure drop of 50 N/m<sup>2</sup>/m.
11. At this point, preliminary design is complete and a pilot test should be conducted to be certain that the mass transfer correlations are correct.
12. Once the mass transfer parameters are confirmed to be correct, the design can be finalized by examining the operational flexibility of the system.

Several of these steps have been demonstrated in previous examples. Calculation of HTU, NTU, and height of the tower is demonstrated in Example 14.7.

### Example 14-7 Height of a packed tower

Determine the packed-tower height required to remove DCP and PCE at 10°C for a water flow rate  $Q$  of 0.1 m<sup>3</sup>/s (1585 gal/min). The basis for design is DCP removal, gas pressure drop  $\Delta P/L = 50 \text{ N/m}^2 \cdot \text{m}$ , and 8.9-cm (3.5-in.) plastic tripacks. From Table 14-3, the dimensionless Henry's constants of DCP and PCE at 10°C are  $H_{YC,DCP} = 0.0525$  and  $H_{YC,PCE} = 0.364$ . As shown in Example 14-4, the air-to-water ratio is determined based on the contaminant with lower Henry constant, DCP, and a factor of  $3.5(Q_a/Q)_{\min,DCP} = 60$ . From Example 14-4, the tower area based on DCP (the compound with the lower Henry constant), for the conditions described above, is 7.3 m<sup>2</sup> [based on a tower diameter of 3.048 m (10 ft)]. From Example 14-5, the actual liquid-phase mass transfer rate constants after applying a safety factor of 0.70 on the Onda  $K_L a$  values for DCP and PCE at 10°C for the conditions described above are  $K_L a_{DCP} = 0.0045 \text{ s}^{-1}$  and  $K_L a_{PCE} = 0.0077 \text{ s}^{-1}$ . The influent concentrations of DCP and PCE are  $C_{0,DCP} = 40 \text{ } \mu\text{g/L}$  and  $C_{0,PCE} = 35 \text{ } \mu\text{g/L}$ . Both DCP and PCE have a treatment objective  $C_e$  equal to 5  $\mu\text{g/L}$ .

**Solution**

1. The tower length is calculated based on the compound with the greatest of removal requirement which is DCP

a. Calculate the stripping factor,  $S$ , from Eq. 14-26:

$$S = \frac{Q_a}{Q} H_{YC} = (60)(0.0525) = 3.15$$

b. Calculate the height of a transfer unit, HTU, using Eq. 14-49:

$$\text{HTU} = \frac{Q}{AK_L a_{\text{DCP}}} = \frac{0.1 \text{ m}^3/\text{s}}{(7.3 \text{ m}^2)(0.0045 \text{ s}^{-1})} = 3.04 \text{ m}$$

c. Calculate the number of transfer units, NTU, using Eq. 14-50:

$$\begin{aligned} \text{NTU} &= \frac{S}{S-1} \ln \left[ \frac{1 + (C_0/C_e)(S-1)}{S} \right] \\ &= \frac{3.15}{3.15-1} \ln \left[ \frac{1 + (40/5)(3.15-1)}{3.15} \right] \\ &= 2.57 \end{aligned}$$

d. Calculate the packed-tower height  $L$  using Eq. 14-48:

$$L = (\text{HTU})(\text{NTU}) = (2.57 \text{ m})(3.04) = 7.8 \text{ m}$$

2. Determine the effluent concentration of PCE for the given design tower area and height to make sure it meets its treatment objective.

a. Calculate the stripping factor for PCE given the air-to-water ratio and Henry's constant using Eq. 14-26:

$$S_{\text{PCE}} = \left( \frac{Q_a}{Q} \right) H_{YC,\text{PCE}} = (60)(0.364) = 21.8$$

b. Calculate the effluent concentration  $C_e$  of PCE using Eq. 14-65:

$$\begin{aligned} C_e &= \frac{C_{0,\text{PCE}}(S_{\text{PCE}} - 1)}{S_{\text{PCE}} \exp\{LK_L a_{\text{PCE}}(S_{\text{PCE}} - 1)/(Q \times S_{\text{PCE}}/A)\} - 1} \\ &= \frac{(35 \mu\text{g/L})(21.8 - 1)}{21.8 \exp\{(7.8 \text{ m})(0.0077 \text{ s}^{-1})(21.8 - 1)/[(0.1 \text{ m}^3/\text{s})(21.8)/(7.3 \text{ m}^2)]\} - 1} \\ &= 0.51 \mu\text{g/L} \end{aligned}$$

**Comments**

The design based on DCP for this example resulted in both components meeting their treatment objectives. While calculation of tower height based on the compound with the highest removal efficiency is suggested as a

guideline, there are cases where the guideline will break down because tower height depends on more than just removal efficiency (see Eqs. 14-49 to 14-51) and a design based on the compound with the higher removal efficiency may not allow the treatment objectives of the other compounds to be met. The situation described above is particularly likely to occur if the compound with the highest removal efficiency has a dimensionless Henry's law constant much higher than one or more of the other compounds. The examples in this chapter demonstrate that the design of countercurrent packed towers is a computationally-intensive process. The spreadsheet identified as Resource E10 at the website listed in App. E can be used to perform the calculations.

Packed-tower performance may be impacted by environmental conditions such as water temperature and water quality such as dissolved solids.

#### TEMPERATURE

Temperature influences both the rate of mass transfer and Henry's constant and thus impacts equipment size, as well as the removal efficiency, in an existing packed tower. A packed tower that is designed to meet treatment objectives at one temperature may not be able to achieve the same treatment objectives at a lower temperature, as shown in Table 14-7. For example, if the temperature decreases from 15 to 5°C, the effluent concentration increases threefold. The information in Table 14-7 is based on a packed tower designed with the following specifications:

1. Trichloroethylene removal with an influent concentration of 100 µg/L = 95 percent. The 95 percent removal value is used to determine the NTU, as shown in Eq. 14-50
2. Design temperature 15°C
3.  $H_{YC} = 0.282$
4.  $Q_a/Q = 12$

**Table 14-7**  
Effect of temperature on packed-tower operation

Temperature $T$ , °C	$C_{E,T}/C_{E,15^\circ\text{C}}$
0	5.2
5	3.3
10	2.0
15	1
20	0.45

#### Factors Influencing Packed-Tower Performance

## 14 Air Stripping and Aeration

5. Packing: Plastic tripacks = 0.089 m (3.5 in.)
6. Flow rate  $0.095 \text{ m}^3/\text{s}$  (1500 gal/min)
7. Pressure drop  $50 \text{ N/m}^2/\text{m}$

**DISSOLVED SOLIDS**

During operation of a packed tower, dissolved inorganic chemicals such as calcium, iron, and manganese may precipitate onto packing media, which can cause a pressure drop increase and a void volume decrease in the tower. The main methods for controlling the negative effects of chemical precipitates are cleaning the precipitate off the packing and controlling precipitate formation.

*Precipitate potential*

The potential for fouling of packing material by precipitates is especially great in waters containing appreciable amounts of carbon dioxide. Groundwater often contains 30 to 50 mg/L of carbon dioxide. Carbon dioxide can be removed in an air-stripping tower, particularly at high air-to-water ratios, but removal of carbon dioxide tends to raise the pH of the water. As pH increases, bicarbonate is converted to carbonate. In natural waters containing significant quantities of calcium ion, calcium carbonate will precipitate when the carbonate ion concentration is high enough that the solubility product of calcium carbonate is surpassed.

Based on a dimensionless Henry's constant for carbon dioxide of 1.3 at 25°C (calculated using data given in Table 14-4) and the fact that air contains about 0.035 percent by volume of carbon dioxide, the aqueous concentration of carbon dioxide in equilibrium with air can be determined as 0.48 mg/L. The concentration of free carbon dioxide can be reduced to its equilibrium concentration with air via air stripping. The amount of carbonate in the tower effluent depends on both the final carbon dioxide concentration and the pH.

Since carbon dioxide (carbonic acid when in solution) is a weak acid, the rate of stripping depends on the apparent Henry's law constant and pH as presented earlier in this chapter. As carbon dioxide is stripped, the pH will rise and the rate of total carbonate stripping will decrease as water flows through the packing. Acid-base chemistry can be incorporated into the design equations presented earlier in this chapter to develop equations that predict the rate of carbonate stripping and pH of the tower effluent (Howe and Lawler, 1989). Once the tower effluent pH is known, the maximum amount and rate of precipitation that will result in fouling of the tower can be estimated using theoretical precipitation calculations [e.g., using a chemical equilibrium model such as MINTEQA2 (U.S. EPA, 1999) or Visual MINTEQ (Gustafsson, 2002)]. Because the free carbon dioxide concentration is most often reduced to a level greater than the concentration in equilibrium with air, the time taken to foul the tower will be much longer than predicted by the theoretical maximum precipitation

calculations. Pilot plant testing is the only method available for determining the actual precipitation rate.

#### *Cleaning*

Plastic packing can be removed periodically and put into a tumbler so that the precipitate can be broken off. Acid treatment dramatically deteriorates the plastic packing (making it very brittle) over time and is not recommended. In some instances, conditioning chemicals may be necessary to add to the cleaning process because precipitates can form within weeks in hard water.

#### *Controlling precipitate*

Larger packing size, which has smaller specific surface area, may be preferable because there is less surface area upon which precipitate can form as well as larger spaces for airflow. Controlling precipitation with scale inhibitors represents a significant cost in certain situations; therefore, the potential for precipitation must be carefully analyzed.

## 14-6 Analysis of Low-Profile Air Strippers

---

Over the past 20 years, low-profile air stripping has become increasingly common. Unit compactness is a key advantage of low-profile air strippers compared to packed towers. Design guidelines for low-profile air strippers, including a comparison with countercurrent packed-tower air strippers, are presented in the following discussion.

A schematic of a low-profile air stripper, which consists of a stack of sieve trays with contaminated water entering the top of the unit and exiting the bottom as treated water and clean air entering the bottom of the unit and exiting at the top containing VOCs, is shown on Fig. 14-8. The operation of a low-profile air stripper has been described by Treybal (1980), and several other researchers have expanded upon that seminal work to explain sieve tray (low-profile) air-stripping columns in detail (LaBranche and Collins, 1996; Mead and Leibbert, 1998; Notthakun et al., 1994; U.S. ACE, 2001). Low-profile air strippers operate as a countercurrent process with water entering at the top of the unit and flowing across each sieve tray, as shown on Fig. 14-8a. Inlet and outlet channels or downcomers are placed at the ends of each tray to allow the water to flow from tray to tray. Fresh air flows upward from a blower positioned beneath the bottom tray through perforated holes into a water layer on each tray. Large air flow rates are typically used, causing very small bubbles or frothing to form upon air contact with the water. The frothing provides a high air–water surface area for mass transfer to occur. Low-profile air stripping can be described conceptually as a countercurrent, staged operation, as demonstrated on Fig. 14-8b.

### **Description**

Both packed towers and low-profile air strippers are capable of providing greater than 99 percent removal of most VOCs. There are numerous advantages and disadvantages of low-profile air strippers when compared to packed towers. Advantages include the following:

- *Unit Compactness.* Because the water flows horizontally across each tray, augmenting the length or width of the trays, instead of the height of the unit, will increase the removal efficiency. A typical low-profile air stripper is less than 3 m (10 ft) tall, whereas packed towers are often on the order of 8 m (26 ft) in height. There are many situations when architectural or height restrictions require use of a compact, low-profile air stripper even when cost analysis favors a packed tower.
- *Fouling.* Low-profile air strippers are less susceptible to fouling by inorganics because there is no packing. Low-profile air strippers are also much easier to disassemble and clean, compared to packed towers, as the trays are stackable and can be easily removed for cleaning.

Disadvantages include:

- *Narrow Range of Air Flow Rates.* A low-profile air stripper must operate under a narrow range of air flow rates. If the air flow rate is too high, a flooding condition results. If the air flow rate is too low, water will flow through the holes in the sieve trays, a condition known as weeping. Because of the importance of operating the low-profile air stripper under proper conditions, it is necessary that the manufacturer design the sieve tray columns to assure proper performance. Because the air flow rate is finely tuned by the manufacturer, it is not possible to adjust the air flow rate downward should the amount of water treated decrease. In contrast, the air flow rate for a packed tower can be more readily adjusted should a shift in water flow rate occur.
- *Higher Air-to-Water Ratios.* The air-to-water ratio required for a low-profile air stripper is on the order of 100 to 900 (LaBranche and Collins, 1996), compared to a typical air-to-water ratio of 30 for a packed tower. The higher air flow rate for low-profile air strippers is an important consideration, especially when off-gas treatment is required. The higher air-to-water ratio for low-profile air strippers will result in higher costs to operate the blower due to a higher pressure drop and higher costs to treat the off-gas.
- *Foaming.* If the water has a tendency to foam, then packed-tower aeration must be used.

### Design Approach

Design equations for low-profile air stripping are not currently available in the literature. The diffused aeration approach is not applicable because of the frothing that occurs in low-profile air stripping. An empirical Fickian approach to mass transfer was applied to low-profile air stripping, and it was shown that the mass transfer rate constants for low-profile air stripping of

TCE and PCE compare favorably to mass transfer rate constants of VOCs in packed-tower aeration and mechanical aeration (LaBranche and Collins, 1996).

The following methods are available for determining the size of a low-profile air stripper:

- Analytical equations: Treybal (1980)
- Manufacturer-supplied software: Carbonair Environmental Systems (2003); North East Environmental Products (2003).
- McCabe–Thiele graphical method: See Sec. 14-4

A description of the recommended method for preliminary sizing of a low-profile air stripper from the U.S. ACE (2001) design manual follows:

1. Determine the minimum and maximum volume of water to be treated, the minimum temperature of the water, and the maximum concentration of VOCs in the untreated water.
2. Determine the desired concentration (percent removed) of the VOCs in the treated water.
3. Calculate the theoretical number of sieve trays needed to remove the VOCs to the desired concentration.
4. Estimate the tray efficiency and the number of actual trays needed.
5. Estimate the size (cross-sectional area) of the perforated plate section of each tray.
6. Estimate the pressure drop through the air stripper.
7. Estimate the size of the air blower motor (in kilowatts).

The McCabe–Thiele graphical approach for determining the number of equilibrium stages (theoretical trays) for low-profile air stripping was discussed in Sec. 14-4. It is also possible to determine the number of theoretical trays from the following relationship (Li and Hsiao, 1990; Treybal, 1980):

$$N_{\text{th}} = \frac{\ln[1 + (C_0/C_{\text{TO}})(S - 1)]}{\ln(S)} - 1 \quad (14-66)$$

where  $N_{\text{th}}$  = number of theoretical trays  
 $S$  = stripping factor, dimensionless  
 $C_0$  = influent liquid-phase concentration, mg/L  
 $C_{\text{TO}}$  = treatment objective, mg/L

Once the number of theoretical trays is known, the number of actual trays can be calculated based on the tray efficiency:

$$N_{\text{act}} = \frac{N_{\text{th}}}{\text{Eff}_{\text{tray}}} \quad (14-67)$$

where  $N_{\text{act}}$  = number of actual trays  
 $\text{Eff}_{\text{tray}}$  = tray efficiency, expressed as decimal fraction

### Example 14-8 Low-profile air stripping

Determine the actual number of trays needed for a low-profile air stripper compared to the theoretical number of trays for the following conditions. The influent concentration of PCE is 15 mg/L and the treatment objective is 0.005 mg/L. The water flow rate is 0.003 m<sup>3</sup>/s (48 gpm) and the water temperature is 10°C. The air flow rate is 0.7 m<sup>3</sup>/s (1500 cfm). The dimensionless Henry's constant of PCE at 10°C is equal to 0.364.

#### Solution

1. Calculate the theoretical number of sieve trays required to remove the compound to the desired concentration.
  - a. Determine air-to-water ratio and the stripping factor:

$$\frac{Q_a}{Q} = \frac{0.7 \text{ m}^3/\text{s}}{0.003 \text{ m}^3/\text{s}} = 233 \quad S = \frac{Q_a}{Q} \times H_{YC,PCE} = 233 \times 0.364 = 85$$

- b. Use Eq. 14-66 to determine the number of theoretical trays:

$$\begin{aligned} N_{th} &= \frac{\ln[1 + (C_0/C_{T0})(S - 1)]}{\ln(S)} - 1 \\ &= \frac{\ln[1 + (15/0.005)(85 - 1)]}{\ln(85)} - 1 = 1.8 \end{aligned}$$

- c. The appropriate number of theoretical trays is thus equal to 2.
2. Determine the number of actual trays using Eq. 14-67. Use a tray efficiency of 0.5, which is within the appropriate range of 0.4 to 0.6:

$$N_{act} = \frac{N_{th}}{\text{Eff}_{tray}} = \frac{2}{0.5} = 4$$

#### Comment

The actual number of trays needed for low-profile air stripping is greater than the theoretical number of trays by a factor of approximately 2 based on manufacturer's data.

Based on manufacturers' data, an appropriate  $\text{Eff}_{tray}$  value appears to be in the range of 0.4 to 0.6 (U.S. ACE, 2001).

## 14-7 Analysis of Spray Aerators

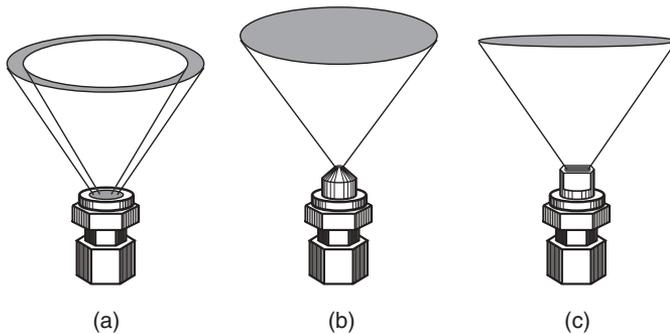

Spray towers and spray fountains are the two main types of spray aerators. A fixed grid of nozzles is used to either spray water in towers (spray

towers) or spray water vertically into the air from the water surface (spray fountains), as shown on Fig. 14-5. The primary type of spray aerator used in water treatment is a fountain spray aerator, which is popular because existing reservoirs and large basins may be readily retrofit with them. When used in reservoirs and large basins, spray aerators are used to strip taste- and odor-causing compounds from raw water stored in reservoirs, oxygenate groundwater to remove iron and manganese, and strip VOCs. Spray fountain aerators are considered in this section; spray towers are discussed in Sec. 14-8.

Air–water contact occurs by spraying fine water droplets from pressurized nozzles into the air, which creates a large air–water surface for mass transfer. Three types of pressurized spray nozzles are typically used in water treatment applications: (1) hollow cone, (2) full cone, and (3) fan spray (see Fig. 14-22). Full-cone nozzles create a uniform pattern of droplets over the entire angle of spray, while hollow-cone nozzles create a circular pattern of droplets, primarily around the circumference of the angle of spray. Although hollow-cone nozzles do not distribute droplets as well as full-cone nozzles and have a larger pressure drop requirement, hollow cones are generally preferred over full cones because they create smaller diameter drops and have a larger nozzle orifice. Hollow-cone spray nozzles are also prone to plugging and may require strainers upstream of the nozzle to discourage nozzle plugging.

Contaminant removal occurs during the time the water droplet is in contact with the air, so the basis for spray aeration design equations is the mass transfer from the droplet across the air–water interface. A mass balance on water droplets of equal size and equal air exposure is given in words in Eq. 14-68 and mathematically in Eq. 14-69 (Hand et al., 1999):

$$\text{Mass lost from water drop per unit time} = \text{Mass transferred across air–water interface of water drop per unit time} \quad (14-68)$$

**Figure 14-22**

Common spray nozzles: (a) hollow cone, (b) full cone, and (c) fan spray.

## Description

## Design Approach

$$V_d \frac{dC}{dt} = K_L a [C(t) - C_s(t)] V_d \quad (14-69)$$

where  $V_d$  = volume of drop,  $m^3$   
 $K_L$  = overall mass transfer coefficient,  $m/s$   
 $a$  = interfacial surface area available for mass transfer for water drop,  $m^2/m^3$   
 $C(t)$  = concentration in water drop at time  $t$ ,  $mg/L$   
 $C_s(t)$  = concentration at air–water interface at time  $t$ ,  $mg/L$

The gas-phase contaminant concentration in the open air is assumed to be zero, and the concentration at the air–water interface,  $C_s$ , is assumed to be in equilibrium with the air, so it is also zero. The final contaminant concentration of the water drop after exposure to air may be determined by rearranging Eq. 14-69 and integrating over the time the drop is exposed to the air:

$$C_e = C_0 e^{-K_L a \theta} \quad (14-70)$$

where  $C_e$  = final contaminant concentration of water drop after being exposed to air,  $mg/L$   
 $C_0$  = initial contaminant liquid-phase concentration of drop before being exposed to air,  $mg/L$   
 $\theta$  = time of contact between water drop and air,  $s$

The time of contact between the water drop and the air,  $\theta$ , is dependent upon the exiting velocity and trajectory and can be estimated from the equation

$$\theta = \frac{2v_d \sin \alpha}{g} \quad (14-71)$$

where  $\alpha$  = angle of spray measured from horizontal,  $deg$   
 $g$  = acceleration due to gravity,  $9.81 \text{ m/s}^2$   
 $v_d$  = exit velocity of water drop from nozzle,  $m/s$

The exit velocity  $v_d$  can be determined using the orifice equation

$$v_d = C_v \sqrt{2gh} \quad (14-72)$$

where  $C_v$  = coefficient of velocity for orifice, unitless  
 $h$  = total head of nozzle,  $m$

The coefficient of velocity  $C_v$  is provided by the nozzle manufacturer and typically varies from 0.4 to 0.65. The area of flow is typically less than the nozzle area so the flow rate  $Q$  may be calculated by using a revised form of Eq. 14-72, as shown in the equation

$$Q_n = C_d A_n \sqrt{2gh} \quad (14-73)$$

where  $Q_n$  = flow rate through nozzle,  $\text{m}^3/\text{s}$   
 $A_n$  = area of nozzle opening,  $\text{m}^2$   
 $C_d$  = coefficient of discharge from nozzle, which is supplied by  
 nozzle manufacturer, unitless

The overall mass transfer coefficient may be computed from either Eq. 14-74 or Eq. 14-75, depending on the value of the dimensionless quantity  $[2(D_l\theta)^{0.5}/d_d]$  (Calvert et al., 1972; Higbie, 1935; Jury, 1967):

$$K_L = \begin{cases} 2 \left( \frac{D_l}{\pi\theta} \right)^{1/2} & \text{for } \frac{2(D_l\theta)^{1/2}}{d_d} < 0.22 \\ \frac{10D_l}{d_d} & \text{for } \frac{2(D_l\theta)^{1/2}}{d_d} > 0.22 \end{cases} \quad (14-74)$$

where  $K_L$  = overall mass transfer coefficient,  $\text{m}/\text{s}$   
 $d_d$  = Sauter mean diameter (SMD) of water drop, equal to total  
 volume of spray divided by total surface area,  $\text{m}$   
 $D_l$  = contaminant liquid diffusivity,  $\text{m}^2/\text{s}$   
 $\theta$  = contact time of water drop with air,  $\text{s}$

The Sauter mean diameter is a design parameter provided by the nozzle manufacturers. The area on the water droplets that is available for mass transfer can be calculated as

$$a = \frac{6}{d_d} \quad (14-76)$$

where  $a$  = interfacial surface area available for mass transfer,  
 $\text{m}^2/\text{m}^3$

### Example 14-9 Spray aeration

It is necessary to strip carbon dioxide,  $\text{CO}_2$ , from a groundwater. Determine the number of nozzles required and the expected carbon dioxide removal efficiency for treating the water with a spray aeration system. The groundwater has a temperature of  $25^\circ\text{C}$  and a dissolved  $\text{CO}_2$  concentration of  $100 \text{ mg/L}$ . The water is pumped from the well at a flow rate of  $0.050 \text{ m}^3/\text{s}$ , and the pump has the capacity to deliver an additional  $30 \text{ m}$  of head. The nozzle manufacturer has supplied the following data:  $\text{SMD} = 0.0010 \text{ m}$ ,  $\alpha = 90^\circ$ ,  $C_v = 0.45$ ,  $C_d = 0.25$ , nozzle diameter =  $0.0125 \text{ m}$ . Refer to Table 7-1 in Chap. 7 for diffusion coefficients.

#### Solution

1. Determine the number of nozzles required.
  - a. Calculate the area of one nozzle:

$$A_n = \left( \frac{1}{4} \pi \right) (0.0125 \text{ m})^2 = 1.2 \times 10^{-4} \text{ m}^2$$

b. Calculate the flow rate through one nozzle,  $Q_n$ , using Eq. 14-73:

$$Q_n = C_d A_n \sqrt{2gh} = 0.25(1.2 \times 10^{-4} \text{ m}^2) \sqrt{2(9.81 \text{ m/s}^2)(30 \text{ m})} \\ = 7.3 \times 10^{-4} \text{ m}^3/\text{s}$$

c. The number of nozzles can be calculated by dividing the total flow by the flow through each nozzle:

$$\text{Required number of nozzles} = \frac{Q}{Q_n} = \frac{0.050 \text{ m}^3/\text{s}}{7.3 \times 10^{-4} \text{ m}^3/\text{s}} = 68$$

2. Determine the  $\text{CO}_2$  removal efficiency.

a. Calculate the velocity of the water exiting the nozzle,  $v_d$ , using Eq. 14-72:

$$v_d = C_v \sqrt{2gh} = 0.45 \sqrt{2(9.81 \text{ m/s}^2)(30 \text{ m})} = 11 \text{ m/s}$$

b. Determine the contact time of the water drop with the air,  $t$ , using Eq. 14-71:

$$\theta = \frac{2v_d \sin \alpha}{g} = \frac{2(11 \text{ m/s}) \sin(90^\circ)}{9.81 \text{ m/s}^2} = 2.2 \text{ s}$$

c. Calculate the overall liquid-phase mass transfer coefficient  $K_L$ . From Table 7-1, the liquid-phase diffusion coefficient of  $\text{CO}_2$  is  $2.0 \times 10^{-9} \text{ m}^2/\text{s}$ .

i. Calculate the dimensionless quantity  $2(D_l\theta)^{1/2}/d_d$ :

$$\frac{2(D_l\theta)^{1/2}}{d_d} = \frac{2[(2.0 \times 10^{-9} \text{ m}^2/\text{s})(2.2 \text{ s})]^{1/2}}{0.0010 \text{ m}} = 0.13 < 0.22$$

ii. Because the dimensionless quantity determined in the previous step is less than 0.22, calculate the overall liquid-phase mass transfer coefficient  $K_L$  using Eq. 14-74:

$$K_L = 2 \left( \frac{D_l}{\pi\theta} \right)^{0.5} = 2 \left( \frac{2.0 \times 10^{-9} \text{ m}^2/\text{s}}{\pi \times 2.2 \text{ s}} \right)^{0.5} \\ = 3.4 \times 10^{-5} \text{ m/s}$$

d. Calculate the interfacial area for mass transfer,  $a$ , using Eq. 14-76:

$$a = \frac{6}{d_d} = \frac{6}{0.0010 \text{ m}} = 6.0 \times 10^3/\text{m}$$

e. Calculate  $K_L a$ :

$$K_L a = (3.4 \times 10^{-5} \text{ m/s})(6.0 \times 10^3/\text{m}) \\ = 0.20 \text{ s}^{-1}$$

- f. Calculate the effluent liquid-phase  $\text{CO}_2$  concentration after stripping using Eq. 14-70:

$$C_e = C_0 e^{-K_L a \times \theta} = (100 \text{ mg/L}) e^{-0.20 \text{ s}^{-1} \times 2.2 \text{ s}}$$

$$= 64 \text{ mg/L}$$

- g. Calculate the carbon dioxide removal efficiency due to stripping:

$$\text{Carbon dioxide removal efficiency} = \frac{C_0 - C_e}{C_0} \times 100$$

$$= \frac{100 - 64}{100} = 36\%$$

## 14-8 Other Air-Stripping and Aeration Processes

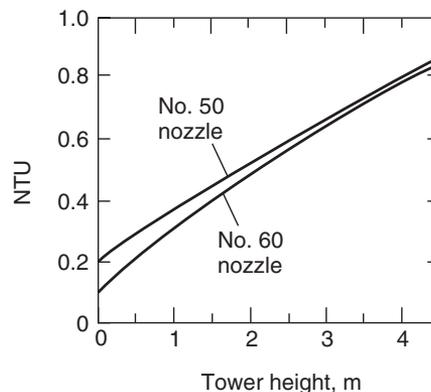

Other types of air-stripping and aeration processes, such as spray towers, diffused aerators, and mechanical aerators, are introduced and discussed briefly in this section.

There are a variety of configurations in which spraying can be used. Some configurations are analogous to packed-tower designs, and some are more complex designs, which are typically used for air pollution control such as cyclone scrubbers and Venturi scrubbers. Historically, spray systems have been used in water treatment for aeration, degasification of well water, and odor removal.

Only a few studies of spray towers have been conducted on mass transfer in clean-water systems. Based on these studies, it has been found that spray systems are limited with respect to the removals that can be achieved, and a substantial portion of removal in a spray system may occur at the nozzle. Typically, one to three transfer units are reported as a maximum limit that can be achieved in spraying systems. The apparent limitation in percent removal is the product of backmixing of air and spray disturbance due to wall or adjacent spray contact (Davies and Ip, 1981; Ip and Raper, 1977; Pigford and Pyle, 1951).

The NTU as a function of the height of the spray tower is shown on Fig. 14-23. The residual NTU at zero height, in this case between 0.1 and 0.2 transfer units, is the result of the removal occurring at the nozzle. Some process designs may take advantage of the removal occurring at the nozzles by recycling flow or by incorporating several banks of nozzles. The aforementioned nonideal effects have hindered development of a general empirical design model. With the data presently available, a spray tower cannot be designed for a precise removal. Rather, the design approach

### Spray Towers

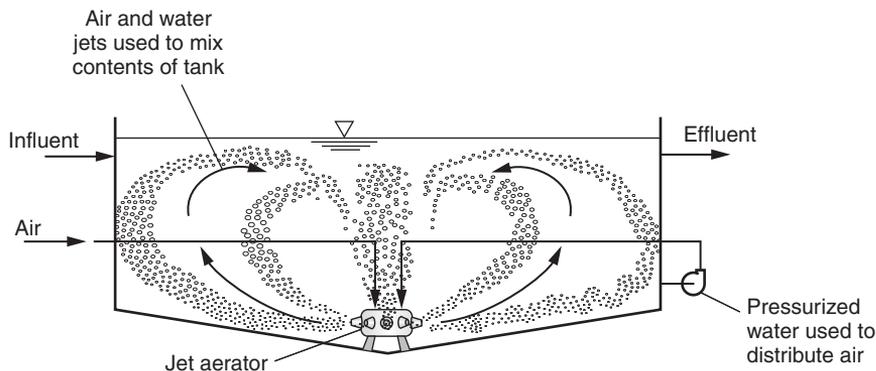

**Figure 14-23**  
Number of transfer units in pilot spray tower as function of tower height  
(Adapted from Davies and Ip, 1981).

serves merely as a basis to estimate the approximate removal efficiency of a spray system.

### Diffused Aeration

The diffused, or bubble, aeration process consists of contacting water with gas bubbles for the purposes of transferring gas to the water (e.g.,  $O_3$ ,  $CO_2$ ,  $O_2$ ) or removing VOCs from the water by stripping. The process can be carried out in a clearwell or special rectangular concrete tanks (contactors) typically 2.7 to 4.6 m (9 to 15 ft) in depth.

A typical diffused-air aeration system is shown on Fig. 14-24. The most commonly used diffuser system consists of a matrix of perforated tubes (or membranes) or porous plates arranged near the bottom of the tank to provide maximum gas-to-water contact. Various types of diffusers and diffuser system layouts are presented in the U.S. EPA's (1989) technology transfer design manual on fine pore aeration systems. Jet aerators, which consist of jets that discharge fine gas bubbles and provide enhanced mixing

**Figure 14-24**  
Typical example of a diffused-air aeration system.

for increased absorption efficiency, are used to provide good air-to-water contact (Mandt and Bathija, 1977). Model development for bubble aeration has been described in the literature (Matter-Müller et al., 1981; Munz and Roberts, 1982; Roberts et al., 1984).

Mechanical aerators typically used in water treatment are surface or submerged turbines or brushes, as shown on Fig. 14-11. Surface aerators can be used in water treatment as an alternative to diffused aeration systems for stripping of volatile contaminants. Surface aeration has been primarily used for oxygen absorption and the stripping of gases and volatile contaminants when the required removals are less than about 90 percent.

The brush-type aerator consists of several blades attached to a rotary drum that is half submerged in water in the center of the tank, as shown on Fig. 14-11. As the drum rotates, it disperses the water into the surrounding air, thus providing interfacial contact between the air and water for mass transfer to take place.

The turbine-type aerator consists of a submerged propeller system located in the center of the tank and surrounded by a draft tube. As the submerged propeller rotates, it draws water from outside the draft tube through the inner section and into the air, creating contact between the air and water.

Model development for surface aeration as applied to water treatment has been described in the literature (Matter-Müller et al., 1981; Munz and Roberts, 1989; Roberts and Dändliker, 1983; Roberts et al., 1984, 1985).

## Mechanical Aerators

## Problems and Discussion Topics

---

Note: Several of these problems pertain to the design of countercurrent packed towers, which is a computationally-intensive process. The spreadsheet identified as Resource E10 at the website listed in App. E can be used to perform the calculations.

- 14-1 What is the dimensionless Henry's law constant for a compound that has a value of 400 atm? What is the Henry's law constant in atmospheres and atm/(mol/L) for a compound that has a dimensionless Henry's law constant of 0.2? Assume the temperature is 15°C.
- 14-2 What is the Henry's law constant in dimensionless form and atmospheres for a compound that has a Henry's law constant of 2.0 atm/(mol/L)? What is the dimensionless Henry's law constant for a compound that has a value of 200 atm? Assume the temperature is 10°C.
- 14-3 Calculate the dimensionless Henry's law constant at 10 and 25°C for benzene using  $\Delta H_{\text{dis}}^0 = 35.44 \text{ KJ/mol}$  and  $K_c = 357,678$ .

## 14 Air Stripping and Aeration

- 14-4 Calculate the dimensionless Henry's law constant at 5 and 15°C for chloroform using  $\Delta H_{\text{dis}}^0 = 38.53 \text{ KJ/mol}$  and  $K_c = 940,789$ .
- 14-5 Calculate the apparent Henry's constant of hydrogen sulfide at pH 6.3 at 25°C.
- 14-6 Calculate the minimum air-to-water ratio for chloroform and benzene with 95 percent removal at 10°C for a countercurrent packed tower.
- 14-7 Using the McCabe–Thiele graphical method, determine the number of equilibrium stages required to strip chloroform from an influent concentration of 200  $\mu\text{g/L}$  to its treatment objective of 5  $\mu\text{g/L}$  in a countercurrent, packed tower at 5°C. Assume clean air enters the tower and  $S = 3.5$ .
- 14-8 Determine the cross-sectional area and diameter for a packed-tower design based on chloroform at 20°C for a water flow rate  $Q$  of 0.15  $\text{m}^3/\text{s}$  (2400 gal/min). The basis for design is stripping factor  $S = 3.5$ , gas pressure drop  $\Delta P/L = 50 \text{ N/m}^2 \cdot \text{m}$ , and 5.1-cm (2-in.) plastic saddles.
- 14-9 Determine the cross-sectional area and diameter for a packed-tower design based on benzene at 10°C for a water flow rate  $Q$  of 0.05  $\text{m}^3/\text{s}$  (800 gal/min). The basis for design is stripping factor  $S = 3.5$ , gas pressure drop  $\Delta P/L = 50 \text{ N/m}^2 \cdot \text{m}$ , and 5.8-cm (2.3-in.) LANPAC packing material.
- 14-10 Determine the mass transfer coefficients for benzene and chloroform at 20°C in packed-tower aeration for the air mass loading rate and water mass loading rate determined in Problem 14-8 using the Onda correlations and a safety factor of 0.75 (actual  $K_L a/\text{Onda } K_L a$ ) for 5.1-cm (2-in.) plastic saddles. The water flow rate  $Q$  is 0.15  $\text{m}^3/\text{s}$  (2400 gal/min). Determine the liquid diffusivity  $D_l$  and gas diffusivity  $D_g$  for benzene and chloroform using the Hayduk–Laudie correlation and the Wilke–Lee modification of the Hirschfelder–Bird–Spotz method, respectively. The viscosity of air,  $\mu_g$ , at 20°C is  $1.77 \times 10^{-5} \text{ kg/m} \cdot \text{s}$ .
- 14-11 Determine the mass transfer coefficients for benzene and chloroform at 10°C in packed-tower aeration for the air mass loading rate and water mass loading rate determined in Problem 14-9 using the Onda correlations and a safety factor of 0.75 (actual  $K_L a/\text{Onda } K_L a$ ) for 5.8-cm (2.3-in.) LANPAC packing material. The water flow rate  $Q$  is 0.05  $\text{m}^3/\text{s}$  (800 gal/min). Determine the liquid diffusivity  $D_l$  and gas diffusivity  $D_g$  for benzene and chloroform using the Hayduk–Laudie correlation and the Wilke–Lee modification of the Hirschfelder–Bird–Spotz method, respectively. The viscosity of air,  $\mu_g$ , of 10°C is  $1.72 \times 10^{-5} \text{ kg/m} \cdot \text{s}$ .

- 14-12 Determine the packed-tower height required to remove chloroform at 20°C for a water flow rate  $Q$  of 0.15 m<sup>3</sup>/s (2400 gal/min). Use the tower area determined in Problem 14-8 and the mass transfer coefficients determined in Problem 14-10 in the solution of the problem. The influent concentration for benzene is 50 μg/L and its treatment objective is 5 μg/L. The influent concentration for chloroform is 100 μg/L and its treatment objective is 5 μg/L.
- 14-13 Determine the packed-tower height required to remove benzene at 20°C for a water flow rate  $Q$  of 0.15 m<sup>3</sup>/s (2400 gal/min). Use the tower area determined in Problem 14-8 and the mass transfer coefficients determined in Problem 14-10 in the solution of the problem. The influent concentration for benzene is 50 μg/L and its treatment objective is 5 μg/L. The influent concentration for chloroform is 100 μg/L and its treatment objective is 5 μg/L.
- 14-14 Determine the packed-tower height required to remove chloroform at 10°C for a water flow rate  $Q$  of 0.05 m<sup>3</sup>/s (800 gal/min). Use the tower area determined in Problem 14-9 and the mass transfer coefficients determined in Problem 14-11 in the solution of the problem. The influent concentration for benzene is 75 μg/L and its treatment objective is 5 μg/L. The influent concentration for chloroform is 100 μg/L and its treatment objective is 5 μg/L.
- 14-15 Determine the packed-tower height required to remove benzene at 10°C for a water flow rate  $Q$  of 0.05 m<sup>3</sup>/s (800 gal/min). Use the tower area determined in Problem 14-9 and the mass transfer coefficients determined in Problem 14-11 in the solution of the problem. The influent concentration for benzene is 75 μg/L and its treatment objective is 5 μg/L. The influent concentration for chloroform is 75 μg/L and its treatment objective is 5 μg/L.
- 14-16 Using the packed-tower height and conditions in Problem 14-12, perform a rating analysis to determine if benzene will be removed to meet its treatment objective.
- 14-17 Using the packed-tower height and conditions in Problem 14-13, perform a rating analysis to determine if chloroform will be removed to meet its treatment objective.
- 14-18 Using the packed-tower height and conditions in Problem 14-14, perform a rating analysis to determine if benzene will be removed to meet its treatment objective.
- 14-19 Using the packed-tower height and conditions in Problem 14-15, perform a rating analysis to determine if chloroform will be removed to meet its treatment objective.
- 14-20 Determine the total power requirement (blower and pump brake power) for a packed-tower aeration design removing chloroform at 20°C and 1 atm (101,325 N/m<sup>2</sup>) for a water flow rate of 0.15 m<sup>3</sup>/s,

- a stripping factor of 3.5, and a gas pressure drop of  $50 \text{ N/m}^2/\text{m}$ . Assume the blower efficiency is 35 percent ( $\text{Eff}_b = 0.35$ ) and the pump efficiency is 80 percent ( $\text{Eff}_p = 0.80$ ). Use the air-to-water ratio and tower area determined in Problem 14-8. Use the tower length determined in Problem 14-12.
- 14-21 Determine the total power requirement (blower and pump brake power) for a packed-tower aeration design removing benzene at  $10^\circ\text{C}$  and 1 atm ( $101,325 \text{ N/m}^2$ ) for a water flow rate of  $0.05 \text{ m}^3/\text{s}$ , a stripping factor of 3.5, and a gas pressure drop of  $50 \text{ N/m}^2/\text{m}$ . Assume the blower efficiency is 35 percent ( $\text{Eff}_b = 0.35$ ) and the pump efficiency is 80 percent ( $\text{Eff}_p = 0.80$ ). Use the air-to-water ratio and tower area determined in Problem 14-9. Use the tower length determined in Problem 14-13.
- 14-22 Design a packed-tower aeration system to treat  $0.075 \text{ m}^3/\text{s}$  of water at  $15^\circ\text{C}$  and remove benzene (influent concentration that equals  $40 \mu\text{g/L}$ ), chloroform (influent concentration equals  $60 \mu\text{g/L}$ ), and carbon tetrachloride (influent concentration equals  $30 \mu\text{g/L}$ ) to a treatment objective of total VOC concentration that equals  $5 \mu\text{g/L}$ . Determine an appropriate tower diameter and tower length. Use 0.0508-m (2-in.) plastic tripacks as the packing material. The viscosity of air at  $15^\circ\text{C}$  is  $1.75 \times 10^{-5} \text{ kg/m} \cdot \text{s}$ .
- 14-23 Determine the actual number of trays needed for a low-profile air stripper for the following conditions. The influent concentration of trichloroethylene (TCE) is  $30 \text{ mg/L}$  and the treatment objective is  $0.005 \text{ mg/L}$ . The water flow rate is  $0.00630 \text{ m}^3/\text{s}$  (100 gpm) and the water temperature is  $10^\circ\text{C}$ . The air flow rate is  $1.42 \text{ m}^3/\text{s}$  (3000 cfm). The Henry's constant of TCE at  $10^\circ\text{C}$  is 0.230.
- 14-24 A well water contains  $1.0 \text{ mg/L}$  of methane with temperature of  $10^\circ\text{C}$ . The well pumps  $0.0600 \text{ m}^3/\text{s}$  (950 gpm) and the pump has the capacity to deliver an additional 28 m (40 psi) of head. Determine the number of nozzles required and the expected methane removal efficiency. The following information was obtained from the nozzle manufacturer:  $\text{SMD} = 0.10 \text{ cm}$ ,  $\alpha = 90^\circ$ ,  $C_v = 0.45$ ,  $C_d = 0.25$ , nozzle diameter = 1.25 cm. Let  $D_l$  for methane be  $1.1 \times 10^{-5} \text{ cm}^2/\text{s}$  at  $10^\circ\text{C}$ .

## Terminology for Adsorption

Term	Definition
Particle properties	
Adsorbent	Solid media on which adsorption occurs.
Adsorbent particle density in an adsorber, $\rho_s$	Weight of the dry (and fresh) adsorbent particles divided by the solid volume. The density of activated carbon is approximately equal to the density of graphite ( $\approx 2$ g/mL).
Apparent particle density, $\rho_a$	Weight of the dry (and fresh) adsorbent particles divided by the total volume of the adsorbent particle. The total volume includes the solid and pore volume.
Particle porosity, $\varepsilon_p$	Ratio of the pore volume to the total volume of an adsorbent particle. This parameter characterizes the fraction of the adsorbent volume that is not occupied by the carbon material. $\varepsilon_p = 1 - (\rho_a/\rho_s)$ .
Sphericity, $\phi$	External surface area of a particle divided by the surface area of a sphere that would have the same volume. Describes the increase in surface area due to a particle having an irregular shape.
Specific surface area	External surface area per weight of a dry particle. Because most adsorbent particles have an irregular shape, the external surface area per unit mass is defined as $3/R\phi\rho_a$ where $R$ is equal to particle radius.
Adsorber properties	
Bed porosity, $\varepsilon$	Void volume in the contactor divided by the total volume that is occupied by the adsorbent particles. This parameter characterizes the fraction of the bed volume in which the fluid moves. $\varepsilon = 1 - (\rho_f/\rho_a)$ .

<b>Term</b>	<b>Definition</b>
Contactor or adsorber density, $\rho_f$	Weight of the dry (and fresh) adsorbent particles divided by the total volume of the packed bed, including the bed pore volume.
Performance properties	
Adsorbate	Molecule that accumulates or adsorbs onto the adsorbent material.
Breakthrough profile	Relationship between the adsorbate concentration leaving the adsorber as a function of the adsorber run time.
Carbon use rate	Mass of adsorbent used per volume of water treated to a given treatment objective.
Equilibrium isotherm	Equilibrium partitioning relationship between the bulk aqueous-phase adsorbate concentration and the solid-phase adsorbate concentration at a constant temperature.
Specific throughput	Volume of water treated per mass of adsorbent used at a given treatment objective.
Treatment objective	Aqueous-phase adsorbate concentration that determines the bed life of a GAC adsorber or maximum value leaving a PAC contactor.
Empty-bed contact time (EBCT)	Volume of the bed occupied by the GAC (including voids) divided by the flow rate to the column.

Adsorption is a mass transfer operation in which substances present in a liquid phase are adsorbed or accumulated on a solid phase and thus removed from the liquid. Adsorption processes are used in drinking water treatment for the removal of taste- and odor-causing compounds, synthetic organic chemicals (SOCs), color-forming organics, and disinfection by-product (DBP) precursors. Inorganic constituents, including some that represent a health hazard, such as perchlorate, arsenic, and some heavy metals, are also removed by adsorption. Reactions with granular activated carbon (GAC), a common adsorbent, can also be used to dechlorinate drinking water.

The primary adsorbent materials used in the adsorption process for drinking water treatment are powdered activated carbon (PAC) and GAC. Powdered activated carbon is added directly to water and can be applied at various locations within a water treatment plant and is usually removed by sedimentation or filtration. Granular activated carbon is usually employed after filtration just prior to postdisinfection and is operated in a fixed-bed mode. Granular activated carbon is also used in the upper layer of

dual- or multimediuim filters or as a substitute for conventional granular filter media.

The discussion that is presented in the following sections is intended to provide an introduction to adsorption processes and methods used for the design of PAC and GAC systems. The topics discussed include (1) development of the adsorption phenomena; (2) manufacture, regeneration, and reactivation; (3) fundamentals of adsorption; (4) development of isotherms and equations used to describe adsorption equilibrium; (5) applications using PAC; and (6) applications using GAC.

## 15-1 Introduction to Adsorption Phenomena

To provide a perspective for the material to be presented in this chapter, the historical development of adsorption processes and present applications of adsorption materials in water treatment is discussed in this section.

### Adsorption Phenomena

The constituent that undergoes adsorption onto a surface is referred to as the *adsorbate*, and the solid onto which the constituent is adsorbed is referred to as the *adsorbent*. During the adsorption process, dissolved species are transported into the porous solid adsorbent granule by diffusion and are then adsorbed onto the extensive inner surface of the adsorbent. Dissolved species are concentrated on the solid surface by chemical reaction (chemisorption) or physical attraction (physical adsorption) to the surface. Physical adsorption and chemisorption mechanisms are listed in Table 15-1. Physical adsorption is a rapid process caused by nonspecific

**Table 15-1**

Comparison of adsorption mechanisms between physical adsorption and chemisorption

Parameter	Physical Adsorption	Chemisorption
Use for water treatment	Most common type of adsorption mechanism	Rare in water treatment
Process speed	Limited by mass transfer	Variable
Type of bonding	Nonspecific binding mechanisms such as van der Waals forces, vapor condensation	Specific exchange of electrons, chemical bond at surface
Type of reaction	Reversible, exothermic	Typically nonreversible, exothermic
Heat of adsorption	4–40 kJ/mol	>200 kJ/mol

binding mechanisms such as van der Waals forces and is similar to vapor condensation or liquid precipitation. Physical adsorption is reversible, that is, the adsorbate desorbs in response to a decrease in solution concentration. Physical adsorption is the most common mechanism by which adsorbates are removed in water treatment.

The physical adsorption process is exothermic with a heat of adsorption that is typically 4 to 40 kJ/mol (about two times greater than the heat of vaporization or dissolution for gases and liquids, respectively). Chemisorption is more specific because a chemical reaction occurs that entails the transfer of electrons between adsorbent and adsorbate, and a chemical bond with the surface can occur. The heat of adsorption for chemisorption is typically above 200 kJ/mol. Chemisorption is usually not reversible, and desorption, if it occurs, is accompanied by a chemical change in the adsorbate. What is commonly referred to as “irreversible adsorption” is chemisorption because the adsorbate is chemically bonded to the surface. While physical adsorption and chemisorption can be distinguished easily at their extremes, some cases fall between the two, as a highly unequal sharing of electrons may not be distinguishable from the high degree of distortion of an electron cloud that occurs with physical adsorption (Adamson, 1982; Kipling, 1965; Satterfield, 1980). Because most water treatment applications involve physical adsorption, physical adsorption mechanisms are discussed in greater detail in this chapter.

Modern purification of water supplies by adsorption has a short history as compared to other processes, although the use of adsorption has been reported in a 4000-year-old Sanskrit text (Sontheimer et al., 1988). Adsorption was first observed in solution by Lowitz in 1785 and was soon applied as a process for removal of color from sugar during refining (Hassler, 1974). In the latter half of the nineteenth century, charcoal adsorbents (charcoal is not activated and contains underdeveloped pores) were used in U.S. water treatment plants (Croes, 1883). The first GAC units for treatment of water supplies were constructed in Hamm, Germany, in 1929 and Bay City, Michigan, in 1930. In the 1920s, Chicago meat packers used PAC to remove taste and odor in water supplies that were contaminated by chlorophenols (Baylis, 1929). Powdered activated carbon was first used in municipal water treatment in New Milford, New Jersey, in 1930 and its use became widespread in the next few decades, primarily for taste and odor control.

During the mid-1970s, interest in adsorption as a process for removal of organics from drinking water was heightened because the public became increasingly concerned about water sources that were contaminated by industrial wastes, agricultural chemicals, and municipal discharges. Another major concern was the formation of DBPs during chlorination of water containing background organic matter (referred to as DBP precursors).

## Historical Development

It has been found that activated carbon can be effective in removing some of the DBP precursors.

### Applications of Adsorption Materials

Three types of commercially available adsorbents merit consideration in water treatment: zeolites, synthetic polymeric adsorbents, and activated carbon. Most activated carbons have a wide range of pore sizes and can accommodate large organic molecules such as natural organic matter (NOM) and synthetic organic compounds (SOCs) such as pesticides, solvents, and fuels. Synthetic polymeric adsorbents usually have only micropores, which prevents them from adsorbing NOM. Zeolites (aluminosilicates with varying Al-to-Si ratios) tend to have very small pores, which will exclude some synthetic organic compounds. Granular ferric hydroxide and iron-impregnated GACs have been developed to remove arsenic. Ammonia-treated GAC has been used to increase the adsorption capacity of GAC for bromated and perchlorate, and it is likely that this would increase GAC adsorption capacity for other anionic species; however, there are no commercially available GACs. Properties of several commercially available adsorbents are reported in Table 15-2.

Porous adsorbents can have a large internal surface area (400 to 1500 m<sup>2</sup>/g) and pore volume (0.1 to 0.8 mL/g) and as a result can have an adsorption capacity as high as 0.2 g of adsorbate per gram of adsorbent,

**Table 15-2**  
Properties of several commercially available adsorbents

Adsorbent	Manufacturer	Type	Surface Area, m <sup>2</sup> /g (BET) <sup>a</sup>	Packed Bed Density, g/cm	Pore Volume, cm <sup>3</sup> /g
Filtrisorb 300 (8×30)	Calgon	GAC	950–1050	0.48	0.851
Filtrisorb 400	Calgon	GAC	1075	0.4	1.071
CC-602	US Filter/Wastates	Coconut-shell-based GAC	1150–1250	0.47–0.52	0.564

<sup>a</sup>BET is the Brunauer, Emmett, and Teller method for measuring surface area based on gas (usually nitrogen) adsorption. Source: Adapted from Sontheimer et al. (1988), Crittenden (1976), Lee et al. (1981), Munakata et al. (2003), and Sigma\_Aldrich Online Catalog (2004).

depending on the adsorbate concentration and type. Synthetic polymeric resins, zeolites, and activated alumina have been used in water treatment applications, but activated carbon is the most commonly used adsorbent because it is much less expensive than the alternatives. Activated carbon is manufactured from natural, carbonaceous materials such as coal, peat, and coconuts by several inexpensive processes (e.g., high temperatures  $\sim 800^{\circ}\text{C}$  and steam). Consequently, most of the discussion in this chapter centers on the use of activated carbon; where appropriate, alternative adsorbents are discussed. Activated carbon is available in essentially two particle size ranges: PAC (mean particle size 20 to 50  $\mu\text{m}$ ) and GAC (mean particle size 0.5 to 3 mm). The principal uses, advantages, and disadvantages of using PAC versus GAC are reported in Table 15-3.

At present, the applications of adsorption in water treatment in the United States are predominantly for taste and odor control. In a 1984 survey, 29 percent of the water utilities used PAC (AWWA, 1986), and in a 1989 survey it was reported that 63 percent of the water plants used PAC and 7 percent used GAC for taste and odor control (Suffet et al., 1996). Currently, it is thought that about 90 percent of the surface water treatment plants worldwide use PAC on a seasonable basis (Hansen, 1975; Sontheimer, 1976). In 1996, there were 300 GAC surface water plants and

**Table 15-3**

Principal uses, advantages, and disadvantages of granular and powdered activated carbon

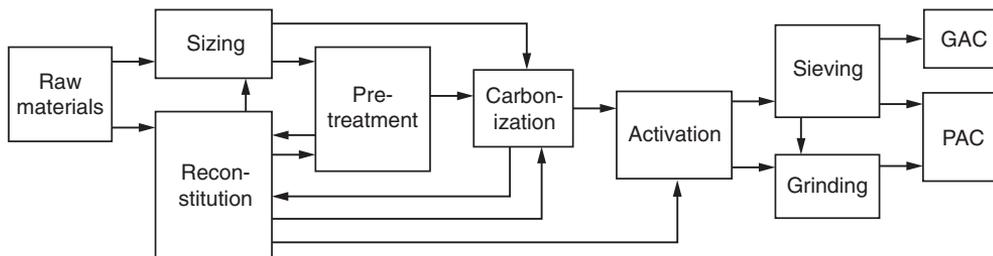

Parameter	Granular Activated Carbon (GAC)	Powdered Activated Carbon (PAC)
Principal uses	<ul style="list-style-type: none"> <li><input type="checkbox"/> Control of toxic organic compounds that are present in groundwater</li> <li><input type="checkbox"/> Barrier to occasional spikes of toxic organics in surface waters and control of taste and odor compounds</li> <li><input type="checkbox"/> Control of disinfection by-product precursors or DOC</li> </ul>	<ul style="list-style-type: none"> <li><input type="checkbox"/> Seasonal control of taste and odor compounds and strongly adsorbed pesticides and herbicides at low concentration (<math>&lt;10 \mu\text{g/L}</math>)</li> </ul>
Advantages	<ul style="list-style-type: none"> <li><input type="checkbox"/> Easily reactivated</li> <li><input type="checkbox"/> Lower carbon usage rate per volume of water treated as compared to PAC</li> </ul>	<ul style="list-style-type: none"> <li><input type="checkbox"/> Easily added to existing water intakes or coagulation facilities for occasional control of organics</li> </ul>
Disadvantages	<ul style="list-style-type: none"> <li><input type="checkbox"/> Need contactors and yard piping to distribute flow and replace exhausted carbon</li> <li><input type="checkbox"/> Previously adsorbed compounds can desorb and in some cases appear in the effluent at concentrations higher than present in influent</li> </ul>	<ul style="list-style-type: none"> <li><input type="checkbox"/> Hard to reactivate and impractical to recover from sludge from coagulation facilities</li> <li><input type="checkbox"/> Much higher carbon usage rate per volume of water treated as compared to GAC</li> </ul>

several hundred groundwater plants (Snoeyink, 2001). European water treatment plants have had longer experience using GAC to remove SOC<sub>s</sub> in water from polluted rivers (Sontheimer et al., 1988). In the future, it is expected that the removal of low concentrations of toxic or carcinogenic compounds using adsorption technology will increase.

For continuous removal of SOC<sub>s</sub> (e.g., pesticides, herbicides, trichloroethylene, tetrachloroethylene, benzene), GAC is preferred because much less GAC is needed than if PAC was used (details provided later in this chapter). In most cases, SOC<sub>s</sub> are present at concentrations of 1 to 500 µg/L, and the background organic matter concentration ranges from 0.5 to 20 mg/L of dissolved organic carbon (DOC), with typical values of 1 to 3 mg/L DOC. Because the background DOC concentration is so high relative to SOC<sub>s</sub>, SOC<sub>s</sub> are sometimes referred to as micropollutants. There are two principal application scenarios for the removal of SOC<sub>s</sub> by GAC: (1) removal of organics from contaminated groundwaters and (2) as a barrier against spikes of organics that occur in susceptible water supplies such as the Ohio and Mississippi Rivers. Contaminated groundwaters typically have a consistent (10 to 300 µg/L) and most often declining concentration of SOC<sub>s</sub>. Surface waters typically have very low concentrations of SOC<sub>s</sub> (most often below the maximum contaminant levels) with occasional spikes of SOC<sub>s</sub> due to spills or the seasonal application of pesticides and herbicides.

## 15-2 Manufacture, Regeneration, and Reactivation of Activated Carbon

The production of activated carbon consists of the pyrolytic carbonization of the raw material and the subsequent or parallel activation. During the carbonization step, volatile components are released and graphite is formed. Further, the carbon realigns to form a pore structure that is developed during the activation process. In the activation step, carbon is removed selectively from an opening of closed porosity and the average size of the micropores is increased. A generalized flow diagram for the production of both GAC and PAC is shown on Fig. 15-1.

**Figure 15-1**  
General flow scheme for production of activated carbon.

**Manufacture from  
Raw Materials**

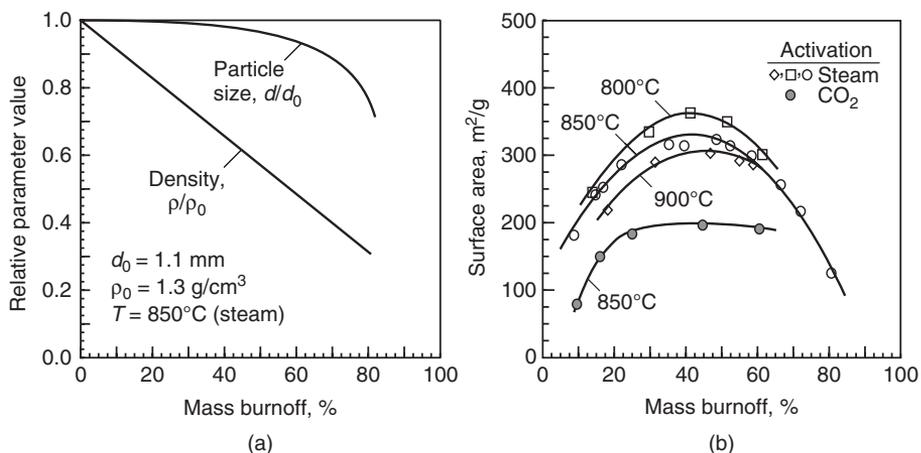

The most direct production method involves sizing of the raw materials, carbonization, activation, and sieving of the product. The direct production method can be applied to coconut shells, relatively hard coals, and materials to be used as powdered carbons. Reconstitution and pretreatment are normally required for peat, lignite, petrol coke, and bituminous coals. For bituminous coals, pretreatment is necessary to control the loss of microporosity during carbonization due to swelling and softening of the coal.

In practice, activated carbon is produced by either chemical or physical activation. Chemical activation is normally utilized for raw materials that contain cellulose and combines the carbonization and activation steps. Dehydrating chemicals, such as zinc chloride or phosphoric acid, are added to the raw materials at elevated temperatures. The resulting product is then heated pyrolytically (causing a degradation of the cellulose) and cooled, and the activating agent is then extracted. Carbons produced using this method are of low density and, without special treatment, have a low proportion of micropores, which makes them less suitable for use in the removal of micropollutants and odor-causing substances.

Carbons that are produced for water treatment utilize an endothermic thermal activation process that involves the contacting of a gaseous activating agent, typically steam, with the char at elevated temperatures, typically 850 to 1000°C. Thermal activation causes a slight reduction in the size of the adsorbent grain due to external oxidation as the oxidizing gas diffuses into the unactivated internal domain of the carbon. While the rudimentary pore structure is determined by the raw material or occasionally by pretreatment, the type of activating agent, and the length and temperature of activation can have a major influence on the adsorbent properties, as shown on Fig. 15-2. The decrease in particle density and particle size for increasing mass burnoff is shown on Fig. 15-2a. The effect of increasing mass burnoff on adsorbent surface area per weight of original char can be seen on Fig. 15-2b for activation with steam at three temperatures and with CO<sub>2</sub> at one temperature.

For most thermally activated carbons, a maximum surface area per weight of original char is found at about 40 to 50 percent mass burnoff. Activation up to this point opens closed pores and enlarges existing pores, resulting in a net increase in surface area. Continued activation beyond this point results in a net surface area decrease as most closed pores are now open and pore walls are burned away (Jüntgen, 1968, 1976; Walker, 1986). As will be shown in Example 15-1, for a given pore volume the surface area decreases with increasing pore size and the concomitant development of more pore volume and large pore sizes gives rise to the trends displayed on Fig. 15-2b.

The types of base materials can influence the distribution of the pores. For the purpose of classifying pore sizes (diameter  $D_p$ ), the International

**Figure 15-2**

Impact of mass burnoff of coal-based carbon on (a) apparent particle density and particle diameter and (b) surface area per weight of original char at three temperatures and with two gases. (Adapted from Hashimoto et al., 1979.)

Union of Pure and Applied Chemistry (IUPAC) uses the following convention:

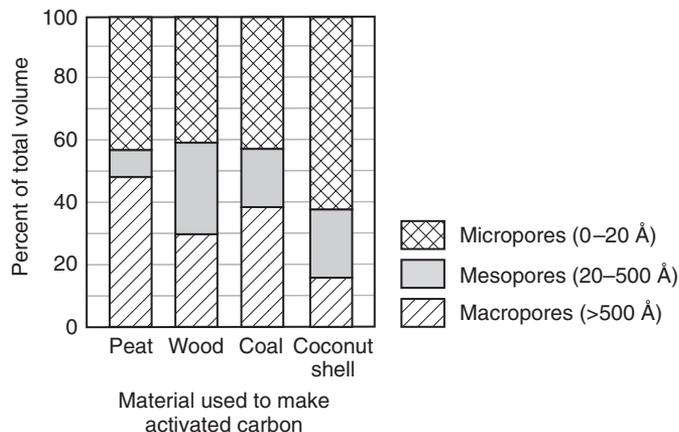

Micropores:  $d_p < 2$  nm.

Mesopores:  $2 \text{ nm} < d_p < 50$  nm.

Macropores:  $50 \text{ nm} < d_p$ .

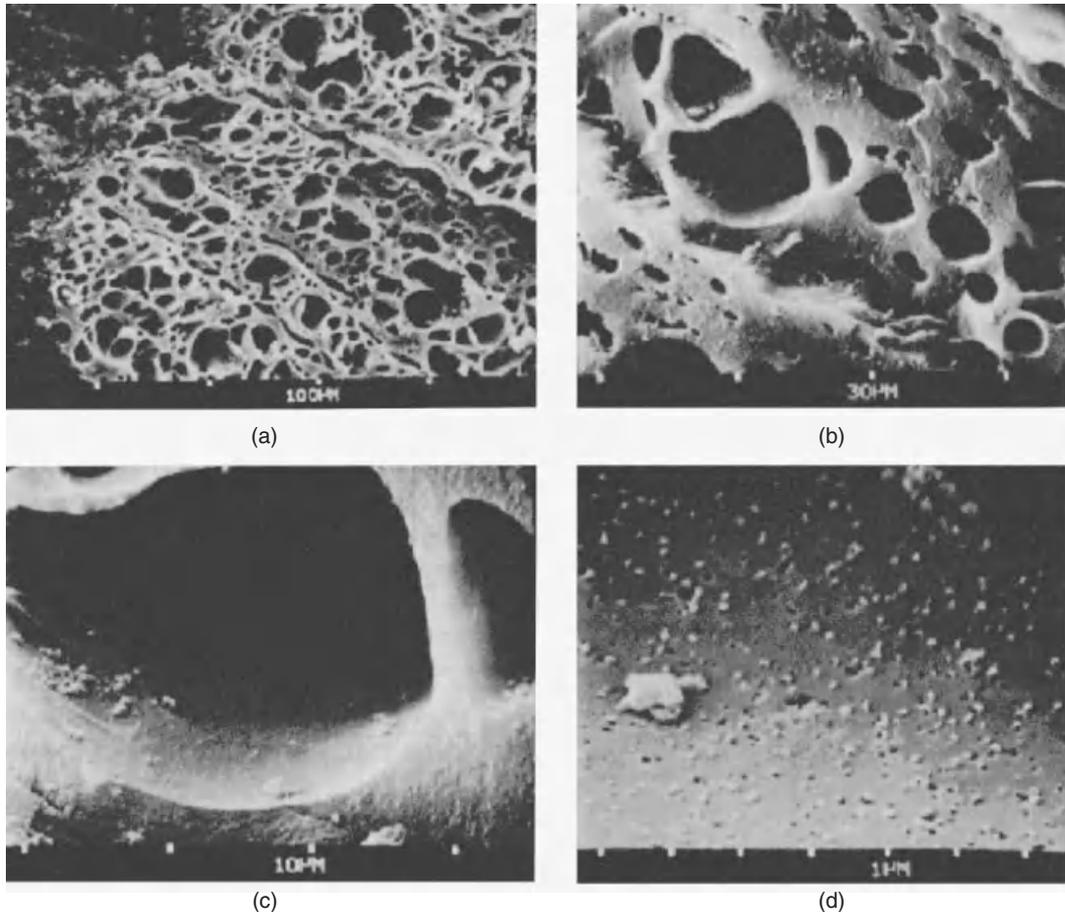

Coconut shell carbons are considered a microporous carbon because the majority of their total void volume is micropores, as shown on Fig. 15-3. Wood-based carbons have a more even distribution of micro-, meso-, and macropores.

The macropore structure of a lignite-based carbon with increasing magnification is displayed on Fig. 15-4. In the scanning electron micrograph

**Figure 15-3**

Pore size distributions for activated carbons with different starting materials.

**Figure 15-4**

Scanning electron micrographs for lignite-based activated carbon. The scale line for all the SEMs is the interval between the white marks (clockwise starting in the upper left the scales are 100, 30, 10, and 1  $\mu\text{m}$ ).

(SEM) shown on Fig. 15-4a, both the external surface and the largest macropores with sizes ranging from about 30 nm to 0.3  $\mu\text{m}$  are visible. In the SEM image shown on Fig. 15-4d, pores with a size of 50 nm are branching off of the large pore, which is also shown under different magnifications on Figs. 15-4b and 15-4c. At all magnification levels pores of different sizes are visible, and even at the greatest magnification small pores can be seen branching off from the large pores.

When the adsorption capacity of the activated carbon has been exhausted, it must be removed from the contactor and replaced with fresh or reactivated carbon. *Regeneration* occurs when adsorbed solute molecules are removed from the carbon surface through desorption in their original

**Regeneration  
and Reactivation  
of Spent GAC**

or a modified state with no change in the carbon surface. Methods of regeneration that have been proposed include thermal, physicochemical, and biologically induced regeneration. *Reactivation* of GAC involves restoration of the adsorption capacity through partial desorption of the solute molecules and then the burnoff of carbonaceous residual on the carbon surface. Reactivation conditions are similar to those in the manufacturing of activated carbon by thermal activation, where part of the carbon surface can be burned off during the process. A summary of regeneration and reactivation methods is presented in Table 15-4.

Regeneration of water treatment carbons is seldom practiced because complete restoration of the adsorption capacity cannot be achieved. In water treatment, the concentrations of even volatile solutes are very low, and humic substances and other large molecular weight compounds, not volatilized under conditions of thermal regeneration, make regeneration of water treatment carbons ineffective. Further, because spent carbon that is reactivated at a central facility is typically commingled with other spent carbons, reactivation is seldom used unless large quantities of carbon are involved. Onsite reactivation facilities only make economic sense if carbon usage is greater than 150,000 kg/yr (Sontheimer et al., 1988). Because regeneration and reactivation are not used in water treatment practice, these subjects are not considered further in this chapter. Detailed information on regeneration and reactivation may be found in Sontheimer et al. (1988).

### 15-3 Fundamentals of Adsorption

---

Knowledge of the fundamental phenomena and factors involved in the adsorption process will provide a basis for understanding the PAC and GAC processes and the process design considerations. The adsorption process on a molecular level and the interactions between the adsorbing compound and the adsorbent and how these interactions are impacted by physical and chemical forces within and surrounding the adsorbing compound and the adsorbent are discussed in this section.

#### **Interfacial Equilibria for Adsorption and Other Solute Surface Phenomena**

In aqueous solution, three interactions compete when considering physical adsorption: (1) adsorbate–water interactions, (2) adsorbate–surface interactions, and (3) water–surface interactions. The extent of adsorption is determined by the strength of adsorbate–surface interactions as compared to the adsorbate–water and water–surface interactions. Adsorbate–surface interactions are determined by surface chemistry, and adsorbate–water are related to the solubility of the adsorbate. Water–surface interactions are determined by the surface chemistry, for example, a graphitic surface is hydrophobic and oxygen containing functional groups are hydrophilic. For

**Table 15-4**

Carbon losses can be as high as 12%</li> </ul>

chemisorption, the primary factor controlling the extent of reaction is the type of reaction that occurs on the surface. In either case, it is important to provide enough surface area for adsorption. The volumetric filling of small pores is also important.

The surface area and pore size are important factors that determine the number of adsorption sites and the accessibility of the sites for adsorbates. Generally, there is an inverse relationship between the pore size and surface area: the smaller the pores for a given pore volume, the greater the surface area that is available for adsorption. In addition, the size of the adsorbate that can enter a pore is limited by the pore size of the adsorbent, and is referred to as steric effects. The relationship between pore size and surface area is shown in Example 15-1.

The porosity of adsorbents generally does not exceed 50 percent, partly due to the manufacturing process and the skeletal strength of the adsorbent. If adsorbents become very porous, they become brittle and break apart when transported into and out of adsorption vessels, which can result in significant adsorbent losses and expense.

There are three interfaces involved in adsorption: adsorbate–adsorbent, adsorbate–water, and water–adsorbent. The forces active at each of these interfaces are summarized in Table 15-5. Some of the forces that occur between the adsorbent surface and adsorbates are illustrated on Fig. 15-5.

### Important Factors Involved in Adsorption

### Surface Chemistry and Forces Involved in Adsorption

#### CHEMICAL ADSORPTION

Chemical adsorption, or chemisorption, occurs when the adsorbate reacts with the surface to form a covalent bond or an ionic bond. In chemisorption,

**Table 15-5**

Summary of forces that are active at the three interfaces involved in adsorption

Force	Approximate Energy of Interaction, kJ/mol	Interface		
		Adsorbate/Adsorbent	Adsorbate/Water	Water/Adsorbent
Coulombic repulsion	>42	Yes	No	No
Coulombic attraction	>42	Yes	No	No
Ionic species–neutral species attraction		Yes	No	No
Covalent bonding	>42	Yes	No	No
Ionic species–dipole attraction	<8	Yes	Yes	Yes

### Example 15-1 Determination of surface area

Determine the surface area of an adsorbent that has a bulk porosity of 50 percent, particle density of  $1 \text{ g/cm}^3$ , and pore sizes (diameters) of 1 and 5 nm. Assume the pore shape is cylindrical in the quantification of surface area and pore volume.

#### Solution

1. Develop a relationship for the ratio of surface area to pore volume for the adsorbent.
  - a. The volume of cylindrical pores in an adsorbent,  $V_{\text{ad}}$  ( $\text{m}^3/\text{g}$ ), can be computed based on the number of pores  $n$  (no./g), the pore radius  $R$  (m), and the pore height  $H$  (m):

$$V_{\text{ad}} = n\pi R^2 H$$

- b. The surface area of pores in an adsorbent,  $A_{\text{ad}}$  ( $\text{m}^2/\text{g}$ ), is also determined assuming a cylindrical pore shape:

$$A_{\text{ad}} = 2n\pi R H$$

- c. The surface area–pore volume ratio for the adsorbent,  $A_{\text{ad}}/V_{\text{ad}}$ , can now be written by combining the expressions developed in steps 1a and 1b:

$$\frac{A_{\text{ad}}}{V_{\text{ad}}} = \frac{2}{R}$$

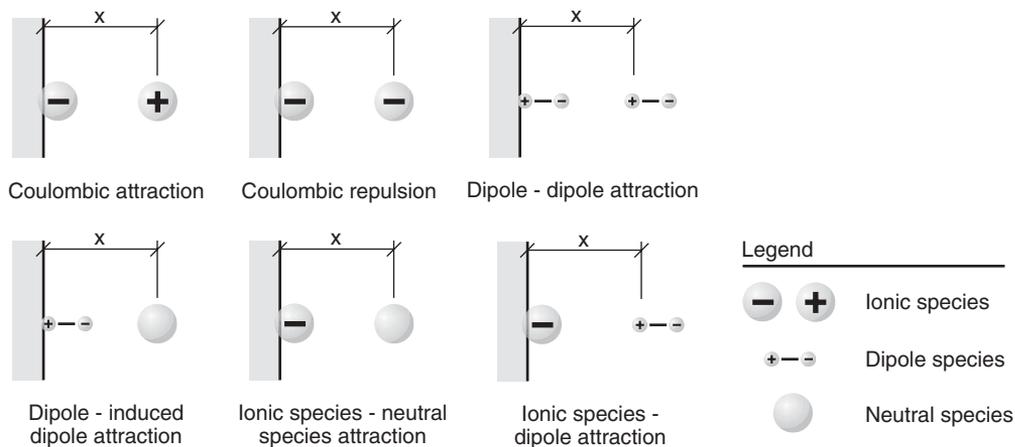

2. Determine the surface area for adsorbents with pore sizes of 1 and 5 nm.
  - a. Compute the adsorbent volume using the porosity and adsorbent density provided in the problem statement. By definition, porosity = pore volume/total volume, so 1 g of adsorbent with a porosity of 0.5 would have a total volume of  $1 \text{ cm}^3$  and a pore volume of  $0.5 \text{ cm}^3$ . Therefore  $V_{\text{ad}} = 0.5 \text{ cm}^3/\text{g}$ .

- b. For a pore diameter  $d_p = 1.0 \text{ nm} = 10 \times 10^{-8} \text{ cm}$ ,

$$\begin{aligned} A_{\text{ad}} &= V_{\text{ad}} \frac{2}{d_p/2} = (0.5 \text{ cm}^3/\text{g}) \frac{2}{(10 \times 10^{-8} \text{ cm})/2} \\ &= 20,000,000 \text{ cm}^2/\text{g} \quad (2000 \text{ m}^2/\text{g}) \end{aligned}$$

- c. For a pore diameter  $d_p = 5.0 \text{ nm} = 50 \times 10^{-8} \text{ cm}$ ,

$$\begin{aligned} A_{\text{ad}} &= V_{\text{ad}} \frac{2}{d_p/2} = (0.5 \text{ cm}^3/\text{g}) \frac{2}{(50 \times 10^{-8} \text{ cm})/2} \\ &= 4,000,000 \text{ cm}^2/\text{g} \quad (400 \text{ m}^2/\text{g}) \end{aligned}$$

**Figure 15-5**  
Surface functional groups and forces of attraction.

the attraction between adsorbent and adsorbate approaches that of a covalent or electrostatic chemical bond between atoms, with shorter bond length and higher bond energy. Adsorbates bound by chemisorption to a surface generally cannot accumulate at more than one molecular layer because of the specificity of the bond between adsorbate and surface. The bond may also be specific to particular sites or functional groups on the surface of the adsorbent. The charged surface groups attract the opposite charges and repel like charges according to Coulomb's law, as discussed in Chap. 16.

#### PHYSICAL ADSORPTION

Adsorbates are said to undergo physical adsorption if the forces of attraction include only physical forces that exclude covalent bonding with the surface and coulombic attraction of unlike charges. In some cases, the difference between physical adsorption and chemisorption may not be that distinct. Physical adsorption is less specific for which compounds sorb to surface sites, has weaker forces and energies of bonding, operates over longer distances (multiple layers), and is more reversible.

In water treatment there is often interest in the adsorption of organic adsorbates from water (polar solvent) onto a nonpolar adsorbent (activated carbon). Because activated carbon has crosslinked graphitic crystallite planes that form micropores, the major attractive force between organics and the adsorbent is van der Waals forces that exist between organic compounds and the graphitic carbon basal planes.

In general, attraction between an adsorbate and polar solvent is weaker for adsorbates that are less polar or have lower solubility. The attraction between an adsorbate and activated carbon surface increases with increasing

polarizability and size, which are directly related to van der Waals forces. More nonpolar and larger compounds tend to adsorb more strongly to nonpolar adsorbents such as activated carbon. This form of adsorption is also known as hydrophobic bonding (Nemethy and Scheraga, 1962); hydrophobic (“disliking water”) compounds will adsorb on carbon more strongly.

#### **ADSORBABILITY OF VARIOUS CLASSES OF COMPOUNDS**

Applying what is known about the adsorption of organics to determine their adsorbability requires consideration of the summation of the interactions and forces described above. Because these interactions and forces are not readily measurable, in a general sense they can be related to some properties of the adsorbate and solvent. For example, solubility is a direct indication of adsorption strength or magnitude of the adsorption force. The lower the solubility of an adsorbate in the solvent, the higher the adsorption strength. Adsorption strength is inversely proportional to solubility. Unfortunately, all other factors are different for different classes of organics (e.g., aliphatic, aromatic, or polar compounds); consequently, solubility alone is not the only indicator of adsorbability. For example, water–adsorbent interactions are only important for adsorption onto polar or ionized surface functional groups, as discussed below. To make more specific statements regarding adsorbability, polar, neutral, and charged compounds must be considered separately.

##### *Polar species*

Polar organics and adsorbates with ionic functional groups will not be removed from water because water–adsorbate forces will be strong and polar functional groups on the adsorbent surface will attract water to the surface. The adsorption of acids and bases on nonpolar adsorbents such as activated carbon depends strongly on pH. The adsorption of neutral forms is generally much stronger (Getzen and Ward, 1969), and the pH of maximum adsorbability depends on the particular dissociation constant of the acid or base. Furthermore, pH affects the charge on activated carbon, which generally tends to be negative at neutral pH and neutral in the pH range of 4 to 5. From a practical point of view, most ionic organics are negatively charged and adsorbents are negatively charged at neutral pH. Thus, lowering the pH to less than 4 to 5 increases adsorbability but is not practical from an operational perspective.

##### *Neutral species*

Neutral organics are strongly held to nonpolar surfaces such as the graphitic surface of activated carbon. The adsorbate–water interaction force is related to the solubility. The adsorbate–adsorbent interaction force is related to the polarizability, which is related directly to the size of the organic compound. The adsorbent–water interactions are related to how many water molecules

must be pulled away from the surface of the adsorbent (the attractive force in this case is a dipole–neutral species interaction) and, in turn, how many water molecules must be removed from the surface of the adsorbent to make room for the adsorbate. Adsorbability is related to the size of the organic compound. Consequently, the adsorbability of neutral organics increases with increasing polarizability and molecule size and decreases with increasing solubility.

#### *Ionic species*

With respect to adsorption of inorganics onto inorganic adsorbents, one class of chemical bonding to specific surface sites is the acid–base reaction at a functional group. An example is the reaction of hydrated metal ions from solution with hydroxide sites on metal oxides (Parks, 1975):

where MeOH = metal ion adsorbate

SOH = hydroxide site on metal oxide adsorbent

Studies comparing theory and experimental evidence for this specific chemical bonding that have relevance to water treatment for removing heavy metals by adsorption onto silicon and aluminum-oxide-based clays and sands are available (James and Healy, 1972; Parks, 1967).

For adsorption of ionic species to surfaces, the most important mechanism is electrostatic attraction, which is highly dependent on pH and ionic strength. This mechanism is described in Chap. 9 for forces controlling coagulation and in Chap. 16 for the process of ion exchange. Adsorption of electrolytes onto metal oxide adsorbents can be used to control heavy metals, fluoride, and a few other minerals.

## 15-4 Development of Isotherms and Equations Used to Describe Adsorption Equilibrium

---

The affinity of the adsorbate for an adsorbent is quantified using adsorption isotherms, which are used to describe the amount of adsorbate that can be adsorbed onto an adsorbent at equilibrium and at a constant temperature. For most applications in water treatment, the amount of adsorbate adsorbed is usually a function of the aqueous-phase concentration and this relationship is commonly called an isotherm. Several researchers have presented procedures, protocols, and problems associated with performing adsorption equilibrium isotherms (Crittenden et al., 1987b; Luft, 1984; Randtke and Snoeyink, 1983; Summers, 1986).

Adsorption isotherms are performed by exposing a known quantity of adsorbate in a fixed volume of liquid to various dosages of adsorbent. To prevent the loss of adsorbate in situations where the adsorbate is volatile,

adsorbs onto the container, and is light sensitive, amber glass bottles (250 to 1000 L) with Teflon screw caps are used for aqueous-phase isotherms. If the adsorbent is granular, it is powdered (<200 mesh or <0.074 mm), washed, and dried to a moisture-free constant weight and stored in a sealed container in a dessicator before using. Approximately 12 headspace free bottles (no air voids in bottle) are used with various dosages of adsorbent and allowed to equilibrate in a rotating tumbler at 25 rev/min at a constant temperature for a period of no less than 6 days. At the end of the equilibration period, the aqueous-phase concentration of the adsorbate is measured and the adsorption equilibrium capacity is calculated for each bottle using the mass balance expression

$$q_e = \frac{V}{M} (C_0 - C_e) \quad (15-2)$$

where  $q_e$  = equilibrium adsorbent-phase concentration of adsorbate, mg adsorbate/g adsorbent

$C_0$  = initial aqueous-phase concentration of adsorbate, mg/L

$C_e$  = equilibrium aqueous-phase concentration of adsorbate, mg/L

$V$  = volume of aqueous phase added to bottle, L

$M$  = mass of adsorbent, g

Equations developed by Langmuir, Freundlich, and Brunauer, Emmet, and Teller (BET isotherm) are used to describe the equilibrium capacity of adsorbents. A discussion of these isotherm expressions is presented following Example 15-2.

### Example 15-2 Determination of adsorption isotherm

A trichloroethene (TCE) isotherm was performed on Calgon F400 GAC. A total of 25 isotherm points were determined using 250-mL amber bottles with Teflon-lined screw caps. The dosage of GAC varied in each bottle. The GAC used was powdered from virgin stock GAC, washed, and dried to a constant weight before use. Pure TCE was added to a solution containing organic free laboratory water to yield a TCE initial concentration of about 10,000  $\mu\text{g/L}$ . The weight of the bottles and the caps were recorded prior to filling the bottles with the GAC dosage and the TCE solution. The bottles were filled headspace free to prevent any TCE from volatilizing out of solution. A total of eight extra empty bottles were filled and allowed to equilibrate. The extra bottles were used as blanks to measure the initial concentration used in the isotherm. All the bottles were placed on a rotating device and rotated at 25 rev/min for a period of 14 days. The bottles were then removed from the tumbler and the carbon was allowed to settle for a few hours, and a sample

was drawn from each bottle and the TCE concentration was analyzed using a gas chromatograph.

Based on the raw data given below, calculate the average initial liquid-phase concentration from the equilibrated blanks and the equilibrium adsorbent-phase concentration. Plot the corresponding values of  $q_e$  and  $C_e$  on arithmetic and log–log paper to determine the nature of the distribution. A summary of the GAC dosages, solution volume, and equilibrated blanks is provided below.

Experimental data:

- Carbon type: F-400
- Temperature: 13°C
- Chemical: trichloroethene
- pH: 6.8
- Carbon size: 200 × 400

Sample No.	Dosage $M$ , g	Volume $V$ , mL	TCE Liquid-Phase Concentration $C_e$ , $\mu\text{g/L}$

16	0.03956	252.3	1109.1
17	0.03315	251.5	1476.9
18	0.02696	255.1	2699.8
19	0.02189	254.6	3271.9
20	0.01609	253.0	4858.4
21	0.01072	251.7	6263.2
22	0.00544	251.5	8427.3
23	0.00343	252.3	10009.8
24	0.00164	252.9	9875.5
25	0.06273	253.0	352.6

□ Equilibrated blank data:

Sample No.	Equilibrated Blank $C_0$ , $\mu\text{g/L}$
1	10,486
2	8,401
3	11,355
4	10,205
5	10,415
6	12,912
7	12,025
8	11,123

### Solution

1. Calculate the average initial TCE aqueous-phase concentration in micrograms per liter:

$$C_0 = \frac{10,486 + 8,401 + 11,355 + 10,205 + 10,415 + 12,912 + 12,025 + 11,123}{8}$$

$$= 10,865 \mu\text{g/L}$$

2. Calculate the equilibrium adsorbent-phase concentration in micrograms per gram. Equation 15-2 can be used to calculate the adsorbent-phase TCE concentration. The required computations for sample 1 is shown below:

$$q_e = \frac{V}{M} (C_0 - C_e) = \frac{V}{M} [(10,865 - C_e) \mu\text{g/L}]$$

$$q_e(1) = \frac{V(1)}{M(1)} [10,865 - C_e(1)] = \frac{0.2471 \text{ L}}{0.44254 \text{ g}} [(10,865 - 3) \mu\text{g/L}]$$

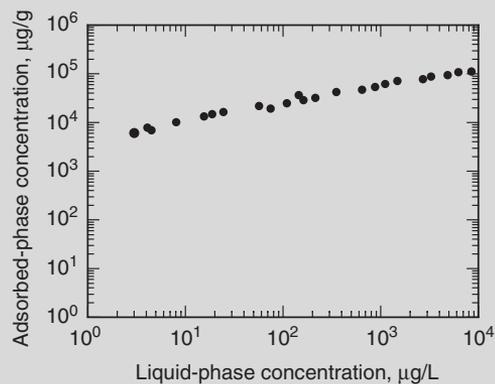

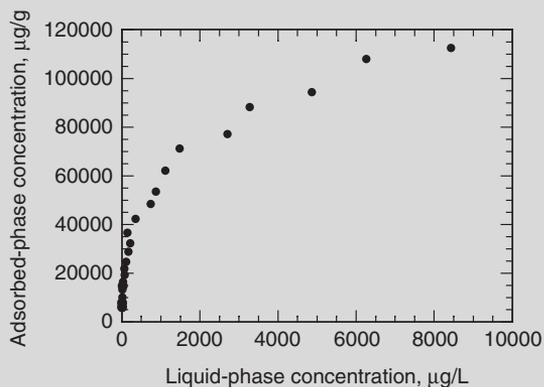

$$= 6065 \mu\text{g/g}$$

The  $q_e$  values are summarized in the following table:

Sample No.	TCE Aqueous-Phase Concentration $C_e$ , $\mu\text{g/L}$	TCE Adsorbent-Phase Concentration $q_e$ , $\mu\text{g/g}$
1	3	6065.0
2	4.5	6995.0
3	4.1	7966.0
4	8.1	10231.0
5	15.5	13309.0

Sample No.	TCE Aqueous-Phase	TCE Adsorbent-Phase
	Concentration $C_e, \mu\text{g/L}$	Concentration $q_e, \mu\text{g/g}$
6	18.9	14877.8
7	24.5	16496.4
8	74.3	19374.7
9	57.0	21945.6
10	109.0	24776.4
11	162.5	28944.6
12	213.6	32390.3
13	144.9	36699.6
14	643.1	47728.9
15	872.6	53643.6
16	1,109.1	62221.6
17	1,476.9	71227.2
18	2,699.8	77263.3
19	3,271.9	88317.9
20	4,858.4	94452.8
21	6,263.2	108054.9
22	8,427.3	112712.7
25	352.6	42339.3

3. Plot the TCE isotherm data on arithmetic and log–log paper.

4. Based on the above plots, the isotherm is linear on a log–log plot.

### Langmuir Isotherm Equation

The Langmuir adsorption isotherm is used to describe the equilibrium between surface and solution as a reversible chemical equilibrium between species (Langmuir, 1918). The adsorbent surface is made up of fixed individual sites where molecules of adsorbate may be chemically bound.

The following reaction describes the relationship between vacant surface sites and adsorbate species and adsorbate species bound to surface sites:

where  $S_V$  = vacant surface sites, mmol/m<sup>2</sup>  
 $A$  = adsorbate species A in solution, mmol  
 $SA$  = adsorbate species bound to surface sites, mmol/m<sup>2</sup>

In the Langmuir expression it is assumed that the reaction has a constant free-energy change ( $\Delta G_{\text{ads}}^\circ$ ) for all sites (see Chap. 5). Further, each site is assumed to be capable of binding at most one molecule of adsorbate; that is, the Langmuir model allows accumulation only up to a monolayer. Accordingly, the equilibrium condition may be written as

$$K_{\text{ad}} = \frac{SA}{S_V C_A} = e^{-\Delta G_{\text{ads}}^\circ/RT} \quad (15-4)$$

where  $K_{\text{ad}}$  = Langmuir adsorption equilibrium constant, L/mg  
 $C_A$  = equilibrium concentration of adsorbate A in solution, mg/L  
 $\Delta G_{\text{ads}}^\circ$  = free-energy change for adsorption, J/mol  
 $R$  = universal gas constant, 8.314 J/mol · K  
 $T$  = absolute temperature, K (273 + °C)

The expression shown in Eq. 15-4 is not a convenient way to express the amount adsorbed as a function of concentration because there are two unknowns,  $S_V$  and  $C_A$ . However, this problem can be eliminated if the total numbers of sites are fixed:

$$S_T = S_V + SA = \frac{SA}{K_{\text{ad}} C_A} + SA \quad (15-5)$$

where  $S_T$  = total number of sites available or monolayer coverage, mol/m<sup>2</sup>

Rearranging and solving for  $SA$  yields

$$SA = \frac{S_T}{1 + 1/(K_{\text{ad}} C_A)} = \frac{K_{\text{ad}} C_A S_T}{1 + K_{\text{ad}} C_A} \quad (15-6)$$

The concentration of occupied sites that are expressed as mmol/m<sup>2</sup> is not particularly useful in mass balances; mass loading per mass of adsorbent is much more useful. Multiplying both sides of Eq. 15-6 by the surface area

per gram and molecular weight, Eq. 15-6 can be expressed in terms of a mass loading  $q$ :

$$q_A = (SA)(A_{ad})(MW) = \frac{K_{ad} C_A S_T A_{ad} MW}{1 + K_{ad} C_A} = \frac{Q_M K_{ad} C_A}{1 + K_{ad} C_A} \quad (15-7)$$

$$= \frac{Q_M b_A C_A}{1 + b_A C_A} \quad (15-8)$$

where  $q_A$  = equilibrium adsorbent-phase concentration of adsorbate A,  
mg adsorbate/g adsorbent (see Eq. 15-2)

$A_{ad}$  = surface area per gram of adsorbent,  $m^2/g$

MW = molecular weight of adsorbate, g/mol

$C_A$  = equilibrium concentration of adsorbate A in solution, mg/L

$Q_M$  = maximum adsorbent-phase concentration of adsorbate  
when surface sites are saturated with adsorbate,  $S_T A_{ad} MW$ ,  
mg adsorbate/g adsorbent

$b_A$  = Langmuir adsorption constant of adsorbate A,  $K_{ad}$ , L/mg

It is convenient to rearrange Eq. 15-8 to a linear form:

$$\frac{C_A}{q_A} = \frac{1}{b_A Q_M} + \frac{C_A}{Q_M} \quad (15-9)$$

A plot of  $C_A/q_A$  versus  $C_A$  using Eq. 15-9 results in a straight line with slope of  $1/Q_M$  and intercept  $1/b_A Q_M$ .

The Freundlich adsorption isotherm (Freundlich, 1906), originally proposed as an empirical equation, is used to describe the data for heterogeneous adsorbents such as activated carbon:

$$q_A = K_A C_A^{1/n} \quad (15-10)$$

where  $K_A$  = Freundlich adsorption capacity parameter,  
(mg/g) (L/mg) $^{1/n}$

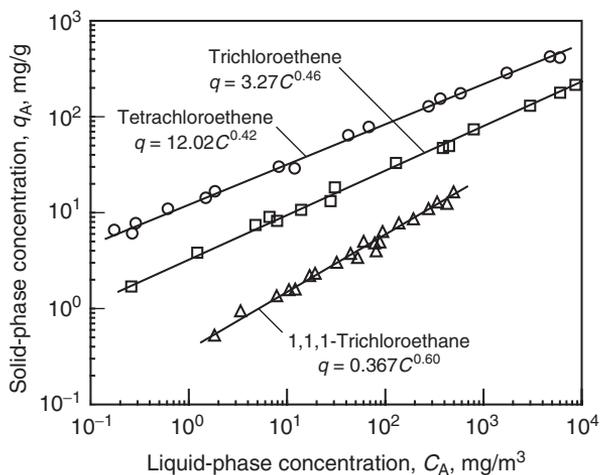

$1/n$  = Freundlich adsorption intensity parameter, unitless

The linear form of Eq. 15-10 is

$$\log(q_A) = \log(K_A) + \left(\frac{1}{n}\right) \log(C_A) \quad (15-11)$$

A log-log plot of  $q_A$  versus  $C_A$  using the form shown in Eq. 15-11 will result in a straight line, as shown on Fig. 15-6 for tetrachloroethene, TCE, and 1,1,1-trichloroethane. While it is possible to graph the data on a log-log plot and determine the Freundlich parameters, nonlinear regression should be used and all data should be weighted according to their precision (Sontheimer et al., 1988). If the logs of  $q_A$  and  $C_A$  are taken and linear regression is

**Freundlich  
Isotherm  
Equation**

**Figure 15-6**

Single-solute isotherms for tetrachloroethene, trichloroethene, and 1,1,1-trichloroethane over a wide concentration range (Zimmer et al., 1988).

applied, more consideration is given to all data, but it does not weight all the data equally.

The Freundlich equation is consistent with the thermodynamics of heterogeneous adsorption (Halsey and Taylor, 1947). The Freundlich equation can be derived using the Langmuir equation to describe the adsorption onto sites of a given free energy and considering the following two assumptions: (1) the site energies for adsorption follow a Boltzmann distribution and the mean site energy is  $\Delta H_M^\circ$ , and (2) the change in site entropy increases linearly with increasing site enthalpy –  $\Delta H_{ad}^\circ$  and the proportionality constant is  $r$ . Based on this development,  $1/n$  will depend on temperature, as shown by the expression

$$n = \frac{\Delta H_M^\circ}{RT} - \frac{r\Delta H_{ad}^\circ}{R} \quad (15-12)$$

where  $\Delta H_M^\circ$  = mean site energy, J/mol  
 $R$  = universal gas constant, 8.314 J/mol · K  
 $\Delta H_{ad}^\circ$  = change in site enthalpy, J/mol  
 $T$  = absolute temperature, K (273 + °C)  
 $r$  = proportionality constant

The Freundlich isotherm equation always provides a better fit to the isotherm data for GAC than the Langmuir equation because many layers of adsorbates can adsorb to the GAC and there is distribution of sites with different adsorption energies. Examples of Freundlich isotherm parameters are shown in Table 15-6, and the procedure for determining Langmuir and Freundlich isotherm parameters is demonstrated in Example 15-3.

### Example 15-3 Determination of Freundlich and Langmuir isotherm parameters

For the experimental isotherm data given below, determine the Freundlich and Langmuir isotherm parameters. Apply linear regression to determine the isotherm parameters. A spreadsheet can be used for this purpose.

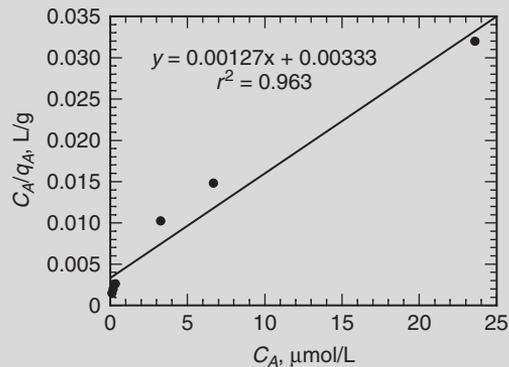

Experimental data:

- Carbon type: F-400
- Carbon size: 200 × 400
- Chemical: Trichloroethene
- Temperature: 13°C
- pH: 7.5–8
- Equilibrium time: 31 days

Sample number	TCE Liquid-Phase Concentration $C_A$ , $\mu\text{mol/L}$	TCE Adsorbent-Phase Concentration $q_A$ , $\mu\text{mol/g}$
1	23.6	737
2	6.67	450
3	3.26	318
4	0.322	121
5	0.169	85.2
6	0.114	75.8

#### Solution

1. Determine Langmuir isotherm parameters.
  - a. For the Langmuir equation, the plot of  $C_A/q_A$  versus  $C_A$  along with the Langmuir isotherm fit obtained from a spreadsheet using linear regression is shown in the following figure:

- b. The Langmuir parameters are obtained by comparing Eq. 15-9 with the results of the linear regression as shown in the above plot.

$$\text{slope} = \frac{1}{Q_M} = 0.00127 \text{ g}/\mu\text{mol}$$

$$Q_M = 787.4 \text{ } \mu\text{mol}/\text{g}$$

$$Q_M = (787.4 \text{ } \mu\text{mol}/\text{g})(131.39 \text{ } \mu\text{g}/\mu\text{mol}) = 1.03 \times 10^5 \text{ } \mu\text{g}/\text{g}$$

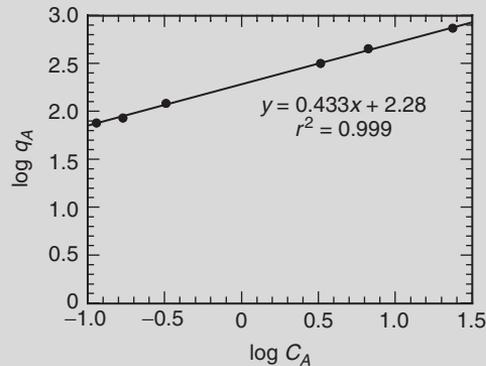

$$\text{intercept} = \frac{1}{b_A Q_M} = 0.00333 \text{ g}/\text{L}$$

$$b_A = \frac{1}{(0.00333 \text{ g}/\text{L})(787.4 \text{ } \mu\text{mol}/\text{g})} = 0.381 \text{ L}/\mu\text{mol}$$

$$b_A = \frac{0.381 \text{ L}/\mu\text{mol}}{131.39 \text{ } \mu\text{g}/\mu\text{mol}} = 2.90 \times 10^{-3} \text{ L}/\mu\text{g}$$

2. Determine Freundlich isotherm parameters.

- a. The Freundlich isotherm plot using linear regression is shown in the following figure:

- b. The isotherm parameters are obtained by comparing Eq. 15-10 with the results of the linear regression as shown in the above plot.

$$\frac{1}{n} = \text{slope} = 0.43$$

$$\log K = \text{intercept} = 2.28$$

$$K = 190 \frac{\mu\text{mol}}{\text{g}} \left( \frac{\text{L}}{\mu\text{mol}} \right)^{0.43}$$

$$\begin{aligned}
 &= 190 \frac{\mu\text{mol}}{\text{g}} \times \frac{131.39 \mu\text{g}}{\mu\text{mol}} \times \frac{1 \text{ mg}}{1000 \mu\text{g}} \\
 &\quad \times \left( \frac{\text{L}}{\mu\text{mol}} \times \frac{\mu\text{mol}}{131.39 \mu\text{g}} \times \frac{1000 \mu\text{g}}{1 \text{ mg}} \right)^{0.43} \\
 &= 59.92 \frac{\text{mg}}{\text{g}} \left( \frac{\text{L}}{\text{mg}} \right)^{0.43}
 \end{aligned}$$

**Comment**

The Freundlich isotherm equation provides a better fit of the data than the Langmuir model.

### Brunauer– Emmett– Teller Isotherm Equation

The BET adsorption isotherm (Brunauer et al., 1938) extends the Langmuir model from a monolayer to several molecular layers. Above the monolayer, each additional layer of adsorbate molecules is assumed to equilibrate with the layer below it, and layers of different thickness are allowed to coexist. To develop the BET equation, the adsorption of the first layer is described using Eq. 15-8. Equation 15-8 is also used to describe the adsorption in subsequent layers by assuming that the free-energy change for layers 2 and higher is equal to the free energy of precipitation and not equal to  $\Delta G_{\text{ads}}^{\circ}$ . The basic assumption is that the first layer adsorbs according to forces between the adsorbent and adsorbate and subsequent layers adsorb as if they were forming precipitating layers  $\Delta G_{\text{prec}}^{\circ}$ . The resulting equation is

$$\frac{q_A}{Q_M} = \frac{B_A C_A}{(C_{S,A} - C_A)[1 + (B_A - 1)(C_A/C_{S,A})]} \quad (15-13)$$

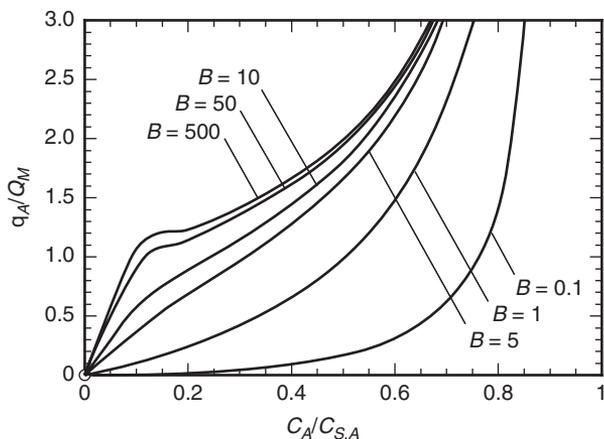

$$B_A = \frac{K_{1,\text{ad}}}{K_{i,\text{ad}}} = \frac{e^{-\Delta G_{\text{ads}}^{\circ}}}{e^{-\Delta G_{\text{prec}}^{\circ}}} \quad (15-14)$$

where

- $q_A$  = equilibrium adsorbent-phase concentration of adsorbate A, mg adsorbate/g adsorbent
- $Q_M$  = maximum adsorbent-phase concentration of adsorbate when surface sites are saturated with adsorbate, mg adsorbate/g adsorbent
- $K_{1,\text{ad}}$  = equilibrium constant for first layer, L/mg
- $K_{i,\text{ad}}$  = equilibrium constant for subsequent layers, L/mg
- $B_A$  = ratio of  $K_{1,\text{ad}}$  and  $K_{i,\text{ad}}$
- $C_A$  = equilibrium concentration of adsorbate A in solution, mg/L
- $C_{S,A}$  = saturated solution concentration of A, mg/L
- $\Delta G_{\text{ads}}^{\circ}$  = free energy of adsorption, J/mol
- $\Delta G_{\text{prec}}^{\circ}$  = free energy of precipitation, J/mol

Here,  $B_A$  is greater than 1 because  $-\Delta G_{\text{ads}}^{\circ}$  is greater than  $-\Delta G_{\text{prec}}^{\circ}$ . The BET isotherm has the general form shown on Fig. 15-7, with surface concentration reaching a plateau as the monolayer is filled, then increasing again with increasing  $C_A$ .

In the Langmuir model, it is assumed that the site energy for adsorption is the same for all surface sites and does not depend on degree of coverage and that the largest capacity corresponds to only one monolayer. These assumptions are not valid for most adsorbents because, for example, activated carbon has a wide range of pore sizes that continue to adsorb organics as the concentration increases. While the BET isotherm does allow for multiple layers, it is assumed in the BET equation that site energy is the same for the first layer and equal to the free energy of precipitation

**Figure 15-7**

The BET isotherm for different values of  $B$  (capacity/monolayer capacity,  $q/Q$ , as function of degree of saturation).

for subsequent layers. In reality, the site energy of adsorption varies widely for most adsorbents because adsorbents, such as activated carbon, are very heterogeneous and the site energy varies considerably with surface coverage. The single-solute data that are displayed on Fig. 15-6 cannot be described with either the BET or Langmuir equations. The Freundlich equation is used to describe isotherm data for heterogeneous adsorbents (varying site energies) and does a much better job describing the data than the Langmuir or BET equations.

Because there are many organic compounds of health concern in drinking water treatment and there are also many different commercially activated carbon adsorbents to choose from, the chances that isotherms are available for all compounds on a given adsorbent are small. Engineers are then faced with either performing the isotherm experiments on the compound and adsorbent of interest or using some existing correlations to estimate the isotherm parameters. In preliminary design phases, engineers may use correlations to estimate isotherm parameters to evaluate the feasibility of using adsorption. A method for estimating isotherms and isotherm parameters for organic compounds onto activated carbon adsorbents based on the Polanyi potential theory is presented in the following discussion.

### Polanyi Correlation for Liquids

#### POLANYI POTENTIAL THEORY

Polanyi potential theory (Polanyi, 1916) has been used to correlate adsorption isotherms of volatile organic compounds in air (Grant and Manes, 1964, 1966; Reucroft et al., 1971; Tang, 1986). In addition, it has also been used to correlate aqueous-phase adsorption of a wide variety of compounds (Crittenden et al., 1999; Greenbank and Manes, 1981, 1982, 1984). While complicated forms of this theory exist, only the simplest form

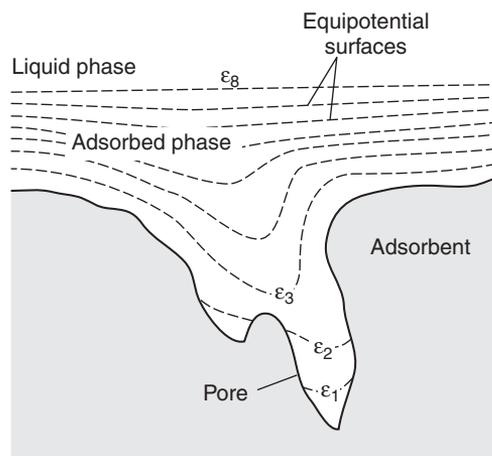

is presented here because of the many adjustable parameters required for various compound classes (Sontheimer et al., 1988; Crittenden et al., 1999).

The following assumptions are made in Polanyi potential theory: (1) a fixed pore volume exists that is close to the adsorbent surface where adsorption occurs; (2) the adsorptive forces originate from London–van der Waals interactions; and (3) adsorbing molecules will concentrate at high-energy sites on the adsorbent surfaces and undergo enhanced precipitation within the pores of the adsorbent. Polanyi defines the adsorption potential  $\varepsilon$  as the work or free energy required for any molecule to move from the bulk solution to the adsorption space assuming the adsorbed state is a saturated solution. If the displacement of the adsorbed fluid (water) is ignored, the following equation for  $\varepsilon$  may be obtained (Polanyi, 1916):

$$\varepsilon = RT \ln\left(\frac{C_s}{C}\right) \quad (15-15)$$

where  $\varepsilon$  = adsorption potential, J/mol  
 $R$  = universal gas constant, 8.314 J/mol · K  
 $T$  = absolute temperature, K (273 + °C)  
 $C_s$  = aqueous solubility of adsorbate, mg/L  
 $C$  = concentration of adsorbate in bulk solution, mg/L

Equation 15-15 is used to calculate the minimum energy required to extract a dissolved species in water. As applied,  $\varepsilon$  is assumed to vary from a maximum value close to the adsorbent surface with low bulk solution concentrations to zero when the pores are filled and the solubility limit is reached in the bulk solution (see Fig. 15-8).

**Figure 15-8**  
 Schematic model of aqueous adsorption with equipotential surfaces.

**ADSORPTION PARAMETERS DERIVED FROM POLANYI THEORY**

A correlation can be developed to obtain adsorption parameters by plotting the volume adsorbed versus the adsorption potential. The adsorption potential needs to be divided by a normalizing physical property accounting for the major cause for adsorption. Previous researchers have used a number of normalizing physical properties such as molar volume, polarizability, and parachlor. For application of Polanyi potential theory to a wide variety of compounds in which more adjustable parameters are used to improve the correlation, it is necessary to consult the literature (Crittenden et al., 1999; Greenbank and Manes, 1981, 1982, 1984).

For several liquid aromatic and chlorinated alkanes and alkenes, Crittenden et al. (1987b) found that molar volume  $V_m$  was the best normalizing physical property. Accordingly, the correlation using  $V_m$  can be described by the equation

$$q = \rho_l W = \rho_l W_0 \exp \left[ -\beta \left( \frac{\varepsilon}{V_m} \right)^\sigma \right] \quad (15-16)$$

$$\ln q = \ln (\rho_l W) = -\beta \left( \frac{\varepsilon}{V_m} \right)^\sigma + \ln (\rho_l W_0) \quad (15-17)$$

where  $q$  = adsorbent-phase concentration of adsorbate, mg  
adsorbate/g adsorbent  
 $\rho_l$  = liquid density of adsorbate, g/L  
 $W$  = volume of adsorbate adsorbed on adsorbent, mL  
adsorbate/g adsorbent  
 $W_0$  = maximum volume of adsorbate adsorbed on adsorbent, mL  
adsorbate/g adsorbent  
 $\beta$  = Polanyi constant determined for particular adsorbent,  
(L/J) $^\sigma$   
 $\varepsilon$  = adsorption potential, J/mol  
 $V_m$  = molar volume of adsorbate, L/mol  
 $\sigma$  = Polanyi constant determined for particular adsorbent,  
unitless

For liquids, it has been found that  $\rho_l$  could be taken as the liquid density (Crittenden et al., 1987b). To obtain a correlation for solids and liquids, correlations were proposed for  $\rho_l$ , and it has been demonstrated that data for a wide variety of compounds could be correlated (Greenbank and Manes, 1981, 1982, 1984).

Isotherms were conducted with solutes that are listed in Table 15-7 on Calgon's Filtrasorb 400 carbon. The concentration range, equilibration time, and 95 percent confidence limits for the isotherms have been reported (Crittenden et al., 1985). Isotherms with F400 carbon plotted as volume adsorbed versus adsorption potential divided by the molar volume are shown on Fig. 15-9. The data essentially fall on a straight line with a small curvature at low adsorption potentials.

**Table 15-7**Experimental and predicted Freundlich isotherm parameters for F400 carbon<sup>a</sup>

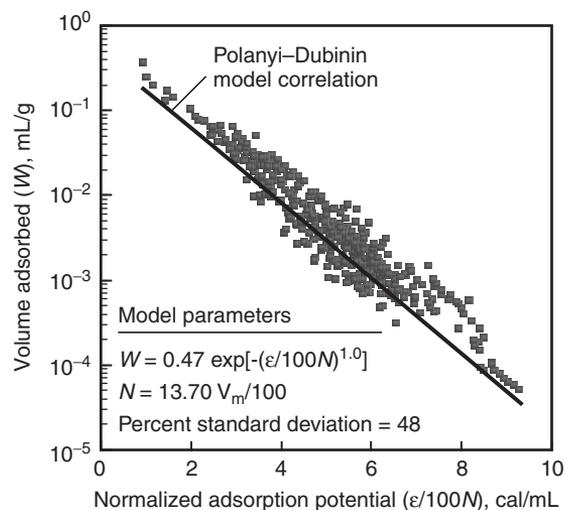

Compound	Freundlich <i>K</i> Value [(mmol/kg) (m <sup>3</sup> /mmol) <sup><i>n</i></sup> ]			1/ <i>n</i> Value

**Figure 15-9**

Correlation of aqueous adsorption isotherm data, using the Polanyi potential theory for isotherms, for halogenated aliphatic organic compounds on F-400 using molar volume as a normalizing factor. The best-fit line was obtained by weighting all of the data equally (adapted from Crittenden et al., 1999). The individual compounds studied are shown on Fig. 2 of the original paper, along with a discussion of appropriate methods of data analysis.

To demonstrate the utility of Eq. 15-16, the Freundlich *K* and 1/*n* values were calculated from the correlation curve and the liquid density and solubility of the solute. Based on the results presented in Table 15-7, if the data are fitted by Eq. 15-16, a reasonable approximation of the Freundlich parameters can be obtained from the correlation. When using the correlation, it is important to recognize that the Freundlich *K* and

$1/n$  values depend on the liquid-phase concentration; consequently, the appropriate concentration range must be used to estimate  $K$  and  $1/n$ . As expected,  $1/n$  increases with decreasing concentration, and this is considered in Eq. 15-15.

For hydrophobic compounds, plotting the volume adsorbed versus adsorption potential divided by the molar volume may correlate isotherm data, and the error associated with estimating isotherm capacity may be generally low. In the case of other classes of compounds such as ketones and alcohols, the error may be larger and more testing may be required to obtain accurate predictions. The correlation shown on Fig. 15-9 is valid only for F-400 GAC. A similar approach has been used for other adsorbents, and some of the Polanyi parameters are summarized in Table 15-8.

#### DETERMINATION OF FREUNDLICH PARAMETERS USING POLANYI THEORY

For the correlation shown in Eq. 15-17, when the value of  $\sigma$  is 1.0, the following equations can be used to directly calculate the Freundlich single-solute  $K$  and  $1/n$  parameters:

$$\frac{1}{n} = \frac{\beta RT \rho_s}{MW} \quad (15-18)$$

$$K = \frac{W_0 \rho_s}{(C_s)^{1/n}} \quad (15-19)$$

where  $\rho_s$  = liquid density of adsorbate, g/L  
 MW = molecular weight of adsorbate, g/mol  
 $R$  = universal gas constant, 8.314 J/mol · K  
 $T$  = absolute temperature, K (273 + °C)  
 $C_s$  = aqueous-phase solubility of adsorbate, mg/L

**Table 15-8**

Summary of various observed Polanyi potential parameters for selected adsorbents

Adsorbent	$W_0$ , cm <sup>3</sup> /g	$\beta$ , mL/J <sup><math>\sigma</math></sup>	$\sigma$
Ambersorb 563, Rohm and Haas	0.3815	0.001974	1.366

APA, Calgon Carbon	1.53	0.01020	1.169
WV-G (12 × 40), Westvaco	2.994	0.02261	1.00

If the value of  $\sigma$  is not 1.0, then the following procedure must be used to determine the Freundlich  $K$  and  $1/n$  parameters. For the aqueous-phase concentration range of interest, Eq. 15-16 is used to calculate the volume adsorbed for several liquid phase values in that range. The  $q$  values are determined by multiplying each value of  $W$  by the liquid density (make certain the mass units are consistent). Constructing a plot in which the values of  $C$  and  $q$  are fit using the Freundlich isotherm equation results in the parameters  $K$  and  $1/n$ . The procedure used to determine the isotherm parameters is demonstrated in Example 15-4.

### Example 15-4 Estimate isotherm parameters using the Polanyi potential theory

Using Calgon Filtrasorb 400 GAC and a water temperature of 10°C, calculate the Freundlich isotherm parameters for TCE using Polanyi potential theory.

#### Solution

1. Summarize the available information. From Table 15-8, the Polanyi parameters for Calgon Filtrasorb 400 (12 × 40) are  $W_0 = 0.63 \text{ cm}^3/\text{g}$ ,  $\beta = 0.0049 \text{ (mL/J)}^\sigma$ ,  $\sigma = 1.208$ . From a handbook of physical and chemical properties, the following properties for TCE were obtained:  $V_m = 88.6 \text{ mL/mol}$ ,  $\rho_l = 1480 \text{ kg/m}^3$ , and  $C_s = 821 \text{ mg/L}$ .
2. Choose several TCE liquid-phase concentrations that span the desired range of liquid-phase concentrations that will be observed in the fixed-bed adsorber. Typically, a spread of two orders of magnitude on either side of the expected average influent is desirable. If the expected influent concentration is 1 mg/L, the following values for  $C$  are selected:

$$C = 0.01, 0.1, 1.0, 10, 100 \text{ mg/L}$$

3. Calculate the adsorption potential of the liquid-phase concentrations using Eq. 15-15. The required calculations for  $C = 1 \text{ mg/L}$  are shown below:

$$\begin{aligned} \varepsilon &= RT \ln \left( \frac{C_s}{C} \right) \\ &= (8.314 \text{ J/mol} \cdot \text{K})(283 \text{ K}) \ln \left( \frac{821 \text{ mg/L}}{1.0 \text{ mg/L}} \right) \\ &= 15,789 \text{ J/mol} \end{aligned}$$

4. Calculate  $q$  using the  $V_m$  correlation shown in Eq. 15-16.
- a. Calculate  $\varepsilon/V_m$  for each adsorption potential. The required calculations for  $C = 1$  mg/L are shown below:

$$\begin{aligned}\frac{\varepsilon}{V_m} &= \frac{15,789 \text{ J/mol}}{88.6 \text{ mL/mol}} \\ &= 178.2 \text{ J/mL}\end{aligned}$$

- b. Calculate the volume adsorbed for each liquid-phase concentration. The required calculations for  $C = 1$  mg/L are shown below:

$$\begin{aligned}W &= W_0 \exp \left[ -\beta \left( \frac{\varepsilon}{V_m} \right)^\sigma \right] \\ &= (0.63 \text{ cm}^3/\text{g}) \exp \left[ -0.00490(\text{mL/J})^{1.208} (178.2 \text{ J/mL})^{1.208} \right] \\ &= 0.0484 \text{ cm}^3/\text{g}\end{aligned}$$

- c. Calculate  $q$  for each liquid-phase concentration. The required calculations for  $C = 1$  mg/L are shown below:

$$\begin{aligned}q &= W \times \rho_l \\ &= (0.0484 \text{ cm}^3/\text{g})(1480 \text{ kg/m}^3) \left( \frac{1 \text{ m}^3}{10^6 \text{ cm}^3} \right) (10^6 \text{ mg/kg}) \\ &= 71.6 \text{ mg TCE/g adsorbent}\end{aligned}$$

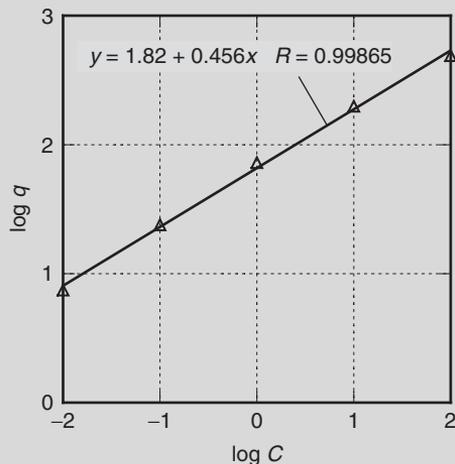

5. Calculate the log of  $q$  and  $C$ . The required calculations for  $C = 1$  mg/L are shown below:

$$\log(q) = \log(71.6) = 1.86 \quad \log(C) = \log(1.00) = 0.0$$

6. Tabulate log  $q$  and log  $C$ . Make a table of several log  $q$  and log  $C$  values spanning at least two orders of magnitude on either side of the expected average liquid-phase influent concentration.

<b>C,</b> <b>mg/L</b>	<b><math>\varepsilon</math>,</b> <b>J/mol</b>	<b><math>\varepsilon/V_m</math>,</b> <b>J/mL</b>	<b>W,</b> <b>cm<sup>3</sup>/g</b>	<b>q,</b> <b>mg/g</b>	<b>log q</b>	<b>log C</b>
0.01	26,624	300.5	0.0051	7.5	0.87	-2
0.1	21,207	239.4	0.0161	23.9	1.38	-1
1	15,789	178.2	0.0484	71.6	1.86	0
10	10,371	117.1	0.1344	199.0	2.30	1
100	4,954	55.9	0.3346	495.3	2.69	2

7. Construct a plot of  $\log q$  as a function of  $\log C$ . The required plot is shown below:

8. Determine the Freundlich isotherm parameters by linear regression:

$$\text{Slope} = \frac{1}{n} = 0.46 \quad \text{Y intercept} = 1.82 = \log K$$

$$K = 66.1 \text{ mg/g (L/mg)}^{1/n}$$

### Comment

The TCE isotherm values calculated using the Polanyi potential theory [ $1/n = 0.46$ ,  $K = 66.1 \text{ mg/g (L/mg)}^{1/n}$ ] compare favorably with the values determined from the isotherm data in Example 15-3 [ $1/n = 0.43$ ,  $K = 60.7 \text{ mg/g (L/mg)}^{1/n}$ ].

## Multicomponent Equilibrium

In water treatment, the ideal case of one adsorbate being removed onto an adsorbent is seldom encountered, and the objective of adsorption in most real systems is to remove several adsorbates. This complicates both the theoretical picture of adsorbates in equilibrium with an adsorbent and the ability of the engineer to apply the theory to practice. The following theory and discussion can elucidate the phenomena of multicomponent adsorption.

Ideal adsorbed solution theory (IAST) has been used successfully to describe the competitive interactions of adsorbates on the surface of adsorbents. To begin, consider the fact that adsorption at an interface causes

a reduction in surface tension. (Surface tension has the units of surface energy per area.) According to Gibbs (1906), this change in surface tension, which represents the two-dimensional work of adsorption, can be related to the amount adsorbed.

$$-A d\sigma_i = A d\pi_i = q_i RT d(\ln C_i) \quad (15-20)$$

where  $A$  = adsorption area per mass unit of adsorbent  
 $d\sigma_i$  = change in surface tension due to adsorption  
 $d\pi_i$  = change in the spreading pressure due to adsorption  
 $d\ln(C_i)$  = change in the natural log of concentration

The spreading pressure is defined as the difference between the surface tension,  $\sigma_i$ , that exists between the interfaces of solid with the pure solvent and with the solution containing the adsorbate (termed sorptive solution below). In the case of an aqueous solution,

$$d\pi_i = -d\sigma_i = \sigma_{\text{Pure Water/Adsorbent}} - \sigma_{\text{Sorptive Solution/Adsorbent}} \quad (15-21)$$

In a sense, the spreading pressure is the tendency of the adsorbate to spread out on the adsorbent surface and lower the surface tension (energy per area) or increase the spreading pressure. Unfortunately, Eq. 15-21 cannot be used to develop single-solute isotherms because it cannot quantify the change in the surface tension at the solution/adsorbent interface. (However, Eq. 15-21 can be used to estimate how much surfactant will concentrate at the air–water interface because we can measure the change in surface tension due to the addition of a surfactant.) The Gibbs isotherm can be used to extend single-solute isotherms to describe multicomponent isotherms using IAST because one can estimate the change in spreading pressure from single-solute isotherms. The IAST makes the following assumptions: (1) single-component concentrations,  $C_i^\circ$ , are in equilibrium with the spreading pressure of the mixture and (2) the single-component concentration,  $C_i$ , that is in equilibrium with the mixture is equal to the product of the mole fraction of component  $i$  in the mixture and  $C_i^\circ$ . This is a surface—solution version of Raoult's law. The five basic equations for IAST are:

$$q_T = \sum_{i=1}^N q_i \quad (15-22)$$

$$z_i = \frac{q_i}{q_T} \quad (15-23)$$

$$C_i = z_i C_i^\circ \quad (15-24)$$

$$\frac{1}{q_T} = \sum_{i=1}^N \frac{z_i}{q_i^\circ} \quad (15-25)$$

$$\frac{\pi_m A}{RT} = \frac{\pi_i A}{RT} = \int_0^{q_i^\circ} \frac{d \ln C_i^\circ}{d \ln q_i^\circ} dq_i^\circ \quad (15-26)$$

where  $q_T$  = total surface loading  
 $q_i$  = single component solid phase loading  
 $z_i$  = mole fraction of component  $i$  on the adsorbent surface  
 $C_i$  = concentration of solute  $i$  in multicomponent system, mg/g  
 $C_i^\circ$  = concentration of solute  $i$  in single solute system, mg/g  
 $A$  = adsorption area per mass unit of adsorbent, m<sup>2</sup>/g  
 $\pi_i$  = spreading pressure of component  $i$ , Pa

Equation 15-24 is analogous to Raoult's law because the mixture concentration is equal to the surface mole fraction times the single component concentration, which is identical to the spreading pressure of the mixture;  $q_i^\circ$  is the single component solid-phase loading that corresponds to the spreading pressure of the mixture. Equation 15-25 states that there is no area change per mole upon mixing in the mixture as compared to the single-solute isotherms, which are evaluated at the spreading pressure of the mixture. Equation 15-26 equates the spreading pressures of the pure component systems to the spreading pressure of the mixture.

If the Freundlich isotherm equation is used to represent single-solute behavior in Eq. 15-26, then the following expression can be obtained:

$$n_i q_i = n_j q_j \quad j = 2 \text{ to } N \quad (15-27)$$

By means of algebraic manipulation, the IAST for a Freundlich isotherm single-solute isotherm is obtained:

$$C_i = \frac{q_i}{\sum_{j=1}^N q_j} \left[ \frac{\sum_{j=1}^N n_j q_j}{n_i K_i} \right]^{n_i} \quad (15-28)$$

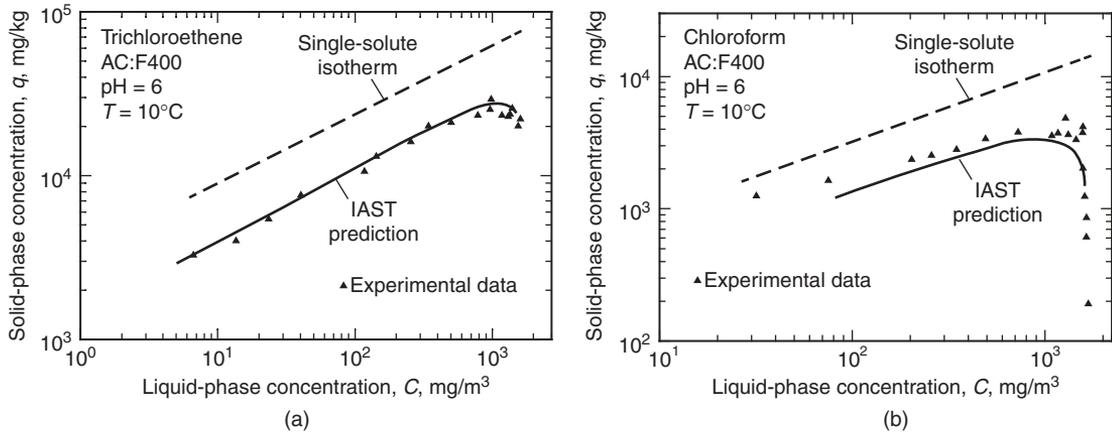

The following expression is another useful form of IAST, which may be derived from Eq. 15-28 by assuming all the  $1/n$  values are identical:

$$q_i = K_i^n C_i \left( \sum_{j=1}^N K_j^n C_j \right)^{1/n-1} \quad (15-29)$$

Crittenden et al. (1985) have compared Eq. 15-28, combined with the following mass balance equation, to data for mixtures of two to six chlorinated aliphatic compounds:

$$q_i = \frac{V}{M} (C_{i,0} - C_i) \quad (15-30)$$

To visualize the difference between the predictions and data, the worst and best predictions are displayed on Figs. 15-10a and 15-10b for trichloroethene and chloroform, respectively.

**Figure 15-10**

Trichloroethene and chloroform single-solute isotherms, isotherms in a six-component mixture, and IAST predictions.

Comparing the dashed lines, which represent the single-solute isotherms to the multicomponent data and predictions, shows the effect of adsorption competition on the adsorption capacity of a particular solute. This displacement is the greatest at high liquid-phase concentrations, that is, at small carbon dosages, because high solid-phase concentrations of the strongly adsorbing components cause more competitive interactions.

One technology that may be used for control of off-gases from stripping operations is gas-phase GAC. The Dubinin–Radushkevich (DR) equation, derived from the Polanyi potential theory, has been shown to describe adsorption isotherms of volatile organic compounds for GAC. Many researchers have shown that this form of the DR equation may be used for correlating data of VOCs:

$$W = W_0 \exp\left(\frac{-B\varepsilon^2}{\mu^2}\right) \quad (15-31)$$

$$\varepsilon = RT \ln\left(\frac{P_s}{P}\right) \quad (15-32)$$

where  $W$  = volume of adsorbate adsorbed on adsorbent, mL  
adsorbate/g adsorbent

$W_0$  = maximum volume of adsorbate adsorbed on adsorbent, mL  
adsorbate/g adsorbent

$B$  = microporosity constant,  $\text{m}^6/\text{J}^2$

$\mu$  = polarizability,  $\text{C} \cdot \text{m}^2/\text{V}$

$\varepsilon$  = adsorption potential, equal to minimum energy to remove  
adsorbate from air and form a liquid or solid precipitate,  
J/mol

**Dubinin–  
Radushkevich  
Correlation for  
Air Stripping  
Off-Gases**

$T$  = absolute temperature, K ( $273 + ^\circ\text{C}$ )

$P_s$  = vapor pressure of adsorbate at  $T$ , Pa

$P$  = partial pressure of adsorbate in gas, Pa

Polarizability appears to be the best normalizing constant for gas-phase adsorption because VOC adsorption appears to be governed primarily by van der Waals force. Unlike adsorption from the aqueous phase, the solvent does not have to be displaced from the adsorbent surface; consequently, polarizability, not molecular size, appears to be the most important factor.

For nonpolar compounds, polarizability can be estimated from the refractive index using the Lorenz–Lorentz equation:

$$\mu = \frac{(\eta^2 - 1)MW}{(\eta^2 + 2)\rho_l} \quad (15-33)$$

where  $\eta$  = refractive index, unitless

MW = molecular weight, g/mol

$\rho_l$  = liquid density of VOC, g/L

Because  $W_0$  and  $B$  in the DR equation are dependent only on the nature of the adsorbent, the relationship between  $W$  and  $\varepsilon/\mu$  is unique for a given adsorbent. The plot of  $W$  versus  $\varepsilon/\mu$  is called the “characteristic curve” and is defined by constant values of  $W_0$  and  $B$  for a given adsorbent. Once the values of  $W_0$  and  $B$  are determined experimentally for an adsorbent, the DR equation 15-31 may be used to predict the adsorption capacity or isotherm for other compounds for that adsorbent. The DR parameters for some widely used gas-phase adsorbents are summarized in Table 15-9.

There are some limitations to the DR equation (Reucroft et al., 1971): (1) It cannot be used to describe equilibrium at relative pressures  $P/P_s$  greater than 0.2 because capillary condensation occurs; (2) it only works for molecules with permanent dipole moments less than 2 debyes (D) because, if the molecule has a larger dipole moment, then dipole induction may be the principal adsorption force rather than van der Waals forces; and (3) it is only valid for relative humidity (RH) values less than when water vapor begins to adsorb, which corresponds to an RF of 40 to 50 percent.

Water vapor can have a large influence on the adsorption capacity of adsorbents such as GAC. When the concentration of the water in the

**Table 15-9**  
 $W_0$  and  $B$  values for various adsorbents

Adsorbent Type	$W_0$ , mL/g	$B$ , cm <sup>6</sup> /J <sup>2</sup>
Calgon BPL (4 × 6 mesh)	0.515	$1.9898 \times 10^{-6}$
Calgon BPL (6 × 16 mesh)	0.460	$1.8478 \times 10^{-6}$
CECA GAC-410G	0.503	$1.300 \times 10^{-6}$

gas stream is high, a phenomenon called capillary condensation takes place where the water vapor will begin to condense in the micropores of the adsorbent. The polar oxygen-containing functional groups, which were discussed above, are responsible for attracting water by dipole–dipole interactions. The condensed water will then reduce the adsorption capacity for VOCs because water that undergoes dipole induction with the carbon surface must be displaced from the surface. For this reason aqueous-phase capacities are about a factor of 10 lower than that of the gas phase. If the off-gas from an air stripper has a relative humidity of 100 percent and is fed to a GAC adsorber, then the pores will fill completely with water and the capacity of the adsorbent will be no greater than that observed for aqueous-phase GAC systems. Furthermore, the rate of adsorption will be reduced by a factor of  $10^5$  because it will proceed by diffusion in water-filled pores rather than by gas diffusion. The relative humidity of air stripping off-gases is usually 100 percent and must be reduced to less than 50 percent to obtain reasonable capacities by heating the off-gas.

## 15-5 Powdered Activated Carbon

---

With a small particle size (mean size about 24  $\mu\text{m}$ ) PAC can be added to water at various locations in the water treatment process to provide time for adsorption to take place and then remove the PAC by sedimentation and/or filtration. The topics considered in this section include the uses of PAC in water treatment, the points of PAC application, and the determination of dosage and how it is related to percent removal.

Powdered activated carbon is primarily used in the treatment of taste and odor compounds and the treatment of low concentrations of pesticides and other organic micropollutants. The convenience of PAC is that it can be employed periodically (when needed) in a conventional water treatment plant with minimum capital costs. For example, PAC can be used during summer months for surface water sources containing taste and odor compounds resulting from algal blooms. It can also be employed to remove chemical pollution (pesticides and herbicides) carried in spring runoff. Discussion of the point of PAC addition in a water treatment train is presented later in this section.

Standard jar testing can be used to evaluate PAC addition in conventional water treatment facilities. Standard jar testing procedures, as discussed in Chap. 9, can be used to determine PAC dosages for use in conventional water treatment plants. A site-specific bench-scale protocol has been developed to predict full-scale PAC performance for geosmin and 2-methyl-isoborneol (MIB) removal (Graham et al., 2000). The steps involved in the protocol

### **Uses of PAC in Water Treatment**

### **Experimental Methods for Determining PAC Dosages**

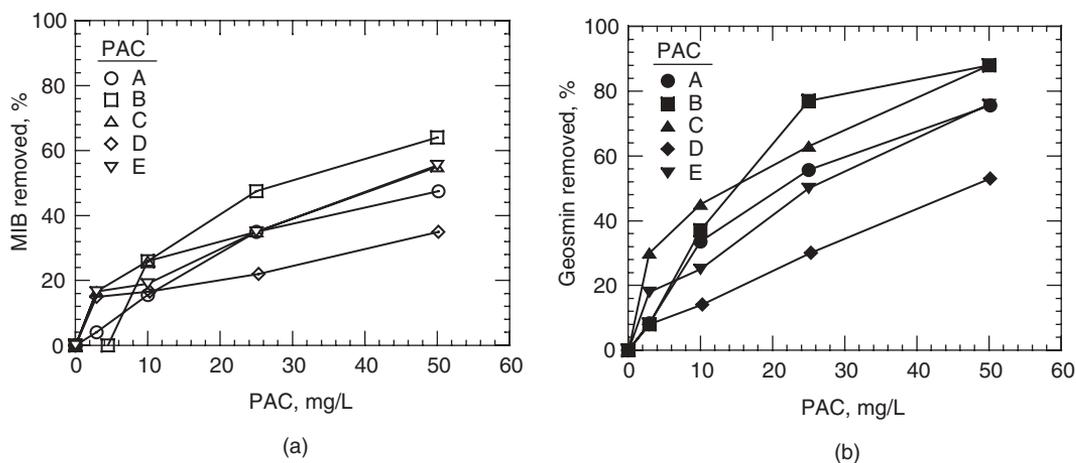

employ a standard jar test procedure. This protocol enables site-specific details of the water treatment plant to be incorporated into the testing procedure. Raw water from the plant is used to perform the jar tests and may be spiked if necessary. The water to be tested is poured into the jars, and the mixing velocities, timing of chemical addition, retention times, and dosages need to be closely mimicked in the jar test. Retention times are inversely related to plant flows and will be the smallest for the largest rates. In other words, PAC will have less contact time with odorous compounds, which will lead to less adsorption. The settling and filtration follow the plant-specific jar testing procedure.

The above protocol is used to develop dose–response curves to evaluate PAC dosages needed for taste and odor episodes. An example of dose–response curves obtained for five different PAC types removing 40 ng/L of odorants is presented on Fig. 15-11. The dose–response curves are given in terms of odorant percent removal as a function of PAC dosage. Five PAC dosages were used for each PAC to develop their dose–response curves. If the treatment objective is 80 percent removal of geosmin (8 ng/L), PAC type B provides the best result with a 34-mg/L PAC dosage.

### Comparison of Carbon Usage Rates for PAC and GAC

To begin the discussion on PAC, it is instructive to compare the theoretical carbon usage rates of PAC and GAC. The following equation is a mass balance on the PAC and water shown on Fig. 15-12:

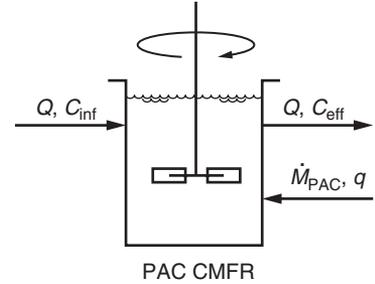

$$QC_{\text{inf}} = qM_{\text{PAC}} + QC_{\text{eff}} \quad (15-34)$$

**Figure 15-11**

Percent removal of MIB and geosmin using Manatee Lake water and testing protocol and 40-ng/L initial contaminant concentrations. Letters A through E correspond to carbons shown in Table 15-10. (Adapted from Graham et al., 2000.)

where  $Q$  = water flow rate, L/d  
 $C_{inf}$  = influent liquid-phase concentration of adsorbate, mg/L  
 $C_{eff}$  = effluent liquid-phase concentration of adsorbate (should meet the treatment objective,  $C_{to}$ ), mg/L  
 $q$  = adsorbent-phase concentration, mg adsorbate/g PAC  
 $\dot{M}_{PAC}$  = mass of PAC added per unit time, g/d

**Figure 15-12**  
 Sketch of CMFR PAC reactor.

If the carbon leaving the process is in equilibrium with the exiting water, then the following expression is obtained:

$$QC_{inf} = q_e|_{C_{eff}} \dot{M}_{PAC} + QC_{eff} \quad (15-35)$$

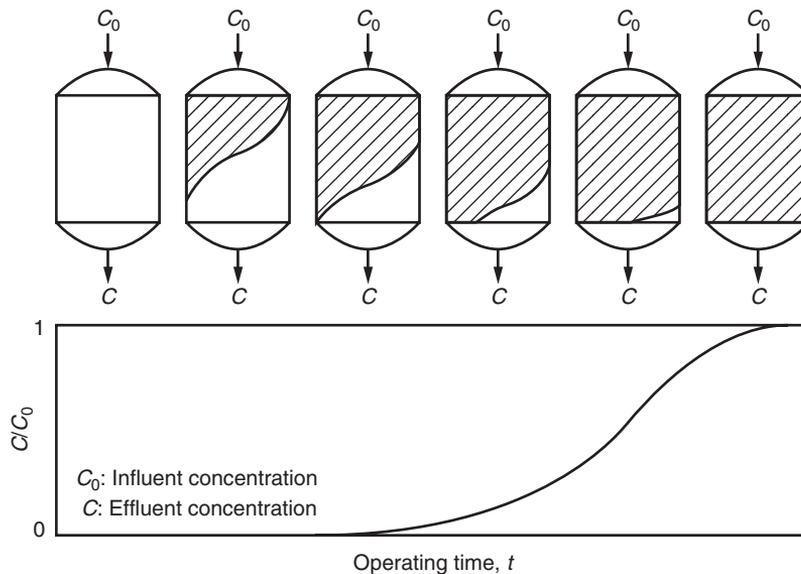

where  $q_e|_{C_{eff}}$  = adsorbent-phase concentration of adsorbate in equilibrium with  $C_{eff}$ , mg adsorbate/g adsorbent

The required PAC dosage is given by the expression

$$D_{PAC} = \frac{\dot{M}_{PAC}}{Q} = \frac{C_{inf} - C_{eff}}{q_e|_{C_{eff}}} \quad (15-36)$$

where  $D_{PAC}$  = powdered activated carbon dosage, g/L

The concentration profile for a single adsorbate in a GAC bed where mass transfer is present is shown on Fig. 15-13. If the mass transfer zone is very

**Figure 15-13**  
 Concentration profiles and breakthrough curves for granular activated carbon columns (Vermeulen, 1958).

small, then no adsorbate will appear in the effluent prior to complete exhaustion of the bed and the GAC will be at equilibrium with the influent concentration. A mass balance for this condition is given by the expression

$$t_{\text{ex}} Q C_{\text{inf}} = q_e|_{C_{\text{inf}}} M_{\text{GAC}} \quad (15-37)$$

The GAC carbon dosage is then given by

$$D_{\text{GAC}} = \frac{M_{\text{GAC}}}{t_{\text{ex}} Q} = \frac{C_{\text{inf}}}{q_e|_{C_{\text{inf}}}} \quad (15-38)$$

where  $D_{\text{GAC}}$  = granular activated carbon dosage, g/L

$M_{\text{GAC}}$  = mass of GAC, g

$t_{\text{ex}}$  = time to GAC exhaustion, d

$q_e|_{C_{\text{inf}}}$  = adsorbent-phase concentration of adsorbate in equilibrium with influent concentration, mg adsorbate/g adsorbent

If adsorption equilibrium can be described by the Freundlich equation, then the ratio of the PAC dosage to GAC dosage can be compared and depends only on  $1/n$ :

$$q_e = K C_e^{1/n} \quad (15-39)$$

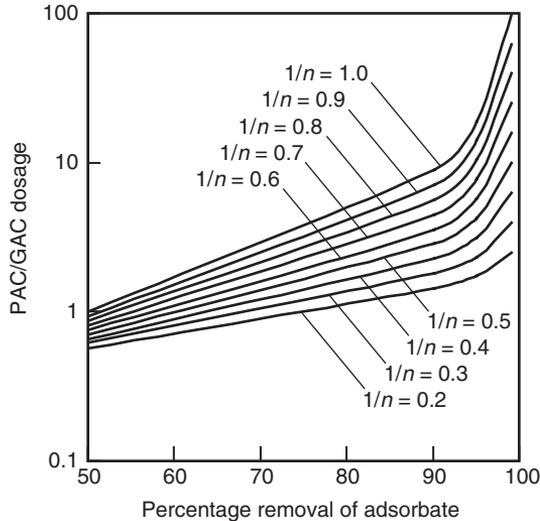

$$\frac{D_{\text{PAC}}}{D_{\text{GAC}}} = \frac{1 - (C_{\text{eff}}/C_{\text{inf}})}{q_e|_{C_{\text{eff}}}/q_e|_{C_{\text{inf}}}} = \frac{1 - (C_{\text{eff}}/C_{\text{inf}})}{(C_{\text{eff}}/C_{\text{inf}})^{1/n}} \quad (15-40)$$

where  $C_e$  = equilibrium liquid-phase concentration, mg/L

The ratio of the PAC to GAC dramatically increases for a higher percentage removal, but the increase decreases as the value of  $1/n$  decreases, as shown on Fig. 15-14, because the PAC is in equilibrium with the effluent concentration and the GAC is in equilibrium with the influent concentration. The difference in capacity is much less as  $1/n$  becomes smaller. Further, GAC and PAC are countercurrent and co-current processes, respectively (see Chap. 7). As a point of reference, most  $1/n$  values are around 0.5 to 0.7 for the compounds that are considered for removal using adsorption. Thus, if removals of less than 95 percent are required and the problem is seasonal, PAC may be the most economical solution. It should be noted that the curves shown on Fig. 15-14 apply to organic-free water and that the presence of NOM in natural waters can reduce the adsorption capacity of GAC and PAC significantly in a number of different ways.

### Factors That Influence PAC Performance

As stated previously, one of the most common uses of activated carbon is the removal of taste and odor compounds. Taste and odor outbreaks are seasonal, and, according to a recent survey in North America, outbreaks

**Figure 15-14**  
Comparison of adsorption capacity for PAC and GAC.

usually occur between June and October (Graham et al., 2000). The two principal odor-causing compounds that are not removed by chlorine are geosmin and MIB. Cyanobacteria are thought to produce and release these compounds into the water. Reported odor threshold concentrations for geosmin and MIB are 4 and 9 ng/L (McGuire et al., 1981). Accordingly, the treatment objective for these compounds must be below these threshold concentrations.

Powdered activated carbon is added to water as a suspension using adsorbent doses in the range of 5 to 25 mg/L. According to a 1994 survey of U.S. water utilities, 90 percent of the plants surveyed used a dosage between 0.5 and 18 mg/L and the average dosage was 5.1 mg/L (Graham et al., 2000). The efficacy of the PAC process is dependent upon these variables: type of PAC, PAC dosage, location of PAC addition, contact time, and presence of competing compounds and oxidants. These variables and their impact on PAC performance are discussed below.

#### **TYPE OF PAC**

The significant properties of five commercially available brands of PAC are reported in Table 15-10. There is considerable variability in the physical and chemical parameters. Studies have shown that these properties do not correlate well with the removal of odorants such as geosmin and MIB (Graham et al., 2000). However, these parameters are useful for quality assurance and control during PAC production and are used to control the activation and carbonization steps during manufacture.

The results of a study on the removal of geosmin and MIB using the brands of PAC in Table 15-10 was shown on Fig. 15-11. At a PAC dose of 50 mg/L, the percent removal for MIB ranged from about 35 percent to

over 60 percent, and the removal of geosmin ranged from about 50 percent to nearly 90 percent. Within experimental error, PAC B performed the best for this source water and these adsorbates. Due to the variability in performance of different adsorbents, an assortment of adsorbents should be evaluated for a specific application.

#### LOCATION OF PAC ADDITION

The most promising locations for the addition of PAC are (1) at the raw-water intake, (2) in the rapid-mix tank, and (3) in a slurry contactor (specially designed for PAC). The advantages and disadvantages of the common points of PAC addition are summarized in Table 15-11. With respect to the point of addition of PAC in a water plant, jar test studies optimizing PAC performance for taste and odor removal of MIB and geosmin show that PAC should be added before coagulation (termed precoagulation time).

#### DISINFECTANTS AND OXIDANTS

For the removal of MIB and geosmin, oxidants such as chlorine and potassium permanganate have a negative impact on PAC removal of taste and odor compounds. The impact is the greatest when the oxidant is

**Table 15-11**

Advantages and disadvantages of different points of addition of PAC

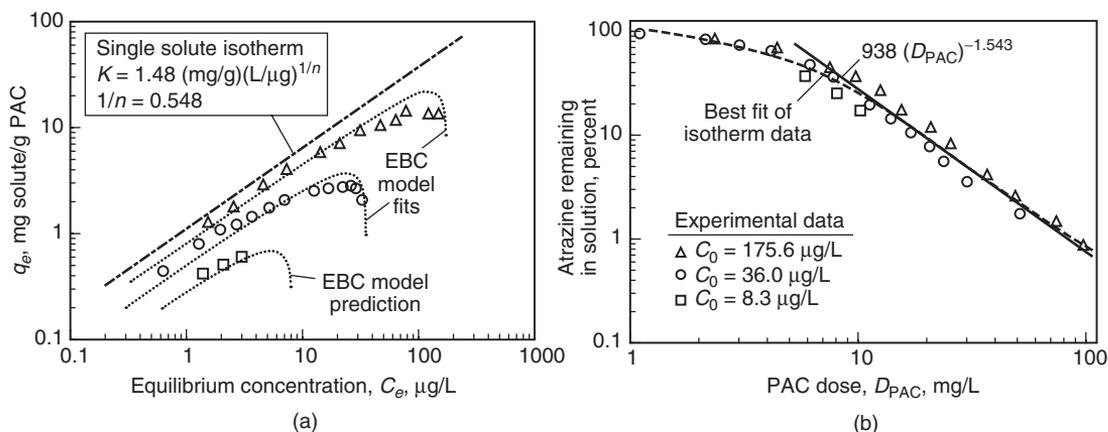

Point of Addition	Advantages	Disadvantages
Intake	Long contact time, good mixing	Interferes with preoxidation process ( $\text{Cl}_2$ or $\text{KMnO}_4$ ). Some substances may be adsorbed that would otherwise probably be removed by coagulation, thus increasing carbon usage rate (this still needs to be demonstrated).
Rapid mix	Good mixing during rapid mix and flocculation, reasonable contact time	Interferes with preoxidation process ( $\text{Cl}_2$ or $\text{KMnO}_4$ ). Possible reduction in rate of adsorption because of interference by coagulants; contact time may be too short for equilibrium to be reached for some contaminants; some competition may occur from molecules that would otherwise be removed by coagulation.
Filter inlet	Efficient use of PAC	Filter breakthrough, compromising finished water quality and making it difficult to meet turbidity requirements.
Slurry contactor preceding rapid mix	Excellent mixing for design contact time, no interference by coagulants, additional contact time possible during flocculation and sedimentation	A new basin and mixer may have to be installed; some competition may occur from the molecules that may otherwise be removed by coagulation.

Source: Adapted from Graham et al. (2000).

added simultaneously with the PAC. For example, when the oxidant is added with the PAC, removal efficiencies for MIB decrease by as much as 50 to 75 percent (Graham et al., 2000). Removal efficiencies for geosmin can decrease by as much as 20 to 40 percent (Graham et al., 2000). Consequently, it is recommended that PAC be added prior to the addition of oxidants or disinfectants.

#### NATURAL ORGANIC MATTER (NOM)

Most waters contain NOM and other organic compounds of anthropogenic origin, as described in Chap. 2. The NOM in water is comprised of thousands of different compounds. Higher-MW compounds will not compete with micropollutants for adsorption sites in smaller pores but can block the entrance to pores. However, micropollutants and smaller competing organics diffuse much faster than larger molecules and can diffuse into the smaller pores and compete for adsorption sites. By either pore blockage or competing for adsorption sites, NOM can reduce the adsorption capacity of micropollutants in PAC. Consequently, single-solute isotherms performed

**Figure 15-15**

Atrazine isotherms for PICA B PAC conducted in organic-free water and Illinois groundwater (adapted from Knappe et al., 1998): (a) atrazine isotherm data and (b) atrazine isotherm data plotted as percentage remaining versus PAC dose.

in organic-free water will predict a higher capacity than would be observed for PAC dosages in natural waters containing NOM. The single-solute isotherm for atrazine is displayed on Fig. 15-15a with the isotherm for atrazine in the presence of a groundwater from a well located in Urbana, Illinois, for different initial atrazine concentrations. The DOC and pH of this water were 3 mg/L and 7.3, respectively. As the initial concentration of atrazine decreases, the impact of NOM is greater and the isotherm capacity for atrazine is less as compared to the single-solute capacity. This is the result of competitive interactions between the NOM and the micropollutant at low carbon dosages. At these low dosages, the strongly adsorbed species from the NOM are adsorbed first and are present at high surface concentrations. As a result, NOM has a greater impact on the micropollutant. As the dosage of PAC increases beyond this point, no additional strongly adsorbed species from the NOM are adsorbed. Consequently, the surface concentration of the strongly adsorbed species decreases, and its competitive impact decreases up to a point where the micropollutant isotherm begins to decrease in a manner that is similar to the single solute isotherm. The unusual feature of the isotherms is that the capacity is lower at high concentrations near the initial concentration and this can be described by IAST.

When the data on Fig. 15-15a are plotted in terms of percent atrazine remaining in solution as a function of PAC dosage, all the data correlate to the same line as shown on Fig. 15-15b. The percent atrazine remaining is only a function of PAC dosage and is independent of initial concentration. This result was demonstrated for several PACs, adsorbates, and natural waters containing NOM (Campos et al., 2000c; Gillogly et al., 1998; Knappe

et al., 1998). Consequently, if an equilibrium isotherm test is conducted for a given initial concentration and the percentage removals for various PAC dosages are determined, then percentage removal for other initial concentrations may be determined from this result. The constant percent reduction that is observed in Fig. 15-15b can be derived from ideal adsorbed solution theory, as shown below.

As discussed above, multicomponent interactions can be predicted using the ideal adsorbed solution theory (IAST), assuming that the entire adsorbent surface is equally available to all solutes. If the Freundlich equation describes the single-solute isotherm, then multicomponent equilibrium interactions can be described using the following equation, which was derived from IAST:

$$C_{i,e} = \frac{q_{i,e}}{\sum_{j=1}^N q_{j,e}} \left( \frac{\sum_{j=1}^N n_j q_{j,e}}{n_i K_i} \right)^{n_i} \quad (15-41)$$

where  $C_{i,e}$  = liquid-phase equilibrium concentration of component  $i$   
 $q_{i,e}$  = solid-phase equilibrium concentration of component  $i$   
 $n_i$  = inverse of slope of the single-solute isotherm data on a  
 $\log(q_{i,e})$  versus  $\log(C_{i,e})$  graph  
 $K_i$  = Freundlich single-solute capacity term for component  $i$ .  
 $N$  = number of components in solution

A mass balance that was written on the PAC process is rewritten here in terms of the nomenclature that is used here:

$$QC_{i,0} = q_{i,e}\dot{M} + QC_{i,e} \quad (15-42)$$

$$C_{i,0} - q_{i,e}D_0 - C_{i,e} = 0 \quad (15-43)$$

where  $C_{i,0}$  = influent liquid-phase equilibrium concentration of component  $i$ ;  
 $Q$  = flowrate of water, L/s  
 $\dot{M}$  = PAC feed rate, mg/s  
 $D_0 = \dot{M}/Q$  = dose of PAC, mg/L

Equation 15-43 can be combined with Eq. 15-41 to yield Eqs. 15-44 and 15-45 which can be used to predict the equilibrium solid-phase concentrations as a function of carbon dosage. Once  $q_{i,e}$  is known,  $C_{i,e}$  can be predicted from Eq. 15-43;  $q_{m,e}$  and  $q_{\text{EBC},e}$  are the the solid-phase concentrations of the micropollutant and equivalent background concentration (EBC) at equilibrium, respectively;  $C_{m,0}$  and  $C_{\text{EBC},0}$  are the liquid-phase concentrations of the micropollutant and EBC at equilibrium, respectively;  $K_{\text{EBC}}$  and  $1/n_{\text{EBC}}$  are the Freundlich single-solute isotherm parameters for the EBC; and  $K_m$  and  $1/n_m$  are the Freundlich single-solute isotherm parameters for the

micropollutant,  $q_{m,e}$  and  $q_{\text{EBC},e}$ . (This assumes that  $K_{\text{EBC}}$ ,  $1/n_{\text{EBC}}$ ,  $C_{\text{EBC},0}$ ,  $C_{m,0}$  and  $D_0$  are specified, and this is the case when  $K_{\text{EBC}}$ ,  $1/n_{\text{EBC}}$ , and  $C_{\text{EBC},0}$  are being determined.) Once  $q_{m,e}$  and  $q_{\text{EBC},e}$  are known, the equilibrium liquid-phase micropollutant concentration,  $C_{m,e}$  and equilibrium liquid-phase EBC concentration,  $C_{\text{EBC},0}$ , can be determined from these equations

$$C_{m,e} = \frac{q_{m,e}}{q_{m,e} + q_{\text{EBC},e}} \left( \frac{n_m q_{m,e} + n_{\text{EBC}} q_{\text{EBC},e}}{n_m K_m} \right)^{n_m} \quad (15-44)$$

$$C_{\text{EBC},e} = \frac{q_{\text{EBC},e}}{q_{m,e} + q_{\text{EBC},e}} \left( \frac{n_m q_{m,e} + n_{\text{EBC}} q_{\text{EBC},e}}{n_{\text{EBC}} K_{\text{EBC}}} \right)^{n_{\text{EBC}}} \quad (15-45)$$

As shown on Fig. 15-15, Knappe et al. (1998) fit the data initial concentrations of 175 and 36  $\mu\text{g/L}$  and determined EBC values for initial concentration and Freundlich parameters. The EBC parameters were then used to predict the isotherm for an initial concentration of 8.3  $\mu\text{g/L}$ . Accordingly, once the EBC properties are determined, they may be used to predict the isotherms at other concentrations.

It must be emphasized that the EBC properties only describe the impact of NOM on the absorbability of micropollutants, and they are not related to the absorbability of NOM. For example, Graham et al. (2000) demonstrated that DOC adsorption isotherms for NOM were not related to the impact of NOM on micropollutant removal. It is likely that the adsorbent surface is not available to all size fractions of the NOM due to its molecular weight distribution and the adsorbent pore size distribution.

Another limitation of the EBC method is that it is dependent on the target compound. For example, Speth and Adams (1993) used the EBC method to describe the adsorption isotherms for 22 compounds in Ohio River water, and they found that EBC parameters were very different depending on the compound. Accordingly, the EBC must be thought of as just a fitting exercise that can only describe the initial concentration impact of NOM on a given target compound.

The EBC is not really needed to describe the impact of NOM on the initial concentration because Eq. 15-44 can be simplified if we make the following assumptions: (1)  $q_{m,e}$  is much less than  $q_{\text{EBC},e}$ ; and (2)  $1/n_m$  and  $1/n_{\text{EBC}}$  are similar and between 0.1 and 1 (Knappe et al., 1998):

$$q_{m,e} = \frac{C_{m,0}}{D_0 + \frac{1}{q_{\text{EBC},e}} \left( \frac{n_{\text{EBC}} q_{\text{EBC},e}}{n_m K_m} \right)^{n_m}} \quad (15-46)$$

in which,  $q_{m,e}$  = solid phase concentrations of the micropollutant  
 $q_{\text{EBC},e}$  = equivalent background concentration (EBC) at equilibrium.

- $C_{m,0}$  = liquid phase concentrations of the micropollutant  
 $K_m$  = Freundlich single solute isotherm capacity factor  
 $n_m$  = Freundlich single solute isotherm intensity factor

Multicomponent isotherms can be predicted using Equation 15-46, if the initial concentrations and single solute isotherm parameters of all components are known. Natural organic matter is comprised of thousands of different compounds and some can block pores and not compete with micropollutants in smaller pores. However, micropollutants and smaller competing organics (from NOM) diffuse much faster than larger molecules and if this is ignored, then IAST has been used to describe competitive interactions between NOM and micropollutants. However, when it comes to the removal of micropollutants from water such as pesticides and taste and odor compounds, the concentrations and the Freundlich isotherm parameters are not known for the natural organic matter.

If we combine Eq. 15-45 with Eq. 15-42, this equation can be obtained:

$$\frac{C_{m,e}}{C_{m,0}} = \frac{\frac{1}{q_{\text{EBC},e}} \left( \frac{n_{\text{EBC}} q_{\text{EBC},e}}{n_m K_m} \right)^{n_m}}{D_0 + \frac{1}{q_{\text{EBC},e}} \left( \frac{n_{\text{EBC}} q_{\text{EBC},e}}{n_m K_m} \right)^{n_m}} \quad (15-47)$$

Knappe et al. (1998) demonstrated that for high PAC dosage that  $C_{\text{EBC},e}$  is negligible and  $q_{\text{EBC},e}$  is given by this expression:

$$q_{\text{EBC},e} = \frac{C_{\text{EBC},0} - C_{\text{EBC},e}}{D_0} \approx \frac{C_{\text{EBC},0}}{D_0} \quad (15-48)$$

Substituting Eq. 15-48 into Eq. 15-47 yields the final form of the equation that relates the percent removal as a function of PAC dosage:

$$\frac{C_{m,e}}{C_{m,0}} = \frac{\frac{1}{C_{\text{EBC},0}} \left( \frac{n_{\text{EBC}} C_{\text{EBC},0}}{n_m K_m} \right)^{n_m}}{D_0^{n_m} + \frac{1}{C_{\text{EBC},0}} \left( \frac{n_{\text{EBC}} C_{\text{EBC},0}}{n_m K_m} \right)^{n_m}} \quad (15-49)$$

Based on EBC values for atrazine that were reported by Campos et al. (2000c), the second term in the denominator of Eq. 15-49 is less than 1% of the first term and can be ignored:

$$\frac{C_{m,e}}{C_{m,0}} = \frac{\frac{1}{C_{\text{EBC},0}} \left( \frac{n_{\text{EBC}} C_{\text{EBC},0}}{n_m K_m} \right)^{n_m}}{D_0^{n_m}} \quad (15-50)$$

As predicted from Eq. 15-50, the percent reduction in the micropollutant is the same for a given PAC dosage, and it does not depend on the initial concentration of the micropollutant. This is what is seen in Fig. 15-15b. Snoeyink and co-workers (Campos et al., 2000c; Knappe et al., 1998; Gillogly et al., 1998) demonstrated this remarkably simple result is valid for several PACs, adsorbates, and natural waters containing NOM. Consequently, if an equilibrium isotherm test is conducted for a given initial concentration and the percentage removal for various PAC dosages are determined, then percentage removal for other initial concentrations may be determined from this result, as demonstrated in Example 15-5.

Seasonal variation in NOM and pH are two additional issues that can impact the removal of micropollutants. Atrazine isotherms that were conducted in distilled deionized water also did not show an impact for these pH values. Consequently, it would appear that pH values that are typical of finished water would not have an impact on the removal of micropollutants. It appears that the season does not change the competitive impact of NOM for Missouri River water even during spring flush. Much of the modeling work that has been presented was for bench-scale tests, and this begs the question as to whether bench-scale PAC tests can be used to predict full-scale performance. Based on the results presented earlier, Graham et al. (2000) developed the optimum scheme for PAC application given the unique features of the plants that were examined. These schemes were developed using bench tests, and the bench test agree with full-scale testing. In total, Graham et al. (2000) compared 140 full-scale data and similar agreement was found for all the data. It is surprising how close the bench tests are to the full-scale data because the bench test protocol used jar tests that simulated a plug flow PAC contactor. Clearly, bench-scale protocols can be used to predict full-scale performance.

#### **CONTACT TIME**

Typically, PAC added in a conventional plant has contact times between 0.5 and 2 h, which is not sufficient to utilize fully the capacity of the PAC for micropollutants. For example, it was reported that for 90 percent removal of atrazine the contact time could be decreased from 4 h to 30 min if the PAC dosage was increased from 23 to 32 mg/L (Gillogly et al., 1998). Other studies have shown similar results (Knappe et al., 1998).

The impact of MIB removal as a function of PAC dosage for various contact times is plotted on Fig. 15-16. As the contact time increases for a given removal efficiency, the PAC dosage decreases. For example, given an MIB removal efficiency of 90 percent (or 10 percent remaining) the PAC dosage for 7.5 min contact time is about 65 mg/L as compared to only about 25 mg/L for a contact time of 4 h. Jar tests can be used to simulate various contact times for various dosages for a given initial micropollutant concentration, if PAC contactor is a plug flow reactor.

### Example 15-5 Adsorption of atrazine on PAC in natural waters

Isotherm experiments were conducted in bottles with three different initial concentrations to measure the adsorption isotherm of atrazine on PAC in a groundwater and the following data were obtained. Plot the percentage of atrazine remaining in the solution as a function of PAC dosage, and determine the PAC dosage corresponding to 90 percent removal of atrazine in a batch reactor for an initial concentration of  $50 \mu\text{g/L}$ .

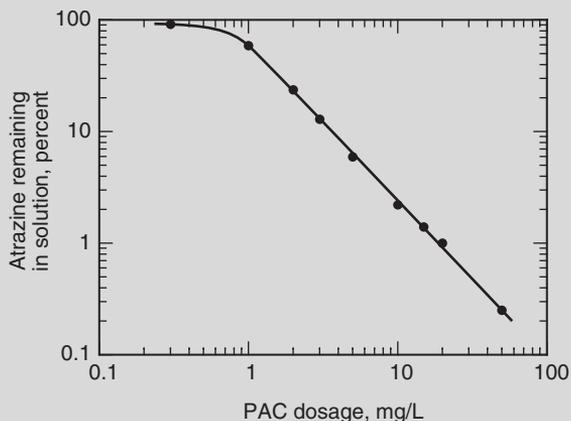

$C_0, \mu\text{g/L}$	PAC Dosage, mg/L	$C_e, \mu\text{g/L}$
8.0	1.0	4.72
	2.0	1.92
	3.0	1.04
35.0	0.3	34.5
	1.0	20.8
	3.0	4.50
	5.0	2.10
	10.0	0.76
	20.0	0.35
	50.0	0.09
100.0	2.0	23.5
	5.0	5.95
	10.0	2.25
	15.0	1.40

#### Solution

1. Calculate the percentage of atrazine remaining in the solution under various experimental conditions:

$C_0, \mu\text{g/L}$	PAC Dosage, mg/L	$C_e, \mu\text{g/L}$	$(C_e/C_0) \times 100\%$
8.0	1.0	4.72	59.0
	2.0	1.92	24.0
	3.0	1.04	13.0
35.0	0.3	34.5	98.6
	1.0	20.8	59.4
	3.0	4.50	12.9
	5.0	2.10	6.00
	10.0	0.76	2.17
	20.0	0.35	1.00
	50.0	0.09	0.25
100.0	2.0	23.5	23.5
	5.0	5.95	5.95
	10.0	2.25	2.25
	15.0	1.40	1.40

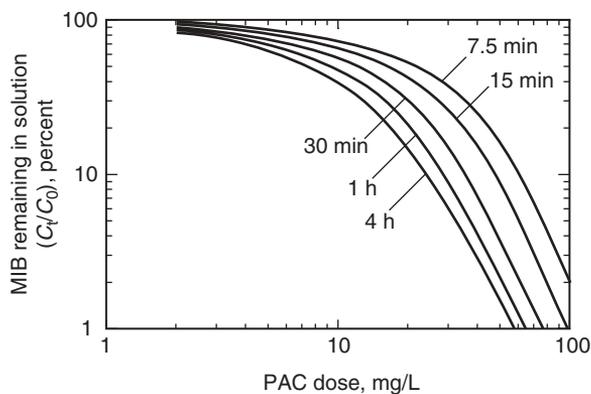

2. Plot the percentage of atrazine remaining in the solution as a function of PAC dosage on a log-log scale:

3. Determine the PAC dosage corresponding to 90 percent removal of atrazine in a batch reactor for an initial concentration of  $50 \mu\text{g/L}$ . The micropollutant removal percentage at a given PAC dosage is independent of its initial concentration. Ninety percent atrazine removal corresponds to 10 percent remaining in the solution. Using the plot developed in step 2, 10 percent atrazine remaining in the solution requires a PAC dosage of  $3.8 \text{ mg/L}$ .

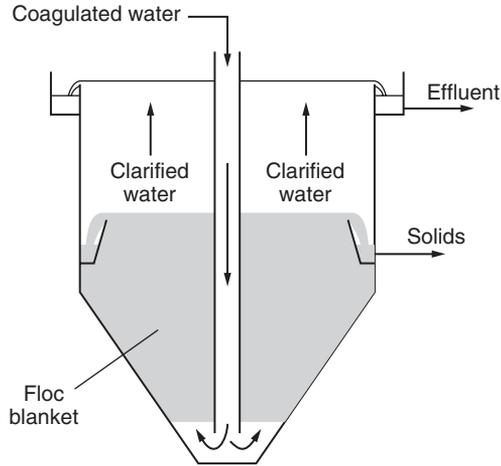

### Use of PAC in Unit Operations

In addition to the application of PAC for control of seasonal water quality problems, PAC may be combined with specific unit processes for improved performance. More efficient methods for usage of PAC include the direct addition to floc blanket reactors or the use of PAC in conjunction with membrane processes.

**Figure 15-16**

MIB remaining in solution as function of PAC dose and contact time.

**Figure 15-17**  
Floc blanket reactor for application in PAC systems (Adapted from AWWA, 1999).

#### PAC APPLICATIONS WITH FLOC BLANKET REACTORS

Floc blanket reactor (FBR) systems may be incorporated into conventional systems to provide for more efficient solid–liquid contact. A schematic of an upflow FBR is displayed on Fig. 15-17. The water containing PAC and coagulated particles is fed down the center of the clarifier and distributed in an upflow manner in the clarifier. Near the center of the clarifier, the sludge is trapped and withdrawn at a specified design rate while the clarifier-treated water continues to travel upward in the clarifier and is removed in the weir.

The detention time of PAC in FBRs may be determined from the following equation:

$$\text{CRT} = \frac{\rho_{\text{bl}} V_{\text{bl}}}{QD_0} = \frac{\rho_{\text{bl}} H_{\text{bl}}}{v_u D_0} \quad (15-51)$$

where CRT = carbon residence time, h

$\rho_{\text{bl}}$  = carbon density in blanket or blanket concentration, mg/L

$V_{\text{bl}}$  = volume of floc blanket, L

$v_u$  = upflow velocity or hydraulic loading in solids contactor, m/h

$H_{\text{bl}}$  = depth of floc blanket, m

$Q$  = water flow rate, L/d

$D_0$  = carbon dosage, mg/L

The PAC dosage, blanket depth, and  $v_u$  all impact the CRT. In full-scale operations, the typical blanket depth is 2 to 3 m and the hydraulic loading ranges from 1.3 to 3 m/h (see Chap. 10). If the hydraulic loading is 1.5 m/h, the depth is 3 m, and PAC dosage is 10 mg/L, a blanket concentration of

120 mg/L would be required for a 24-h CRT based on Eq. 15-51. If the blanket were 2 m deep and the hydraulic loading were 4 m/h, a blanket concentration of 480 mg/L would be required and this may be infeasible. In practice, operators will not usually be able to adjust the hydraulic loading and depth, and floc blanket clarifiers require a fairly consistent water quality and flow rate (see Chap. 10).

#### PAC APPLICATIONS WITH MEMBRANE REACTORS

Powdered activated carbon treatment has been combined with cross-flow micro- or ultrafiltration membranes. Fresh PAC is continually added to the raw water, mixed to contact the particles with the constituents to be removed, and sent to a cross-flow ultrafiltration (UF) membrane where PAC particles are concentrated as the water is filtered through the UF membrane. The concentrated PAC solution is sent to waste and recycled back to the mixing basin. A number of full-scale plants operating in France have used this process (Anselme et al., 1997).

The PAC/UF technologies appear to have a great deal of potential for the reduction of DOC and DBPs. For example, the Vigneux-sur-Seine plant uses the PAC/UF process and, as shown in Table 15-12, significant removal of TOC, BDOC, and DBP was achieved after installation in 1998. The design parameters are reported in Table 15-13. The PAC/UF Vigneux-sur-Seine plant includes preozonation to break down organic matter and increase its adsorbability. Given the reliability, performance, and increasingly stringent treatment objectives, the PAC/UF process was considered to be the more viable alternative (Anselme et al., 1999).

#### Homogeneous Surface Diffusion Model

Adsorption kinetics for PAC systems can be quantified using the pore surface diffusion model (PSDM). As shown on Fig. 15-18, an adsorbate can diffuse from the bulk solution to the exterior surface of the PAC, which is

**Table 15-12**  
Impact of PAC/UF process on Vigneux-sur-Seine finished water

Parameter	Unit	1997 <sup>a</sup>	1998 <sup>b</sup>	Reduction, %
TOC	mg/L	2.6	0.8	69
BDOC	mg/L	0.7	0.2	70

called film diffusion. The adsorbate can then diffuse into the PAC particle by diffusing in the liquid in the pores, which is called pore diffusion, or the adsorbate can adsorb to the surface and then diffuse along the surface, which is called surface diffusion. The following expression can be used to determine the intraparticle flux:

$$J = -D_s \rho_a \frac{\partial q}{\partial r} - \frac{D_l \varepsilon_p}{\tau_p} \frac{\partial C_p}{\partial r} \quad (15-52)$$

**Figure 15-18**  
Mechanisms involved in  
adsorption kinetics.

where  $J$  = intraparticle flux,  $\text{mg}/\text{m}^2 \cdot \text{s}$   
 $D_s$  = surface diffusion coefficient,  $\text{m}^2/\text{s}$   
 $D_p$  = pore diffusion coefficient,  $D_l \varepsilon_p / \tau_p$ ,  $\text{m}^2/\text{s}$   
 $\rho_a$  = adsorbent particle density (carbon mass divided by the total particle volume including pore volume),  $\text{kg}/\text{m}^3$   
 $D_l$  = liquid phase diffusion coefficient,  $\text{m}^2/\text{s}$   
 $\varepsilon_p$  = porosity of the particle, dimensionless  
 $\tau_p$  = tortuosity of the path that the adsorbate must take as compared to the radius, dimensionless  
 $C_p$  = liquid-phase concentration of the adsorbate in the PAC pores,  $\text{mg}/\text{L}$   
 $q$  = adsorbent-phase concentration,  $\text{mg adsorbate}/\text{g PAC}$   
 $r$  = radial coordinate,  $\text{m}$

Pore diffusion can be ignored in most cases with a single component because the pore concentration is small compared to the adsorbate surface concentration. When the model includes only surface diffusion, this model is called the homogeneous surface diffusion model (HSDM). The reason

that the model is called the HSDM is that the surface diffusion coefficient and particle porosity are assumed to be isotropic throughout the particle. This assumption is clearly not completely correct because activated carbon has a distribution of pore sizes and various locations within PAC. For the HSDM, pore diffusion is ignored, and, if a mass balance is written on the spherical shell ignoring the second term in the right-hand side of Eq. 15-52, then the following expression may be written:

$$\text{In} - \text{out} = \text{accumulation} \quad (15-53)$$

$$-D_s \rho_a \frac{\partial q}{\partial r} \Big|_r 4\pi r^2 - \left[ -D_s \rho_a \frac{\partial q}{\partial r} \Big|_{r+\Delta r} 4\pi (r + \Delta r)^2 \right] = \rho_a 4\pi r^2 \Delta r \frac{\partial q}{\partial t} \quad (15-54)$$

Dividing Eq. 15-54 by  $\rho_a 4\pi r^2 \Delta r$  yields the following expression:

$$\frac{-D_s \frac{\partial q}{\partial r} \Big|_r 4\pi r^2 - \left[ -D_s \frac{\partial q}{\partial r} \Big|_{r+\Delta r} 4\pi (r + \Delta r)^2 \right]}{4\pi r^2 \Delta r} = \frac{\partial q}{\partial t} \quad (15-55)$$

If the limit as  $\Delta r \rightarrow 0$  is taken, then the following expression is obtained.

$$\frac{D_s}{r^2} \frac{\partial}{\partial r} \left( r^2 \frac{\partial q}{\partial r} \right) = \frac{\partial q}{\partial t} \quad (15-56)$$

The model must be made dimensionless in order to provide general answers. The model is based on the following dimensionless variables:

$$\bar{r} = \frac{r}{R} \quad (15-57)$$

$$\bar{t} = \frac{t D_s}{R^2} \quad (15-58)$$

$$\bar{q} = \frac{q}{q_e} \quad (15-59)$$

where  $R$  = adsorbent particle radius, m  
 $q_e$  = solid-phase concentration in equilibrium with  $C_e$   
 $t$  = elapsed time, min  
 $\bar{r}$  = dimensionless radial coordinate  
 $\bar{t}$  = dimensionless elapsed time  
 $\bar{q}$  = dimensionless adsorbent-phase concentration

Substitution of Eqs. 15-57, 15-58, and 15-59 into 15-56 yields the following dimensionless expression, which is known as Fick's second law in spherical coordinates:

$$\frac{1}{\bar{r}^2} \frac{\partial}{\partial \bar{r}} \left\{ \bar{r}^2 \frac{\partial \bar{q}}{\partial \bar{r}} \right\} = \frac{\partial \bar{q}}{\partial \bar{t}} \quad (15-60)$$

There are two boundary conditions and one initial condition for Eq. 15-60. Because of symmetry, the first derivative of the solid-phase loading is equal to zero for dimensionless time values greater than or equal to zero:

$$\frac{\partial \bar{q}}{\partial \bar{r}} = 0 \quad (15-61)$$

As shown in Fig. 15-18, the other boundary conditions come from equating the exterior mass flux to the intraparticle mass flux:

$$k_f(C - C_s) = D_s \rho_a \frac{\partial q}{\partial r} \quad (15-62)$$

where  $k_f$  = external mass transfer coefficient, m/s

$C$  = liquid-phase concentration of the adsorbate, mg/L

$C_s$  = liquid-phase concentration of the adsorbate at the particle surface, mg/L

Converting Eq. 15-62 to dimensionless by substituting Eqs. 15-57, 15-58, and 15-59 into Eq. 15-62 and noting that  $\bar{C}_s = C_s/C_0$  yields the second dimensionless boundary condition.

$$\text{Bi}_s (\bar{C} - \bar{C}_s) = \frac{\partial \bar{q}}{\partial \bar{r}} \quad (15-63)$$

$$\text{Bi}_s = \frac{k_f C_0 R}{D_s \rho_a q_e} = \frac{\text{external mass transfer rate}}{\text{surface diffusion intraparticle mass transfer rate}} \quad (15-64)$$

where  $\text{Bi}_s$  = Biot number

$C_0$  = initial liquid-phase concentration in the reactor at time zero, mg/L

The Biot number is a good indicator of which phase controls the rate of mass transfer. For low  $\text{Bi}_s$  numbers ( $\text{Bi}_s < 1.0$ ), external mass transfer controls the adsorption rate. For large  $\text{Bi}_s$  numbers ( $\text{Bi}_s > 30$ ) surface diffusion controls the adsorption rate. For  $\text{Bi}_s$  numbers between 1 and 30 both external and intraparticle mass transfer rates contribute to the adsorption rate.

The initial condition for Eq. 15-60 states that there is no adsorbate within the adsorbent:

$$\bar{q}(\bar{t} = 0, 0 \leq \bar{r} \leq 1) = 0 \quad (15-65)$$

Mixing conditions affect the liquid-phase mass balance. If it is assumed that the PAC moves along with the fluid and plug flow conditions prevail, then the liquid-phase mass balance is identical to that which is obtained for a completely mixed batch reactor, and time corresponds to the contact time of PAC with the water. A mass balance on the liquid phase that moves at the fluid velocity may be written as follows:

$$\text{In} - \text{out} + \text{generation} - \text{loss} = \text{accumulation} \quad (15-66)$$

$$-k_f a (C - C_s) V_p = V_p \frac{dC}{dt} \quad (15-67)$$

$$a = \frac{3\phi D_0}{R \rho_a} = \frac{\text{area available for mass transfer}}{\text{solution volume}} \quad (15-68)$$

$$- \frac{3\phi k_f (1 - \varepsilon_p)}{R} (C - C_s) = \frac{dC}{dt} \quad (15-69)$$

where  $a$  = area available for mass transfer per volume of solution,  
m<sup>2</sup>/m<sup>3</sup>

$\phi$  = particle sphericity, dimensionless

$V_p$  = solution volume per particle, L/particle

$D_0$  = PAC dosage =  $\rho_a(1 - \varepsilon_p)$

Applying the dimensionless variables to Eq. 15-69 yields the following dimensionless form of the equation:

$$\text{Sh}_s (\bar{C} - \bar{C}_s) = \frac{d\bar{C}}{d\bar{t}} \quad (15-70)$$

$$\text{Sh}_s = \frac{3\phi k_f (1 - \varepsilon_p) R}{D_s} \quad (15-71)$$

where  $\text{Sh}_s$  = Sherwood number based on the surface diffusivity,  
dimensionless.

The initial condition for Eq. 15-70 is

$$\bar{C}(\bar{t} = 0) = 0 \quad (15-72)$$

The concentration on the adsorbed phase is represented by  $q$  and the liquid-phase concentration is represented by  $C$ . Equations 15-60 and 15-70 can be coupled to the Freundlich equation. When both phases are at local equilibrium, the Freundlich expression can be written as follows (by noting that the adsorbed-phase concentration at the exterior or the adsorbent is in equilibrium with the liquid-phase adsorbate concentration at the exterior of the adsorbent):

$$q(r = R, t) = K C_s^{1/n} \quad (15-73)$$

$$q_e = K C_e^{1/n} \quad (15-74)$$

$$\bar{q}(\bar{r} = 1, \bar{t}) = (\bar{C}_e)^{-1/n} \bar{C}_s^{1/n} \quad (15-75)$$

where  $\bar{C}_s = C_s / C_0$   
 $\bar{C}_e = C_e / C_0$

For most PAC applications, neglecting the impact of external mass transfer in Eq. 15-67 can provide a good model/data comparison (Najm, 1996; Campos et al., 2000a). If the overall mass balance does not include external mass transfer, the following expression is obtained:

$$0 = \text{accumulation} = \text{final mass} - \text{initial mass} \quad (15-76)$$

$$0 = q_{\text{ave}} M_p + V_p C - V_p C_0 \quad (15-77)$$

where  $M_p$  = mass of PAC, g

$q_{\text{ave}}$  = average adsorbent-phase concentration, mg/g

The average adsorbent-phase concentration can be calculated using the following equation:

$$q_{\text{ave}} = \frac{3}{4\pi R^3} \int_0^R q 4\pi r^2 dr \quad (15-78)$$

The final form of the overall mass balance in dimensionless form is developed by substituting Eq. 15-78 into Eq. 15-77, taking the derivative with respect to time, and inserting the dimensionless variables from Eqs. 15-57 to 15-59:

$$0 = \frac{3D_0}{4\pi R^3} \int_0^R q 4\pi r^2 dr + C - C_0 \quad (15-79)$$

$$\frac{3D_0 q_e}{C_0} \int_0^1 \frac{\partial \bar{q}}{\partial \bar{t}} \bar{r}^2 d\bar{r} = -\frac{d\bar{C}}{d\bar{t}} \quad (15-80)$$

Equation 15-79 may be simplified further by substituting the following equation into Eq. 15-79:

$$q_e = \frac{C_0 - C_e}{D_0} \quad (15-81)$$

$$\frac{d\bar{C}}{d\bar{t}} = -3(1 - \bar{C}_e) \int_0^1 \frac{\partial \bar{q}}{\partial \bar{t}} \bar{r}^2 d\bar{r} \quad (15-82)$$

The final set of dimensionless equations that ignore external mass transfer resistance and pore diffusion can be presented by noting that  $\bar{C}^{1/n} = \bar{C}_s^{1/n}$  because there is assumed to be no concentration gradient in the liquid phase:

$$\frac{d\bar{C}}{d\bar{t}} = -3(1 - \bar{C}_e) \int_0^1 \frac{\partial \bar{q}}{\partial \bar{t}} \bar{r}^2 d\bar{r} \quad (15-83)$$

$$\frac{1}{\bar{r}^2} \frac{\partial}{\partial \bar{r}} \left\{ \bar{r}^2 \frac{\partial \bar{q}}{\partial \bar{r}} \right\} = \frac{\partial \bar{q}}{\partial \bar{t}} \quad (15-84)$$

$$\bar{q}(\bar{r} = 1, \bar{t}) = (\bar{C}_e)^{-1/n} \bar{C}^{1/n} \quad (15-85)$$

$$\frac{\partial \bar{q}}{\partial \bar{r}} = 0 \quad (15-86)$$

$$\bar{q}(\bar{t} = 0, 0 \leq \bar{r} \leq 1) = 0 \quad (15-87)$$

$$\bar{C}(\bar{t} = 0) = 0 \quad (15-88)$$

Inspection of Eq. 15-83 to 15-88 implies that only two parameters determine  $\bar{C} = C/C_0$  at any  $\bar{t} = D_s t/R^2$  (Hand et al., 1983). Consequently, all possible solutions can be presented here by varying  $\bar{C}_e$  for several  $1/n$  values. Figure 15-19 displays  $(C - C_e)/(C_0 - C_e)$  as a function of time for  $1/n$  values from 0.1 to 0.9 and a  $C_e/C_0$  value of 0.1.  $(C - C_e)/(C_0 - C_e)$  was used instead of  $C/C_0$  because it tends to bring the curves together and make them easier to display and interpolate. The following equation was fit to the HSDM for various  $1/n$  values, and may be used to analyze contaminant removal by PAC batch reactors and plug flow reactors with a given residence time.

$$\frac{C - C_e}{C_0 - C_e} = A_0 + A_1(\ln \bar{t}) + A_2(\ln \bar{t})^2 + A_3(\ln \bar{t})^3 \quad (15-89)$$

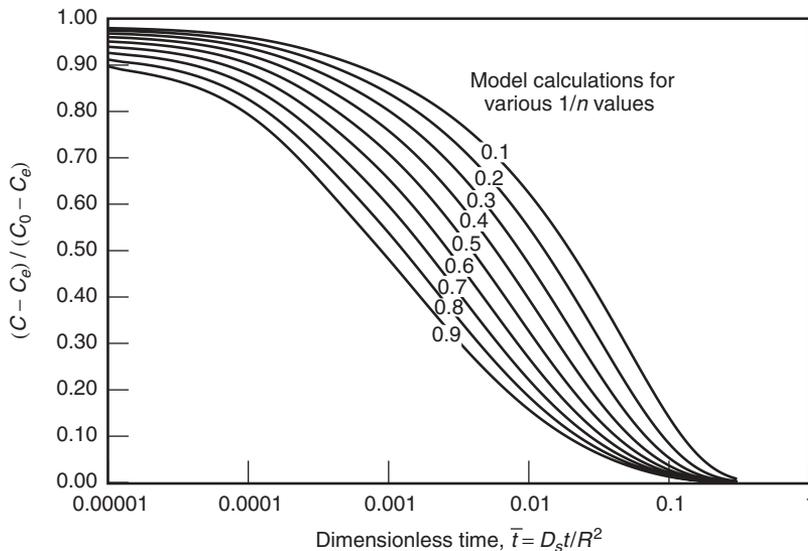

An example of the constants in Eq. 15-89 for a  $1/n$  value of 0.2 are shown in Table 15-14 [constants for additional  $1/n$  values are provided in Zhang et al. (2009) and the electronic Table E-6 at the website listed in App. E].

Steady state can be achieved in a completely mixed flow PAC contactor in approximately three hydraulic contact times or  $\bar{t} = 3$ , whichever is larger. Under steady-state conditions, the concentration of the micropollutant in water is a constant and the appropriate mass balance for the liquid phase is as follows:

$$\text{in} - \text{out} + \text{generation} - \text{loss} = 0 = \text{accumulation} \quad (15-90)$$

$$\text{in} = \text{out}$$

$$QC_0 = QC(t) + q_{ave}\dot{M} \quad (15-91)$$

**Figure 15-19**  
HSDM calculations for either a batch reactor or plug flow reactor with a similar detention time.

**Table 15-14**

Parameters used for the empirical equation that describe solutions to the HSDM for a batch reactor for Freundlich adsorption intensity parameter  $(1/n) = 0.2^a$

$C_e/C_0$	Equation Coefficients						Equations Valid for the Following $\bar{t}$ Range	
	$A_0$	$A_1$	$A_2$	$A_3$	Lower	Upper

<sup>a</sup>Parameters for other values of  $1/n$  are available in the electronic Table E-6 at the website listed in App. E.

where  $\dot{M}$  = mass flow rate of PAC, g/min

$$\bar{C}(t) = 1 - \frac{q_{\text{ave}} \dot{M}}{C_0 Q} = 1 - \frac{q_e |_{C(t)}}{C_0} \bar{q}_{\text{ave}} D_0 \quad (15-92)$$

where  $\bar{q}_{\text{ave}}$  = dimensionless average adsorbed-phase concentration

$$\frac{q_{\text{ave}}}{q_e}$$

$q_e$  = solid-phase concentration in equilibrium with  $C(t)$  and equals  $[KC(t)^{1/n}]$ , mg/g

Substituting  $q_e = KC(t)^{1/n} = K [C_0 \bar{C}(t)]^{1/n}$  and  $\bar{t}$  into Eq. 15-92 yields a nonlinear equation in  $\bar{C}(\bar{t})$  for the liquid-phase mass balance:

$$C_0 [1 - \bar{C}(\bar{t})] - K [C_0 \bar{C}(\bar{t})]^{1/n} \bar{q}_{\text{ave}} D_0 = 0 \quad (15-93)$$

The appropriate mass balance for the adsorbent phase is Eq. 15-60:

$$\frac{1}{\bar{r}^2} \frac{\partial}{\partial \bar{r}} \left\{ \bar{r}^2 \frac{\partial \bar{q}}{\partial \bar{r}} \right\} = \frac{\partial \bar{q}}{\partial \bar{t}} \quad (15-94)$$

The first boundary condition utilizes the fact that the solution concentration is equal to effluent concentration of the contactor:

$$\bar{q}(\bar{r} = 1, \bar{t}) = [\bar{C}(t)]^{1/n} = 1 \quad (15-95)$$

The second boundary condition and initial condition for Eq. 15-93 are as follows:

$$\frac{\partial \bar{q}}{\partial \bar{r}} = 0 \quad (15-96)$$

$$\bar{q}(\bar{t} = 0, 0 \leq \bar{r} \leq 1) = 0 \quad (15-97)$$

Crank (1964) has provided a solution to this problem for the average solid-phase loading:

$$\bar{q}_{\text{ave}} = 1 - \frac{6}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp(-n^2 \pi^2 \bar{t}) \quad (15-98)$$

Traegner et al. (1996) noted that the PAC is completely mixed and the PAC has an exponential exit age distribution corresponding that of to a CMFR. The exit age distribution for a CMFR is discussed in Chap. 7. Using the CMFR exit age distribution and Eq. 15-98, Traegner et al. (1996) developed the following closed-form analytical solution:

$$\bar{q}_{\text{ave}} = 3\bar{t} \left[ \frac{1}{\sqrt{\bar{t}}} \coth \left( \frac{1}{\sqrt{\bar{t}}} \right) - 1 \right] \quad (15-99)$$

To use these equations, first select a  $\bar{t}$  and calculate  $\bar{q}_{\text{ave}}$  using Eq. 15-99. Then use Eq. 15-93 to calculate  $\bar{C}(\bar{t})$  for a given PAC dose.

Although the HSDM assumes that the surface diffusion coefficient and particle porosity are isotropic throughout the particle, the HSDM can

predict the surface diffusion coefficient that is consistent with the experimental data. Example 15-6 demonstrates the HSDM user-oriented solutions with the batch rate data. Examples 15-7 and 15-8 demonstrate the use of PAC kinetic models using different reactors.

### Example 15-6 Estimation $D_s$ of using the HSDM

Given the following batch rate data for atrazine, initial atrazine concentration of 175.1 ng/L, PAC particle radius  $R = 5 \mu\text{m}$ , and PAC dose of 11.5 mg/L, calculate  $D_s$  using the HSDM user-oriented solutions. The Freundlich isotherm parameters are  $1/n = 0.216$  and  $K = 10^{0.402} = 2.52 \text{ (ng/mg)(L/ng)}^{1/n}$ .

$t$ (min)	$C_t/C_0$	$t$ (min)	$C_t/C_0$
0	1.012	30	0.730
0	1.007	45	0.662
1.42	0.924	59.5	0.691
4.08	0.856	90	0.635
7.08	0.836	120	0.600
13.52	0.753	186	0.576
16.37	0.774	240	0.569

#### Solution

Estimation of  $D_s$  involves the following steps:

1. Calculate the equilibrium concentration  $C_e$  by equating Eq. 15-74 with 15-81:

$$q_e = \frac{C_0 - C_e}{D_0} = KC_e^{1/n}$$

$$\frac{175.1 - C_e}{11.5} = 2.52C_e^{0.216}$$

$$C_e = 97.2163$$

$$\frac{C_e}{C_0} = 0.5552$$

2. Calculate the dimensionless time  $\bar{t}$  and dimensionless concentration  $\bar{C}$  for the batch rate data given in the above table:

$$\bar{t} = \frac{tD_s}{R^2}$$

$$\bar{C}_{\text{data}} = \frac{C_t - C_e}{C_0 - C_e} = \frac{\frac{C_t}{C_0} - \frac{C_e}{C_0}}{1 - \frac{C_e}{C_0}}$$

3. Pick the appropriate empirical equation from Table 15-14 for  $1/n = 0.216$  and  $C_e/C_0 = 0.5552$ . The appropriate equation for  $1/n = 0.2$ ,  $C_e/C_0 = 0.6$  in Table 15-14 was used to calculate the dimensionless concentration for the given time using Eq. 15-89:

$$\bar{C}_{\text{model}} = \frac{C(\bar{t}) - C_e}{C_0 - C_e} = A_0 + A_1(\ln \bar{t}) + A_2(\ln \bar{t})^2 + A_3(\ln \bar{t})^3$$

$$C_e/C_0 = 0.6:$$

$$A_0 = -1.6232 \times 10^{-2}$$

$$A_1 = 5.5330 \times 10^{-2}$$

$$A_2 = 8.1230 \times 10^{-2}$$

$$A_3 = 7.9024 \times 10^{-3}$$

4. Use Excel Solver to find the optimum  $D_s/R^2$  by minimizing the objective function (OF) value, which can be calculated using the following equation:

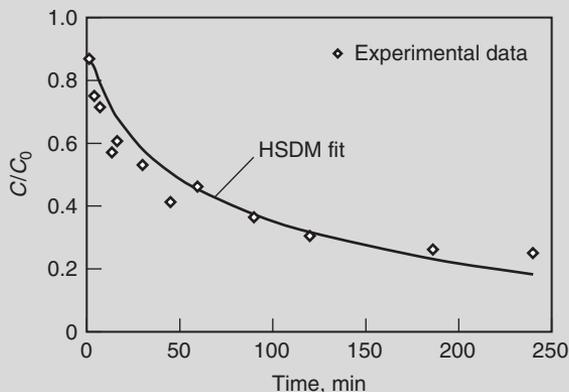

$$\text{OF} = \sqrt{\frac{\sum_{i=1}^n \left( \frac{\bar{C}_{\text{data},i} - \bar{C}_{\text{model},i}}{\bar{C}_{\text{data},i}} \right)^2}{n-1}}$$

#### Excel table of HSDM user-oriented model fit and PAC data

t (min)	$C_t/C_0$ (data)	$\bar{t}$	$\bar{C}$ (data)	$\bar{C}$ (model)	$C_t/C_0$ (model)
0	1.012	0	—	—	1
0	1.007	0	—	—	1
1.42	0.925	0.00176	0.829315	$8.84 \times 10^{-1}$	$9.49 \times 10^{-1}$
4.10	0.856	0.00507	0.676721	$7.94 \times 10^{-1}$	$9.08 \times 10^{-1}$
7.10	0.8357	0.00880	0.630528	$7.04 \times 10^{-1}$	$8.68 \times 10^{-1}$
13.5	0.753	0.01680	0.444397	$5.75 \times 10^{-1}$	$8.11 \times 10^{-1}$
16.4	0.774	0.02930	0.491019	$5.34 \times 10^{-1}$	$7.93 \times 10^{-1}$
30	0.730	0.03730	0.393238	$3.99 \times 10^{-1}$	$7.33 \times 10^{-1}$
45	0.662	0.05590	0.240476	$3.10 \times 10^{-1}$	$6.93 \times 10^{-1}$
59.5	0.691	0.07390	0.304178	$2.51 \times 10^{-1}$	$6.67 \times 10^{-1}$
90	0.634	0.11200	0.178435	$1.69 \times 10^{-1}$	$6.31 \times 10^{-1}$
120	0.600	0.14900	0.101117	$1.18 \times 10^{-1}$	$6.08 \times 10^{-1}$
186	0.576	0.23100	0.046059	$5.21 \times 10^{-2}$	$5.78 \times 10^{-1}$
240	0.568	0.56881	0.03058	$2.18 \times 10^{-2}$	$5.65 \times 10^{-1}$

The optimum  $D_s/R^2 = 1.2424 \times 10^{-3}$ .

The final result for  $D_s = 1.2424 \times 10^{-3} \times (0.0005)^2 = 5.18 \times 10^{-12}$  ( $\text{cm}^2/\text{s}$ ) and a plot of the experimental data and model fit is shown in the following graph:

### Example 15-7 Generate a plot of $C(t)/C_0$ versus PAC dosage for plug flow reactor times using the parameters for atrazine

Using the data presented in Example 15-6 (i.e.,  $C_0 = 174.5$  ng/L,  $R = 0.0005$  cm, Freundlich isotherm parameters  $K$  and  $1/n$ , and  $D_s$ ), generate a plot of reduced concentration as a function of contact times for 7.5, 15, 30, 60, and 240 min. Assume the PAC process follows a plug flow reactor.

#### Solution

To generate the plot,  $C(t)/C_0$  needs to be calculated for different PAC dosage using the following steps:

1. Calculate PAC dosage for each  $C_e/C_0$  using Eq. 15-36:

$$D_0 \frac{C_0 - C_e}{q_e} = \frac{C_0 - C_e}{KC_e^{1/n}}$$

2. Calculate dimensionless time  $\bar{t}$  for  $t = 7.5$  min, 15 min, 30 min, 1 h, and 4 h using Eq. 15-58.

$$\bar{t} = \frac{(t \text{ min})(5.18 \times 10^{-12} \text{ cm}^2/\text{s})(60 \text{ s/min})}{(0.0005 \text{ cm})^2}$$

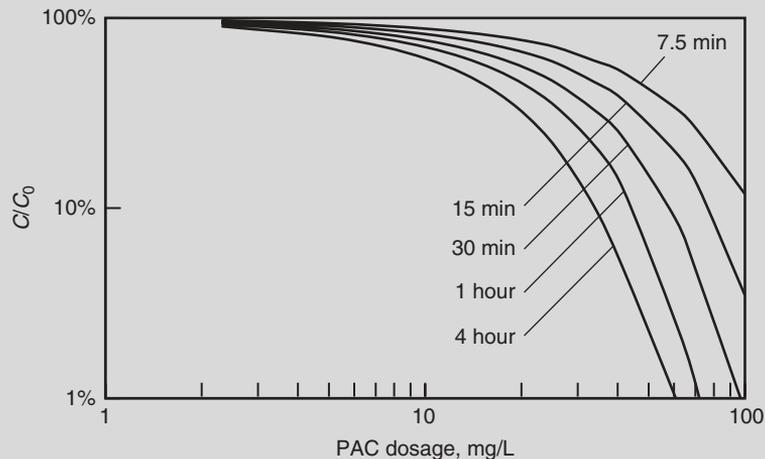

3. Calculate equilibrium adsorbed-phase concentrations, PAC dosages, and the HSDM user-oriented solutions associated with the  $C_e/C_0$  values and  $1/n = 0.2$  from Table 15-14.

$C_e/C_0$	0.005	0.01	0.05	0.1
$C_e$ (ng/L)	0.8725	1.745	8.725	17.45
$q_e$	2.446842	2.842028	4.023517	4.67335
$D_0$ (mg/L)	70.95984	60.78582	41.20151	33.60544
$A_0$	0.645253	0.513173	0.224322	0.122475
$A_1$	0.55068	0.492388	0.30597	0.212696
$A_2$	0.139005	0.139344	0.121216	0.105034
$A_3$	0.008369	0.009083	0.009265	0.008516

Using these parameters with Eq. 15-89 calculate the  $\bar{C}$  values for each  $C_e/C_0$  and  $\bar{t}$  values. Calculate a  $C_t/C_0$  value from each  $\bar{C}$  for each  $C_e/C_0$  and  $\bar{t}$  value. An Excel spreadsheet can be used to perform the calculations. The following table summarizes the  $C_t/C_0$  values for each retention time for  $C_e/C_0$  values of 0.005, 0.01, 0.05, and 0.1.

$t$ (min)	$\bar{t}$	$C_t/C_0$			
		$C_e/C_0 = 0.005$	$C_e/C_0 = 0.01$	$C_e/C_0 = 0.05$	$C_e/C_0 = 0.1$
7.5	$9.33 \times 10^{-3}$	0.257445	0.335248	0.521619	0.59817
15	$1.87 \times 10^{-2}$	0.132426	0.196458	0.375738	0.462845
30	$3.73 \times 10^{-2}$	0.044742	0.087018	0.239495	0.330394
60	$7.46 \times 10^{-2}$	0.011033	0.024898	0.130477	0.216131
240	$2.99 \times 10^{-1}$	0.005	0.01	0.05	0.103422

4. Plot  $C_t/C_0$  versus PAC dosage for different times.

### Example 15-8 Compare PFR performance to CMFR performance for the same PAC dosage

Using an initial atrazine concentration of 174.5 ng/L, compare the performance of a PFR with a  $C_e/C_0 = 0.1$  to a CMFR. Use the equilibrium ( $K$  and  $1/n$ ) and kinetic ( $D_s$ ) parameters from Example 15-7.

#### Solution

The results for  $1/n = 0.2$  and a  $C_e/C_0 = 0.1$  were determined in Example 15-7. The dosage of PAC for the CMFR will be the same as that for the PFR, and the PAC dosage for the PFR is determined from this mass balance on the PFR.

$$C_0 - C_e - q_e \times D_0 = 0$$

$$C_0 - C_e - KC_e^{1/n} \times D_0 = 0$$

$$D_0 = \frac{C_0 - C_e}{KC_e^{1/n}} = \frac{(174.5 - 17.4) \text{ ng/L}}{2.52 \text{ (ng/mg)} (\text{L/ng})^{1/n} 17.4^{1/n}} = 33.6 \text{ mg/L}$$

To solve for CMFR results, the overall mass balance equation that includes both the liquid and PAC phases for a completely mixed flow reactor is written as follows. First, the average loading on the PAC is given by Eq. 15-99 for a CMFR:

$$\bar{q}_{ave} = 3\bar{t} \left[ \frac{1}{\sqrt{\bar{t}}} \coth \left( \frac{1}{\sqrt{\bar{t}}} \right) - 1 \right]$$

For a CMFR, the equilibrium solid-phase concentration is that which is in equilibrium with the steady-state liquid concentration as shown in the following equation:

$$q_e = KC_t^{1/n}$$

$$q_{ave} = \bar{q}_{ave} q_e$$

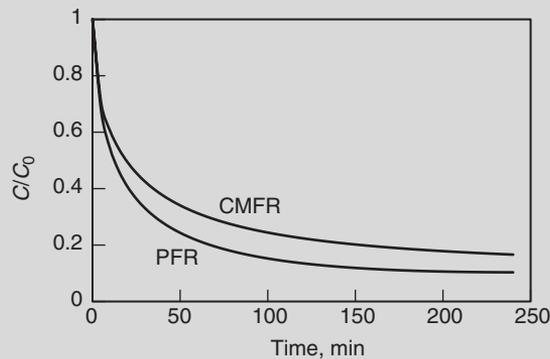

The overall mass balance is given by

$$C_0 = C_t + q_{ave} D_0$$

$$C_0 - C_t - 3\bar{t} \left( \frac{1}{\sqrt{\bar{t}}} \coth \left( \frac{1}{\sqrt{\bar{t}}} \right) - 1 \right) \times KC_t^{1/n} \times D_0 = 0$$

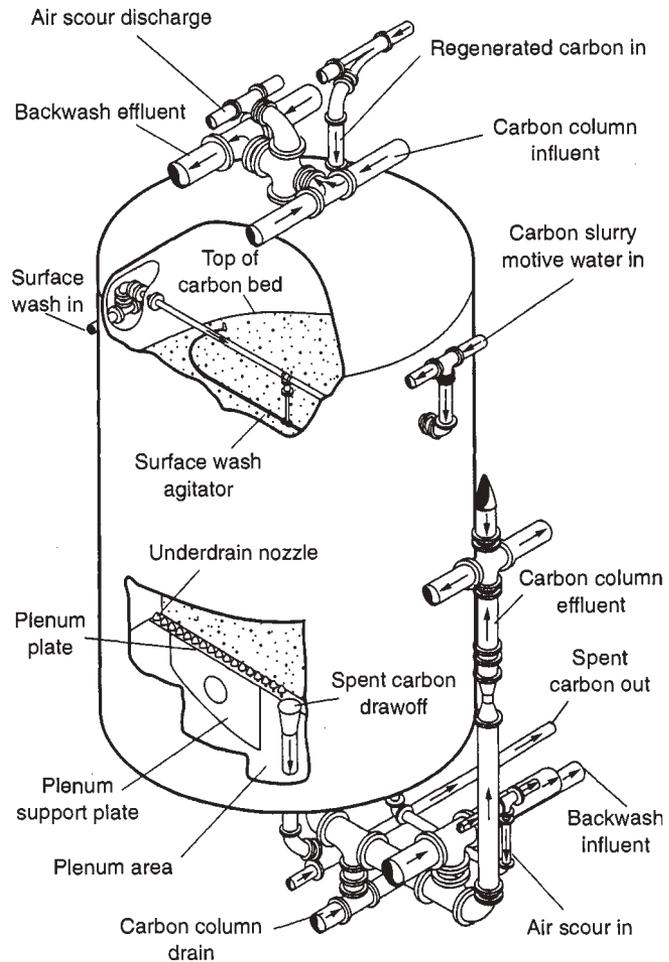

The above equation was used to solve for the effluent concentration  $C_t$  using Excel Solver tool. Then,  $C_t/C_0$  can be calculated. The following table provides some of the calculations that were used to generate the figure that follows the table.

$t$ (min)	$\bar{t}$	PFR $C_t/C_0$	CMFR $\bar{q}_{ave}$	CMFR $C_t/C_0$
0	0	1	0	1
5	$6.22 \times 10^{-3}$	0.672545	$2.18 \times 10^{-1}$	0.701265
10.00	$1.24 \times 10^{-2}$	0.542638	$2.97 \times 10^{-1}$	0.605253
15.00	$1.87 \times 10^{-2}$	0.462845	$3.54 \times 10^{-1}$	0.541367
20.00	$2.49 \times 10^{-2}$	0.406647	$3.99 \times 10^{-1}$	0.493583
25.00	$3.11 \times 10^{-2}$	0.364095	$4.36 \times 10^{-1}$	0.455765
30.00	$3.73 \times 10^{-2}$	0.330394	$4.68 \times 10^{-1}$	0.424787

## 15-6 Granular Activated Carbon

Granular activated carbon operations can be divided into the following two categories: (1) trace contaminant removal and (2) DOC removal. In water treatment, physical adsorption is typically the mechanism responsible for the removal of organics; surface reactions, complexation, and ion exchange with surface functional groups are responsible for the removal of inorganic constituents. Biological activity on the carbon surface can also play a role in extending GAC bed life by using adsorbed molecules for electron donors or acceptors. Three GAC contactor options are (1) gravity feed contactors, (2) pressure contactors, and (3) upflow and/or fluidized-bed contactors. Granular activated carbon can also be used both as a filter and an adsorber in sand replacement filtration operations. Gravity feed contactors have the same features as granular media filters, which are described in Chap. 11, but can be deeper than conventional granular filters. A typical schematic of a pressure GAC contactor is illustrated on Fig. 15-20.

**Figure 15-20**  
Schematic of GAC pressure adsorber (from Tchobanoglous et al., 2003).

### Terms Used in GAC Application

Before continuing the discussion on GAC contactors, it is useful to provide a few definitions of important terms. The definitions for some of the terms defined at the beginning of the chapter have been expanded upon here.

#### MASS TRANSFER ZONE

The concentration–history profile for a GAC contactor was shown previously on Fig. 15-13. As time proceeds, the adsorbate slowly saturates the GAC in the contactor near the inlet, and a concentration profile known as the mass transfer zone develops and moves through the bed. The mass transfer zone (MTZ) is the length of bed needed for the adsorbate to be transferred from the fluid into the adsorbent. Eventually, the adsorbate at the front of the MTZ appears in the effluent, and the time when the concentration exceeds the treatment objective in the effluent is called

breakthrough. The time when the effluent concentration essentially equals the influent is called the point of exhaustion because the bed is no longer able to remove the adsorbate.

For a single component and constant influent concentration, the following expression can be derived by writing a mass balance on the mass transfer zone that moves with the mass transfer zone:

$$\frac{C(z)}{C_{\text{inf}}} = \frac{q(z)}{q_e|_{C_{\text{inf}}}} \quad (15-100)$$

where  $C(z)$  = liquid-phase concentration of adsorbate at location  $z$  within the mass transfer zone, mg/L  
 $C_{\text{inf}}$  = influent liquid-phase concentration of the adsorbate, mg/L  
 $C(z)/C_{\text{inf}}$  = normalized liquid-phase concentration at location  $z$  within the mass transfer zone, dimensionless  
 $q(z)$  = adsorbent-phase concentration of the adsorbate at location  $z$ , mg adsorbate/g adsorbent  
 $q_e|_{C_{\text{inf}}}$  = adsorbent-phase concentration of the adsorbate in equilibrium with the influent concentration, mg adsorbate/g adsorbent  
 $q(z)/q_e|_{C_{\text{inf}}}$  = degree of saturation at location  $z$  within the mass transfer zone, dimensionless

The relationship given in Eq. 15-100 is useful because the ratio of the liquid concentration as compared to the influent concentration equals the degree of saturation at any point in the fixed bed.

#### EMPTY-BED CONTACT TIME

The empty-bed contact time (EBCT) equals the volume of the bed occupied by the adsorbent divided by the flow rate:

$$\text{EBCT} = \frac{V_F}{Q} = \frac{A_F L}{v A_F} = \frac{L}{v} \quad (15-101)$$

where EBCT = empty-bed contact time, h  
 $V_F$  = volume occupied by adsorber media including porosity volume, m<sup>3</sup>  
 $Q$  = flow rate to adsorber, m<sup>3</sup>/h  
 $A_F$  = adsorber area available for flow, m<sup>2</sup>  
 $L$  = adsorber or media depth, m  
 $v$  = superficial flow velocity ( $Q/A_F$ ), m/h

The range of EBCTs in fixed-bed adsorption processes can vary from 5 to 60 min for GAC. For removal of SOCs from water, EBCTs in the range of 5 to 30 min are common. The superficial flow velocity is equal to the flow

rate divided by the cross-sectional area perpendicular to the flow. Typical adsorber velocities (approach velocity) range from 5 to 15 m/h (2 to 7 gpm/ft<sup>2</sup>).

#### SPECIFIC THROUGHPUT

Specific throughput is used to quantify the performance of a GAC adsorber and is defined as the volume fed to the adsorber divided by the mass of GAC in the adsorber:

$$\text{Specific throughput} = \frac{Q t_{bk}}{M_{GAC}} = \frac{V_F t_{bk}}{EBCT M_{GAC}} = \frac{V_F t_{bk}}{EBCT \rho_F V_F} = \frac{t_{bk}}{EBCT \rho_F} \quad (15-102)$$

where specific throughput = volume fed to adsorber divided by mass of GAC in adsorber, m<sup>3</sup>/kg

$M_{GAC}$  = mass of GAC, kg

$t_{bk}$  = time to breakthrough at the treatment objective, d

$\rho_F$  = adsorber density or filter bed density, g/L (or kg/m<sup>3</sup>)

$\rho_F$  is defined using the following equation:

$$\rho_F = \frac{M_{GAC}}{V_F} \quad (15-103)$$

The range of adsorber densities for GAC is 350 to 550 kg/m<sup>3</sup> (22 to 34 lb/ft<sup>3</sup>).

#### CARBON USAGE RATE

A more common way to quantify the performance of a GAC adsorber is in terms of carbon usage rate (CUR):

$$\text{CUR} = \frac{M_{GAC}}{Q t_{bk}} = \frac{1}{\text{specific throughput}} \quad (15-104)$$

#### PARTICLE SIZE

For GAC, two of the most important physical properties are hardness and particle size. Much of the operating cost of GAC results from losses by attrition during handling and reactivation. It is important to have large sweeping turns in GAC transport lines to the contactors to reduce clogging and GAC attrition. Losses are smaller for harder carbons. Similarly, the friability of the carbon used in adsorber beds controls the rate with which particles are broken down in size, leading to short adsorber runs (because high head loss) and loss during backwashing (which also mixes up the bed and results in poor performance). Particle size also influences head loss across a bed of GAC; if very small particles are used, higher head loss and crushing of the bed may result. The typical GAC particle diameters are 0.6 to 2.36 mm (8 × 30 U.S. mesh) and 0.425 to 1.70 mm (12 × 40 U.S. mesh).

**BED POROSITY**

The other important bed and particle properties, including bed porosity, were reported in the nomenclature table at the beginning of the chapter. The bed porosity of a GAC contactor fixed bed is complicated by the fact that GAC is porous and the activated carbon itself can have a porosity of 0.2 to 0.7, and this needs to be considered when bed porosity is estimated. In this regard, it is important to discuss how one could obtain the various carbon densities. The apparent density,  $\rho_a$ , is the density of the GAC per volume of GAC particle. The solid density,  $\rho_s$ , is that of graphite, which is about 2.0 to 2.2 g/cm<sup>3</sup>. The filter or bulk density,  $\rho_F$ , is the density of the GAC per volume of bed and is about 0.35 to 0.5 g/cm<sup>3</sup>. These relationships can be established for the porosity of a particle  $\varepsilon_p$  and the porosity of void fraction of the bed  $\varepsilon$ :

$$\varepsilon_p = 1 - \frac{\rho_a}{\rho_s} \quad (15-105)$$

$$\varepsilon = 1 - \frac{\rho_F}{\rho_a} \quad (15-106)$$

If the MTZ is short, the GAC column will be completely saturated at the point when the adsorbate reaches the end of the column, which corresponds to the largest specific throughput or smallest carbon usage rate that can be achieved. In effect, all the adsorbate fed is adsorbed in the column, and the adsorption capacity is in equilibrium with the influent concentration. Relating the total quantity of adsorbate fed to the column to the ultimate capacity of the GAC in the column, expressions for the maximum specific throughput and minimum carbon usage rate can be derived as follows:

$$QC_{\text{inf}} t_{\text{bk}} = M_{\text{GAC}} q_e|_{C_{\text{inf}}} \quad (15-107)$$

The maximum specific throughput and minimum carbon usage rate are then given by the expressions

$$\text{Maximum specific throughput} = \frac{Qt_{\text{bk}}}{M_{\text{GAC}}} = \frac{q_e|_{C_{\text{inf}}}}{C_{\text{inf}}} \quad (15-108)$$

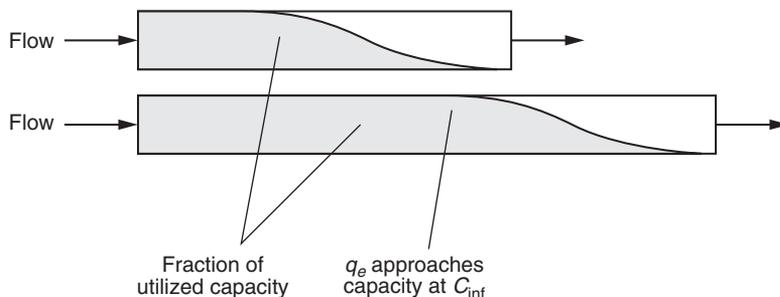

$$\text{Minimum CUR} = \frac{M_{\text{GAC}}}{Qt_{\text{bk}}} = \frac{C_{\text{inf}}}{q_e|_{C_{\text{inf}}}} \quad (15-109)$$

The fraction of utilized capacity increases for a GAC column as the length of column is increased, as shown on Fig. 15-21. The increase in capacity results from a mass transfer zone that has a constant shape and size, which occurs for compounds that have favorable isotherms (Freundlich  $1/n < 1.0$ ). The use of Eqs. 15-108 and 15-109 is demonstrated in Example 15-9.

If a treatment objective of  $C_{\text{eff}}/C_{\text{inf}}$  or  $\bar{C}_{\text{to}}$  is chosen, then the specific throughput and carbon usage rate can be calculated using the following equations:

$$QC_{\text{inf}} t_{\text{bk}} = Q \int_0^{t_{\text{bk}}} C_{\text{eff}} dt + q_c M_{\text{GAC}} \quad (15-110)$$

**Determination  
of Specific  
Throughput and  
Carbon Usage  
Rate**

column lengths.

### Example 15-9 GAC column analysis

Calculate the bed life, volume of water treated, minimum CUR, and maximum specific throughput for trichloroethene (TCE) given the following design specifications:

Influent concentration = 1 mg/L

Carbon type: Calgon Filtrasorb 400 (12 × 40 mesh);  $\rho_b = 450$  g/L

Freundlich parameters for TCE can be obtained from Table 15-6.

- Freundlich capacity parameter  $K = 55.9$  (mg/g)(L/mg)<sup>1/n</sup>
- Freundlich intensity parameter  $1/n = 0.48$

Treatment objective = 0.005 mg/L TCE

Flow rate = 378.5 L/min (100 gal/min)

EBCT = 10 min

#### Solution

1. Calculate the minimum GAC usage rate and maximum specific throughput. The best performance for the GAC is given by assuming that only TCE is in the influent and the MTZ is small compared to the column length. The GAC usage rate and specific throughput are given by Eqs. 15-109 and 15-108, respectively:

$$\begin{aligned} \text{CUR} &= \frac{M_{\text{GAC}}}{Q t_{\text{bk}}} = \frac{C_{\text{inf}}}{q_e} = \frac{C_{\text{inf}}}{K(C_{\text{inf}})^{1/n}} \\ &= \frac{1.0 \text{ mg/L}}{[55.9 \text{ (mg/g)(L/mg)}^{0.48}](1.0 \text{ mg/L})^{0.48}} \\ &= 0.018 \text{ g GAC/L H}_2\text{O treated} \end{aligned}$$

$$\begin{aligned}\text{Specific throughput} &= \frac{1}{\text{GAC usage rate}} = \frac{1}{0.018 \text{ g/L}} \\ &= 55.9 \text{ L H}_2\text{O treated/g GAC}\end{aligned}$$

2. Determine the volume of water treated. The volume of water treated can be calculated in the following manner. First, the mass of carbon in the vessel is calculated:

$$\begin{aligned}\left\{ \begin{array}{l} \text{Mass of GAC in} \\ \text{10-min EBCT bed} \end{array} \right\} &= V_F \rho_F = (\text{EBCT})(Q)(\rho_F) \\ &= (10 \text{ min})(378.5 \text{ L/min})(450 \text{ g/L}) = 1.7 \times 10^6 \text{ g}\end{aligned}$$

The volume treated can be determined from the definition of the GAC usage rate:

$$\begin{aligned}\left\{ \begin{array}{l} \text{Volume of H}_2\text{O treated} \\ \text{for 10-min EBCT bed} \end{array} \right\} &= \left\{ \frac{\text{mass of GAC in 10-min EBCT bed}}{\text{GAC usage rate}} \right\} \\ &= \frac{1.7 \times 10^6 \text{ g}}{0.018 \text{ g/L H}_2\text{O}} = 9.4 \times 10^7 \text{ L H}_2\text{O}\end{aligned}$$

3. Calculate the bed life. The bed life can be determined from the volume of water treated and the flow rate:

$$\begin{aligned}\text{Bed life} &= \frac{\text{volume of H}_2\text{O treated for 10-min EBCT bed}}{Q} \\ &= \frac{9.4 \times 10^7 \text{ L}}{(378.5 \text{ L/min})(1440 \text{ min/d})} \\ &= 172 \text{ d}\end{aligned}$$

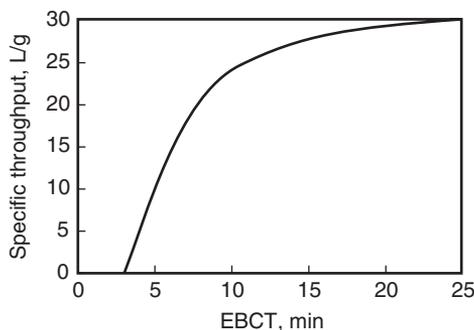

### Comment

The presence of NOM will reduce bed life significantly. The bed life determined in this example represents the maximum expected value, as the influence of NOM is ignored and the MTZ is assumed to be very short.

where  $q_c$  = average adsorbent-phase concentration of adsorbate in GAC column, mg adsorbate/g adsorbent  
 $C_{\text{eff}}$  = effluent liquid-phase concentration at  $t$ , mg/L

The adsorbent-phase concentration is given as

$$q_c = \frac{\int_0^{t_{\text{bk}}} Q(C_{\text{inf}} - C_{\text{eff}}) dt}{M_{\text{GAC}}} \quad (15-111)$$

**Figure 15-22**

Specific throughput versus EBCT for a single GAC column.

The specific throughput can then be determined by rearranging Eq. 15-109:

$$\frac{Q_{hk}}{M_{GAC}} = \frac{Q \int_0^{t_{hk}} C_{eff} dt}{C_{inf} M_{GAC}} + \frac{q_c}{C_{inf}} \quad (15-112)$$

If  $\bar{C}_{eff}/\bar{C}_{inf}$  or  $\bar{C}_{to}$  is small (e.g.,  $< 0.05$ ), then the first term on the right-hand side is negligible and the specific throughput is equal to the expression:

$$\frac{Q_{hk}}{M_{GAC}} = \frac{q_c}{C_{inf}} \quad (15-113)$$

Consequently, the specific throughput increases as the EBCT increases as shown on Fig. 15-22 and demonstrated in Example 15-10. The specific throughput approaches the maximum value given by Eq. 15-108 when the mass transfer zone is much smaller than the EBCT and  $q_c$  approaches  $q_e$ . As shown in Fig. 15-22, when the bed length equals the MTZ, the specific throughput approaches zero because the effluent concentration of the adsorbate appears in the effluent very quickly.

As shown on Fig. 15-22, the specific throughput is zero up to a minimum EBCT because the column must be longer than the MTZ or the effluent concentration immediately exceeds the treatment objective. From a cost perspective, it is important to realize that as the specific throughput increases (by increasing the EBCT) the operation and maintenance costs decrease, but it comes at the expense of increasing capital cost because the contactor size needed is larger.

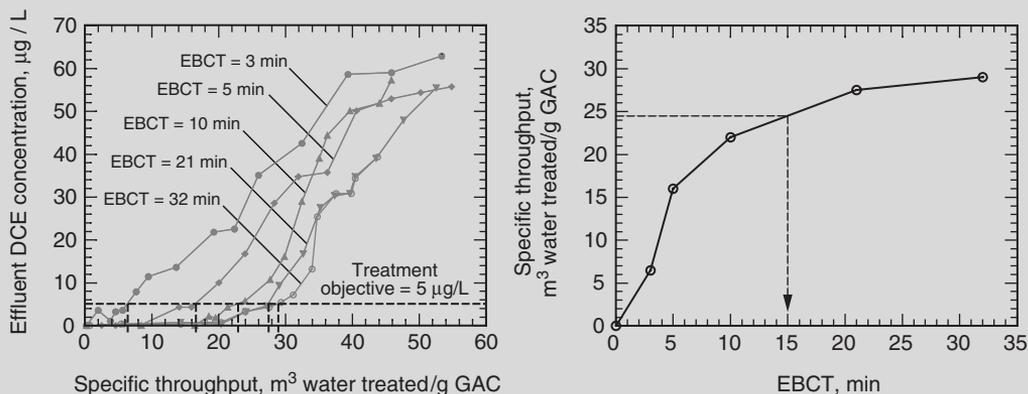

### Example 15-10 Analysis of pilot plant adsorption data

A GAC pilot plant study was performed on a groundwater containing *cis*-1,2-dichloroethene (DCE). The impact of EBCT on GAC performance was evaluated by conducting column experiments for EBCTs of 3, 5, 10, 21, and 32 min. The DCE effluent concentration for each EBCT was plotted in terms of

specific throughput (liters of water treated per gram GAC) using Eq. 15-102 and is displayed below. Using the column data, plot the specific throughput for a treatment objective of  $5 \mu\text{g/L}$  as a function of EBCT and determine a reasonable EBCT for DCE in this groundwater.

### Solution

1. Construct a plot of the specific throughput for a treatment objective of  $5 \mu\text{g/L}$  as a function of EBCT.
  - a. On the y axis locate the  $5\text{-}\mu\text{g/L}$  treatment objective and draw a line parallel to the x axis so it intersects the effluent profile.
  - b. Where the  $5\text{-}\mu\text{g/L}$  line intersects effluent profiles, draw a line down to the x axis to obtain the specific throughput for each EBCT as shown. For EBCTs of 3, 5, 10, 21, and 32 the specific throughputs are 6.5, 16.0, 22.0, 27.5, and  $29.0 \text{ m}^3$  water treated per gram of GAC, respectively.
  - c. Plot the specific throughput as a function of EBCT.

2. Determine a reasonable EBCT for a single adsorber for DCE in this groundwater. From the plot constructed in step 1c, it is clear that the specific throughput reaches a point of diminishing returns at about 15 min of EBCT.

### Comments

The concepts that were introduced above for evaluating the specific throughput as a function of EBCT are useful for fixed beds that are used to treat contaminated groundwaters containing mixtures of organics.

However, the pilot data that was presented in this example took one year to collect. Not only is this time in most cases unacceptably long, but a pilot

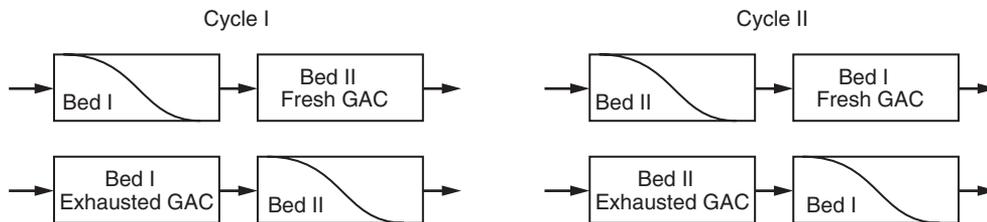

test like this is very costly. Accordingly, rapid small-scale column tests may be useful in determine the carbon usage rate. These tests are presented later in this chapter.

### GAC Operation

Countercurrent operation is the most efficient operation when high degrees of removal are needed ( $C_{to}/C_{inf} < 0.05$ ) because, in principle, the GAC can be saturated with respect to the influent concentration. Furthermore, the effluent concentration will be less than the treatment objective if the column is longer than the MTZ. However, GAC is friable and cannot withstand the movement in a countercurrent operation without suffering significant losses (fines generation). Although countercurrent GAC columns have been commercially available, it has been found that the increase in specific throughput did not warrant the extra cost. Consequently, GAC operations may be operated as two beds (or perhaps more beds) in series to achieve similar efficiencies. Series operation will reduce the amount of GAC needed by as much as 25 to 50 percent. The series arrangement is often not worth the expense of the extra yard piping and additional vessel(s) unless the GAC bed life is less than 3 to 6 months. A detailed economic analysis must be conducted to be certain. Longer EBCTs are easily achieved by increasing the sidewall depth, which is less expensive than operating more vessels in series.

#### BEDS IN SERIES

The operation of two beds in series is illustrated on Fig. 15-23. During cycle I, the MTZ forms in bed I and moves into bed II. Once the treatment objective is exceeded in the effluent from bed II, cycle II begins. During the first phase of cycle II, bed I is taken offline and the GAC is replaced with fresh carbon and bed II is switched to the influent. The operation continues until the mass transfer zone moves from bed II into bed I and the effluent from bed I exceeds the treatment objective. At this point, cycle III begins and bed I receives the influent, and bed II is recharged with fresh carbon and put into operation just as shown in cycle I. If the length

**Figure 15-23**  
Operation of two beds in series.

of beds I and II are greater or equal to the length of the MTZ, then the GAC will be saturated fully and the GAC usage rate can be calculated using Eq. 15-109. The CUR and specific throughput for this type of operation can be determined from a pilot study that is conducted in this manner using the following expressions:

$$\text{Specific throughput} = \frac{Qt_c}{M_1} \quad (15-114)$$

$$\text{CUR} = \frac{M_1}{Qt_c} \quad (15-115)$$

where  $M_1$  = mass of carbon in first bed that is removed after a number of cycles, g

$Q$  = water flow rate, L/s

$t_c$  = cycle time, d

The specific volume for two beds in series operation can be determined from pilot study data, as shown in the previous example, by considering what happens to the mass of adsorbate during a cyclic operation after several cycles and how that is related to a two-beds-in-series pilot column operation. To use the data from the example, which is a noncyclic pilot plant, the loading on the first and second columns will be assumed to be the same as for a cyclic operation. This condition will be met in most instances for the following two reasons. First, the two columns in a cyclic pilot study will have a similar history to a noncyclic pilot study if the influent to the second column in a noncyclic pilot study is close to the influent concentration when the effluent concentration exceeds the treatment objective. Second, similar loadings will also occur if the total EBCT is long enough to reestablish a MTZ that is similar to that observed in pilot plant data, even if the lag column sees an increase in influent concentration after being switched from the lag position to the lead position. Consequently, the specific throughput can be determined by ignoring the adsorbate in the second column because it would be equal to the mass that was in the first column at startup, and this would move to the second column at the end of the cycle and balance out. With these arguments in mind, the mass fed to a cyclic operation can be determined from a noncyclic pilot study:

$$\text{Mass fed for a cyclic operation} = \text{mass retained on first column} + \text{mass in effluent of the second column} \quad (15-116)$$

$$QC_{\text{inf}} t_c = q_1 M_1 + Q \int_0^{t_0} C_2 dt \quad (15-117)$$

$$q_1 = \frac{Q \left[ C_{\text{inf}} t_c - \int_0^{t_0} (C_1) dt \right]}{M_1} \quad (15-118)$$

where  $C_{\text{inf}}$  = influent liquid-phase concentration of adsorbate, mg/L  
 $q_1$  = loading observed in column 1 in noncyclic pilot study, mg adsorbate/g adsorbent  
 $C_1$  = effluent concentration from column 1 in noncyclic pilot study, mg/L  
 $C_2$  = effluent concentration from column 2 in noncyclic pilot study, mg/L  
 $t_o$  = time of operation of noncyclic pilot study up to time when effluent exceeds treatment objective, d

The specific throughput and CUR can then be determined from the following equations:

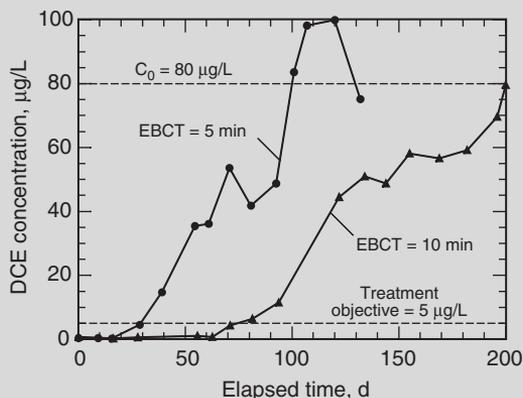

$$\text{Specific throughput} = \frac{Qt_c}{M_1} = \frac{q_1}{C_{\text{inf}}} + \frac{Q \int_0^{t_o} \bar{C}_2 dt}{M_1} \quad (15-119)$$

$$\text{CUR} = \frac{M_1}{Qt_c} = \frac{1}{q_1/C_{\text{inf}} + Q \int_0^{t_o} \bar{C}_2 dt / M_1} \quad (15-120)$$

where  $\bar{C}_2$  = dimensionless effluent concentration from column 2 in a noncyclic pilot study, =  $C_2/C_{\text{inf}}$

### Example 15-11 Analysis of carbon beds in series

For the GAC pilot plant data presented in Example 15-10, determine the specific throughput for DCE for two beds in series with each bed having an EBCT of 5.0 min. The flow rate is 232 L/d, the adsorber density is 0.457 g/cm<sup>3</sup>, the average DCE influent concentration is 80 μg/L, and the DCE treatment objective is 5 μg/L. The concentration–history profiles for DCE as a function of elapsed time in days are given below.

Column data:

EBCT, min	M, g	t, d	Q · t, L	L/g
5.0	395.5	27.3	6,334	16.0
10.0	791.1	75	17,400	22.0

### Solution

1. Calculate the specific throughput. The specific throughput can be calculated using Eq. 15-119. The contribution from both the first and second columns is given by:

$$\text{Specific throughput} = \frac{Qt_c}{M_1} = \underbrace{\frac{q_1}{C_0}}_{\text{contribution from first column}} + \underbrace{\frac{Q \int_0^{t_0} \bar{C}_2 dt}{M_1}}_{\text{contribution from second column}}$$

- a. Calculate the contribution from the amount of adsorbate in the effluent from the second column using the expression shown in Eq. 15-119 for the second column. For two beds in series with 5.0-min EBCT, the treatment objective from the second column is exceeded after 75 days and the average influent concentration is 80  $\mu\text{g/L}$ . The contribution from the amount of adsorbate in the effluent from the pilot study in cycle is given by the expressions:

$$\begin{aligned} \frac{Q}{M_1 C_{\text{inf}}} \int_0^{t_0} C_2 dt &= \frac{Q}{V_{F\rho_F} C_{\text{inf}}} \int_0^{t_0} C_2 dt = \frac{1}{\text{EBCT}_1 \rho_F C_{\text{inf}}} \int_0^{t_0} C_2 dt \\ \frac{1}{\text{EBCT}_1 \rho_F C_{\text{inf}}} \int_0^{t_0} C_2 dt &\approx \left( \frac{1}{5.0 \text{ min}} \right) \left( \frac{\text{L}}{457 \text{ g}} \right) \left( \frac{\text{L}}{80 \mu\text{g}} \right) \frac{1}{2} (75 - 50) \text{d} \\ &\quad \times (1440 \text{ min/d})(5 \mu\text{g/L}) \\ &= 0.49 \text{ L/g} \end{aligned}$$

- b. Calculate the contribution to the specific throughput due to adsorption onto the first column. The loading on the first column, when the effluent is 5  $\mu\text{g/L}$  from the second column, is computed using Eq. 15-118 as follows:

$$q_1 = \frac{Q \left( C_{\text{inf}} t_0 - \int_0^{t_0} C_1 dt \right)}{M_1} = \frac{1}{\text{EBCT}_1 \rho_F} \left( C_{\text{inf}} t_0 - \int_0^{t_0} C_1 dt \right)$$

$$\int_0^{t_0} C_1 dt \approx \frac{1}{2}(75 - 20)d \times (48 \mu\text{g/L})(1440 \text{ min/d})$$

$$= 1.90 \times 10^6 \mu\text{g} \cdot \text{min/L}$$

$$C_{\text{inf}} t_0 = (80 \mu\text{g/L})(75 \text{ d})(1440 \text{ min/d}) = 8.64 \times 10^6 \mu\text{g} \cdot \text{min/L}$$

$$q_1 = \frac{(8.64 \times 10^6 - 1.90 \times 10^6) \mu\text{g} \cdot \text{min/L}}{5.0 \text{ min} \times (457 \text{ g/L})} = 2950 \mu\text{g/g}$$

The contribution to the specific throughput due to adsorption onto the first column is given by the following expression, which is the expression shown in Eq. 15-119 for the first column:

$$\frac{q_1}{C_0} = \frac{2950 \mu\text{g/g}}{80 \mu\text{g/L}} = 37 \text{ L/g}$$

2. Calculate the specific throughput using Eq. 15-119 and the values computed in step 1:

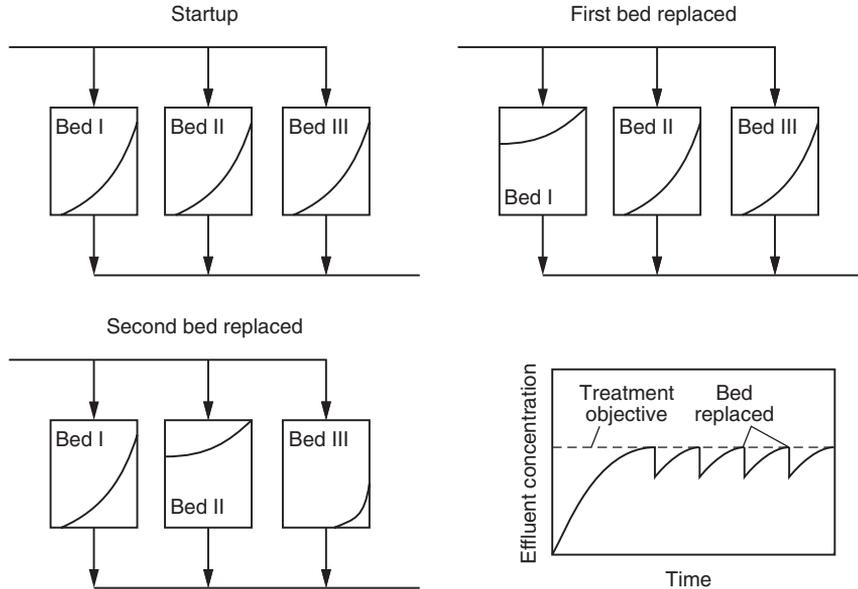

$$\text{Specific throughput} = \frac{Qt_c}{M_1} = \frac{q_1}{C_0} + \frac{Q \int_0^{t_0} \bar{C}_2 dt}{M_1} = 37 + 0.49 = 37.5 \text{ L/g}$$

### Comment

If one compares the specific throughput for two 5-min-EBCT beds in series (37.5 L/g) with a single adsorber with 10-min EBCT (22 L/g), the beds-in-series operation can treat about 70 percent more water.

### BEDS IN PARALLEL

Dissolved organic carbon can also be removed using GAC, but a high degree of DOC removal cannot be achieved using reasonable specific throughputs and EBCTs. Typically, 30 to 70 percent of the DOC can be removed using GAC. Using beds that are operated in parallel can significantly increase specific throughput and can reduce the amount of GAC that is required. Backwashing of the columns is not as much of an issue for DOC removal because high degrees of removal are not achieved and performance, therefore, will not be significantly impacted by backwashing. Further, the mass transfer rate for DOC is slow; consequently, the concentration profiles within particles at different depths may not be significantly different.

**Figure 15-24**  
Operation of three beds  
in parallel.

The blending of effluent from three GAC adsorbers operating in parallel after startup and after several cycles is shown on Fig. 15-24. At startup, all three adsorbers have similar bed profiles; once the treatment objective is exceeded, the first adsorber is replaced with fresh GAC. After replacement, the treatment objective can be met with blended effluent from the adsorbers. Operation continues until the treatment objective cannot be met and then the second bed is replaced. At this point, there are three adsorbers with different degrees of saturation, and the treatment objective is still being met because effluent from nearly exhausted adsorbers is blended with effluent from fresh adsorbers. After the treatment objective is exceeded, the third bed is replaced and the cycle begins again by replacing the first column, which will be the column that has been online for the longest period of time. A pilot study can be used to determine the activated carbon usage rate for GAC beds in parallel. The following simple approach can be used to calculate the concentration of organic compound remaining in the effluent of parallel adsorbers just prior to the replacement of one of the beds operated in parallel (Roberts and Summers, 1982):

$$\bar{f} = \frac{1}{n} \sum_{i=1}^n f_i \quad (15-121)$$

where  $\bar{f}$  = concentration of organic compound remaining in effluent, mg/L

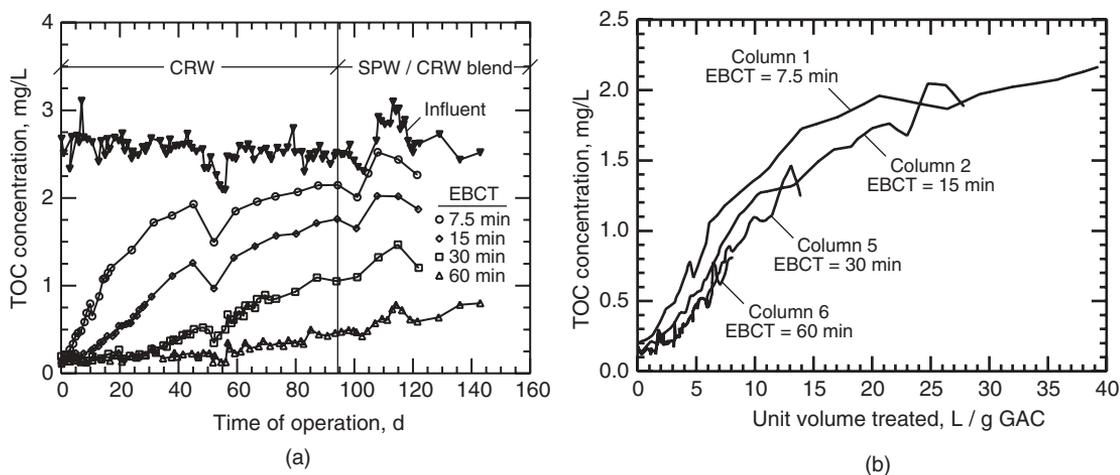

$f_i$  = concentration of organic compound remaining in effluent from  $i$ th adsorber, which is determined by dividing the effluent profile from a single adsorber into a number of intervals, mg/L

$n$  = number of equal-capacity adsorbers in parallel

The value of  $f_i$  can be determined from a single breakthrough curve. Assume that replacement of GAC in each adsorber will take place at equal intervals. If  $\theta_n$  is the number of bed volumes processed through each adsorber in the parallel system at the time of replacement, the abscissa of the breakthrough curve for the individual contactor from 0 to  $\theta_n$  is divided into  $\theta_n/n$  equal increments. For a given value of  $\theta_n$ , Eq. 15-121 can be used with a single breakthrough profile to calculate the concentration of the blended water and the specific throughput. To determine  $\theta_n$ , one needs to choose the number of bed volumes from a single adsorber such that, if you divide the bed volumes by  $n$  and add the effluent concentrations of the beds in parallel, the sum will equal the treatment objective. The idea is that these beds would be operating parallel, and one of them would be replaced when the sum of the effluent concentrations from the adsorbers equals the treatment objective. The starting concentration for the next cycle would shift to the left by  $\theta_n$  and then would be equal to the sum of all the adsorbers operating in parallel. The effluent profile of all the adsorbers would then operate for another  $\theta_n$  before the adsorber that has been online for the longest period is replaced. An example of this approach may be found in Snoeyink and Summers (1999). It must be stated that this method assumes the same flow for each adsorber and that if biological activity does occur, it does not change with time.

#### **MULTIPLE BEDS IN PARALLEL**

The utility of using multiple beds in parallel will be illustrated by discussing a pilot study that was conducted by the Metropolitan Water District of Southern California, MWH Global, and Michigan Technological University (Crittenden et al., 1993; McGuire et al., 1991; McGuire, 1989). The purpose of the study was to determine the cost associated with removing TOC and the associated trihalomethane formation potential (THMFP) from two Southern California water supplies. During the study, mixtures of California State Project water (SPW) and Colorado River water (CRW) were used, and the mean TOCs for SPW and CRW were 2.64 and 2.52 mg/L, respectively, and were very consistent. The concentration of TOC as a function of operation time and EBCT is shown on Fig. 15-25a. The concentration of TOC as a function of specific throughput and EBCT is shown on Fig. 15-25b. The column with 60-min EBCT was backwashed at 38 and 112 days of operation, and the column with 30-min EBCT was backwashed at 108 days of operation. Backwashing had essentially no impact on performance, as shown on Fig. 15-25a.

**Figure 15-25**

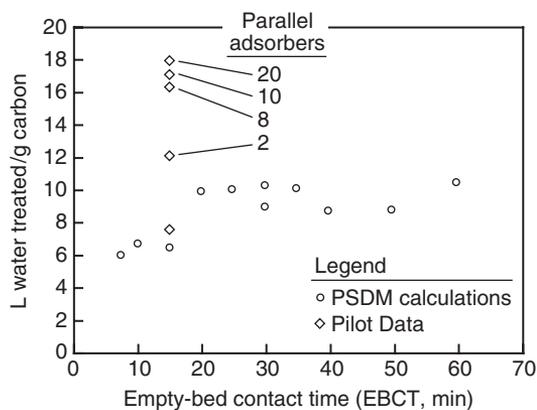

TOC concentration history profiles for EBCTs of 7.5, 15, 30, and 60 min: (a) TOC concentration versus time of operation and (b) TOC concentration versus specific throughput.

The following equations were used to describe the relationship between TOC and THMFP for the two waters (McGuire, 1989):

$$\text{THMFP } (\mu\text{g/L}) = \text{TOC } (\text{mg/L}) \times 59 - 2.3 \quad (15-122)$$

$$\text{THMFP } (\mu\text{g/L}) = \text{TOC } (\text{mg/L}) \times 97.41 - 6.36 \quad (15-123)$$

Assuming a treatment objective for THMFP of 50  $\mu\text{g/L}$ , the effluent TOC concentration cannot exceed 1 mg/L for CRW, which corresponds to a  $\bar{C}_{\text{to}}$  value of 0.4. The specific throughput as a function of EBCT for a treatment object of 1 mg/L is shown on Fig. 15-26. The specific throughput

**Figure 15-26**

Liters of water treated per gram of GAC for a DOC treatment objective of 1 mg/L as function of EBCT. The specific throughput values at some EBCTs were calculated using the pore surface diffusion model (PSDM).

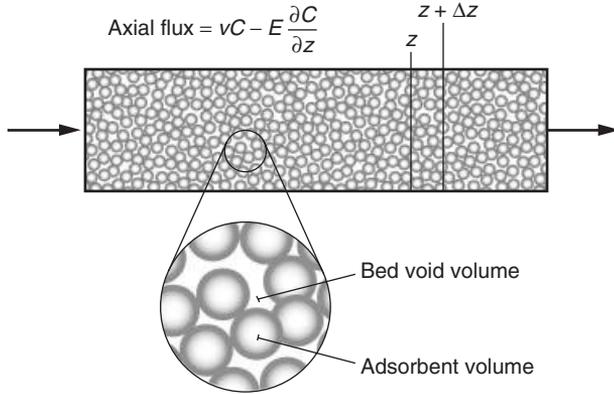

for this DOC treatment objective using a single GAC contactor reaches diminishing returns after about 15 to 25 min of EBCT. The variability in the specific throughput is due to the time-variable influent concentration for the pilot studies and modeling predictions of the time-variable influent concentration. However, as shown on Fig. 15-26, no significant change in the specific throughput is observed after more than eight adsorbers are operated in parallel and about 2.4 times more water can be treated as compared to a single adsorber with 15 min of EBCT. This type of information has been used to optimize the GAC process in terms of costs (Lee et al., 1983; McGuire, 1989; McGuire et al., 1991). A number of researchers have shown that UV absorption can be used to assess the DOC and DBP precursor removal and for process control (Sontheimer et al., 1988).

#### **SUMMARY OF THE BENEFITS OF SERIES AND PARALLEL BED OPERATION**

The largest specific throughput is obtained for EBCTs around 10 to 20 min for the removal of SOCs ( $MW < \sim 300$ ) with stringent treatment objectives. Two beds that are operated in series may increase the specific throughput by 20 to 50 percent. For TOC removal [disinfection by-product formation potential (DBPFP)], beyond EBCTs of 15 to 30 min the specific throughput does not increase. In addition, it may not be reasonable to achieve more than 70 percent removal of TOC using GAC. In situations where only 30 to 80 percent removal of organics is required, single beds that are operated in parallel may be the least expensive option because the flow from exhausted columns can be blended with the flow from fresh columns. Furthermore, there will always be a GAC barrier that can removal spikes of organic contaminants.

#### **Modeling GAC Performance**

To describe the migration of an adsorbate through a fixed bed, mass balances on the solid (immobile phase) and liquid (mobile phase) phases are written and the following assumptions are made: (1) liquid-phase concentration gradients in a fixed-bed adsorber exist only in the axial direction; that is, concentration gradients only exist in the flow direction; (2) the liquid-phase concentration gradient in the axial direction is small enough such that the concentration difference across any single adsorbent particle is negligible (this implies that the bulk solution concentration surrounding any single-adsorbent particle is identical); (3) the adsorbent is in a fixed position in the adsorber (backwashing that may disturb the mass transfer zone is not considered); (4) the adsorbate contained in the liquid phase (not adsorbed onto the surface) in the carbon pores can be neglected; and (4) the hydraulic loading is constant. The liquid-phase mass balance on a thin or differential element of the bed, which is shown in

**Figure 15-27**

Axial transport mechanisms in a fixed-bed adsorber.

Fig. 15-27, is given by the following word equation:

$$\left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{entering by advection} \\ \text{and dispersion} \\ \text{in liquid phase at } z \end{array} \right\} - \left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{entering by advection} \\ \text{and dispersion} \\ \text{in liquid phase at } z + \Delta z \end{array} \right\} \quad (15-124)$$

$$= \left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{accumulating in} \\ \text{the liquid phase} \\ \text{between } z \text{ and } z + \Delta z \end{array} \right\} + \left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{accumulating in} \\ \text{the solid phase} \\ \text{between } z \text{ and } z + \Delta z \end{array} \right\}$$

The four terms that appear in Eq. 15-124 are given by these expressions:

$$\left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{entering by advection} \\ \text{and dispersion in} \\ \text{liquid phase at } z \end{array} \right\} = v\varepsilon AC|_z - E\varepsilon A \left. \frac{\partial C}{\partial z} \right|_z \quad (15-125)$$

$$\left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{entering by advection} \\ \text{and dispersion in} \\ \text{liquid phase at } z + \Delta z \end{array} \right\} = v\varepsilon AC|_{z+\Delta z} - E\varepsilon A \left. \frac{\partial C}{\partial z} \right|_{z+\Delta z} \quad (15-126)$$

$$\left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{accumulating in} \\ \text{the liquid phase} \\ \text{between } z \text{ and } z + \Delta z \end{array} \right\} = \varepsilon A \Delta z \frac{\partial C}{\partial t} \quad (15-127)$$

$$\left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{accumulating in} \\ \text{the solid phase} \\ \text{between } z \text{ and } z + \Delta z \end{array} \right\} = A_p k_f (C - C_s) \quad (15-128)$$

where  $\varepsilon$  = bed void fraction, dimensionless  
 $A$  = fixed-bed cross-sectional area,  $\text{m}^2$   
 $E$  = dispersion coefficient,  $\text{m}^2/\text{s}$   
 $v$  = interstitial velocity,  $\text{m}/\text{s}$   
 $A_p$  = total external surface area of adsorbent particle available for mass transfer,  $\text{m}^2$   
 $z$  = axial position in bed,  $\text{m}$   
 $t$  = elapsed time,  $\text{s}$   
 $k_f$  = film transfer coefficient,  $\text{m}/\text{s}$   
 $C$  = adsorbate liquid-phase concentration,  $\text{mg}/\text{L}$   
 $C_s$  = adsorbate liquid-phase concentration at adsorbent exterior surface,  $\text{mg}/\text{L}$

Combining Eq. 15-124 to 15-128 and dividing by  $\Delta z$  results in the expression:

$$-v\varepsilon A \frac{C|_{z+\Delta z} - C|_z}{\Delta z} + \varepsilon EA \frac{\left. \frac{\partial C}{\partial z} \right|_{z+\Delta z} - \left. \frac{\partial C}{\partial z} \right|_z}{\Delta z} = \varepsilon A \frac{\partial C}{\partial t} + \frac{A_p k_f (C - C_s)}{\Delta z} \quad (15-129)$$

Dividing Eq. 15-129 by  $\varepsilon A$  and taking the limit as  $\Delta z$  approaches zero results in

$$-v \frac{\partial C}{\partial z} + E \frac{\partial^2 C}{\partial z^2} = \frac{\partial C}{\partial t} + \frac{A_p k_f (C - C_s)}{A \varepsilon \Delta z} \quad (15-130)$$

The total adsorbent surface area per volume of bed,  $A_p$ , may be expressed as

$$A_p = \left( \frac{\text{Adsorbent area}}{\text{Adsorbent volume}} \right) \left( \frac{\text{Adsorbent volume}}{\text{Bed volume}} \right) \quad (15-131)$$

The adsorbent area per adsorbent volume is independent of the number of particles (as long as a representative sample is used).

$$\frac{\text{Adsorbent area}}{\text{Adsorbent volume}} = \frac{4\pi R^2 \mathfrak{3}}{\phi 4\pi R^3} = \frac{3}{\phi R} \quad (15-132)$$

where  $R$  = radius of adsorbent particle,  $\text{m}$   
 $\phi$  = adsorbent particle sphericity, dimensionless

$$\phi = \frac{\frac{\text{Sphere area}}{\text{Sphere volume}}}{\frac{\text{Adsorbent area}}{\text{Adsorbent volume}}} \quad (15-133)$$

$$\frac{\text{Adsorbent volume}}{\text{Bed volume}} = 1 - \varepsilon \quad (15-134)$$

Substituting Eqs. 15-132 and 15-134 into Eq. 15-131 yields:

$$A_p = \frac{3}{\phi R} (1 - \varepsilon) \quad (15-135)$$

The sphericity value,  $\phi$ , depends on how the radius is determined. A wide variety of  $\phi$  values based on a volume average diameters have been reported in the literature for as-received carbons and a few are reported here: F-300,  $1.41 \pm 0.10$ ; ROW 0.8S,  $1.40 \pm 0.07$ ; SNK12,  $1.37 \pm 0.08$ ; SLSS,  $1.24 \pm 0.09$  (Sontheimer et al., 1988). These values were obtained using image analysis. If sieve analysis is used to determine the particle diameter, sphericity values of 1.0 yield adequate results because the GAC particles usually have a cylindrical shape and tend to pass through smaller sieve openings. For example, Sontheimer et al. (1988) reported a 30 percent larger  $A_p$  value for F-300, if the diameter from sieve analysis is used as compared to the volume average diameter. This is very similar to the sphericity value that has been estimated by image analysis.

Substituting Eq. 15-135 into Eq. 15-130 yields the final form of the liquid-phase mass balance for adsorbate  $i$  in the fixed bed:

$$-v \frac{\partial C}{\partial z} + E \frac{\partial^2 C}{\partial z^2} = \frac{\partial C}{\partial t} + \frac{3k_f(1-\varepsilon)}{\phi R \varepsilon} (C - C_s) \quad (15-136)$$

To solve Eq. 15-136, one initial condition and two boundary conditions are needed. The initial condition is given by

$$C(0 \leq z \leq L, t = 0) = 0 \quad (15-137)$$

where  $L$  = length of the bed occupied by the GAC, m

The first boundary condition used to solve Eq. 15-136 can be derived by writing a mass balance over the entire fixed bed and may be considered a dynamic version of the Dankwerts boundary condition (Dankwerts, 1953). In words, this may be expressed as

$$\begin{aligned} & \left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{entering the fixed bed} \end{array} \right\} - \left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{leaving the fixed bed} \end{array} \right\} \\ &= \left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{accumulating in} \\ \text{the liquid phase} \\ \text{in the fixed bed} \end{array} \right\} + \left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{accumulating in} \\ \text{the solid phase} \\ \text{in the fixed bed} \end{array} \right\} \end{aligned} \quad (15-138)$$

The four terms appearing in Eq. 15-138 are show below:

$$\left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{entering the fixed} \end{array} \right\} = vA\varepsilon C_0(t) \quad (15-139)$$

$$\left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{leaving the fixed} \end{array} \right\} = vA\varepsilon C(z = L, t) \quad (15-140)$$

$$\left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{accumulating in} \\ \text{the liquid phase} \\ \text{in the fixed bed} \end{array} \right\} = A\varepsilon \int_0^L \frac{\partial C}{\partial t} dz \quad (15-141)$$

$$\left\{ \begin{array}{l} \text{Mass of adsorbate } i \\ \text{accumulating in} \\ \text{the solid phase} \\ \text{in the fixed bed} \end{array} \right\} = \rho_a (1 - \varepsilon) A \int_0^L \frac{\partial q_{\text{ave}}}{\partial t} dz \quad (15-142)$$

The final form of the first boundary condition is given by

$$vC_0(t) - vC(z=L, t) = \int_0^L \frac{\partial C}{\partial t} dz + \frac{\rho_a(1-\varepsilon)}{\varepsilon} \int_0^L \frac{\partial q_{\text{ave}}}{\partial t} dz \quad (15-143)$$

where  $C_0$  = adsorbate influent concentration entering fixed bed, mg/L  
 $q_{\text{ave}}$  = adsorbate average solid-phase concentration, mg/g

The average solid-phase loading is given by

$$q_{\text{ave}} = \frac{3}{4\pi R^3} \int_0^R q 4\pi r^2 dr \quad (15-144)$$

where  $q$  = adsorbate solid-phase concentration at radial coordinate in adsorbent and axial coordinate within fixed bed, mg/g  
 $r$  = radial coordinate within adsorbent particle, m

The second boundary condition for the liquid-phase mass balance is the Dankwerts condition at the exit boundary,  $z = L^-$ .

$$\frac{\partial^2 C(z=L^-, t)}{\partial t \partial z} = 0 \quad (15-145)$$

$$\frac{\partial C(z, t=0)}{\partial z} = 0 \quad (15-146)$$

The solution to Eq. 15-136 requires the liquid-phase concentration at the adsorbent surface  $C_s$ . To obtain  $C_s$ , a mass balance on the adsorbent phase has to be derived. Equation 15-56, which was developed for PAC applications, is also valid for GAC, but the solid-phase concentration depends on the axial position in the bed:

$$\frac{D_s}{r^2} \frac{\partial}{\partial r} \left( r^2 \frac{\partial q}{\partial r} \right) = \frac{\partial q}{\partial t} \quad (15-147)$$

The boundary and initial conditions for Eq. 15-147 are given by these expressions:

$$k_f(C - C_s) = D_s \rho_a \frac{\partial q}{\partial r} \quad (15-148)$$

$$\frac{\partial q(r=0, 0 \leq z \leq L, t \geq 0)}{\partial r} = 0 \quad (15-149)$$

$$q(0 \leq r \leq R, 0 \leq z \leq L, t=0) = 0 \quad (15-150)$$

The model must be made dimensionless to provide general answers and using dimensionless time, and positions,  $\bar{z} = z/L$  and  $\bar{r} = r/R$  yields the

desired equation. Dimensionless time is defined by the following word equation and mathematical equivalent for a single component:

$$\left( \frac{\text{Mass}}{\text{throughput}} \right) = T = \frac{\text{mass fed}}{\text{mass adsorbed at equilibrium}} \quad (15-151)$$

$$T = \frac{QC_0 t}{Mq_e} = \frac{QC_0 t}{V\rho_a(1-\varepsilon)q_e} \quad (15-152)$$

$$\tau = \frac{L}{v} = \frac{L}{Q/\varepsilon A} = \frac{\varepsilon V}{Q} \quad (15-153)$$

$$T = \frac{\varepsilon C_0 t}{\tau\rho_a(1-\varepsilon)q_e} \quad (15-154)$$

where  $T$  = mass throughput, dimensionless  
 $Q$  = liquid flow rate, m<sup>3</sup>/s  
 $M$  = mass of adsorbent, g  
 $q_e$  = solid-phase concentration in equilibrium with influent concentration  $C_0$ , mg/g  
 $\tau$  = EBCT  $\times \varepsilon$  = fluid residence time in bed, min  
 EBCT =  $V/Q$ , min  
 $V$  = bed volume, m<sup>3</sup>  
 $v$  = fluid velocity in bed pore space, m/s

A dimensionless group, the surface solute distribution parameter is defined as

$$D_g = \frac{\rho_a q_e (1 - \varepsilon)}{\varepsilon C_0} = \frac{\text{adsorbate on the adsorbent}}{\text{adsorbate in bed voids}} \Bigg|_{\text{equilibrium}} \quad (15-155)$$

Substituting Eq. 15-153 into Eq. 15-152 results in the final expression of dimensionless time:

$$T = \frac{t}{\tau D_g} = \frac{t}{\varepsilon (\text{EBCT}) D_g} \approx \frac{C_0 t}{\text{EBCT} \rho_a q_e (1 - \varepsilon)} \quad (15-156)$$

The throughput is a valuable way to express time because the area above the effluent profile must be equal to 1.0 when the effluent concentration is plotted as  $C/C_0$ . Substitution of Eqs. 15-57, 15-59, and 15-156 into Eq. 15-136 and rearrangement yields the following dimensionless liquid-phase mass balance:

$$-\frac{\partial \bar{C}}{\partial \bar{z}} + \frac{1}{\text{Pe}} \frac{\partial^2 \bar{C}}{\partial \bar{z}^2} = \frac{1}{D_g} \frac{\partial \bar{C}}{\partial T} + 3\text{St} (\bar{C} - \bar{C}_s) \quad (15-157)$$

Two dimensionless groups arise in the process of conversion and they are defined as

$$\text{Pe} = \frac{Lv}{E} \quad (15-158)$$

$$\text{St} = \frac{k_f \tau (1 - \varepsilon)}{\varepsilon R} \quad (15-159)$$

**Table 15-15**

Dimensionless groups used in the modeling of adsorption processes

Dimensionless Group	Equation	Definition
$D_g$	$\frac{\rho_a q_e (1 - \epsilon)}{\epsilon C_0}$	$\frac{\text{Mass of solute in solid phase}}{\text{Mass of solute in liquid phase}} \Big _{\text{equilibrium}}$
$Pe$	$\frac{LV}{E}$	$\frac{\text{Solute transfer rate by advection}}{\text{Solute transfer rate by axial dispersion}}$
$St$	$\frac{k_f \tau (1 - \epsilon)}{\epsilon R}$	$\frac{\text{Solute liquid-phase mass transfer rate}}{\text{Solute transfer rate by advection}}$
$Bi$	$\frac{k_f R (1 - \epsilon)}{D_s D_g \epsilon}$	$\frac{\text{Solute liquid-phase mass transfer rate}}{\text{Solute intraparticle mass transfer rate}}$
$Ed_s$	$\frac{D_s D_g \tau}{R^2}$	$\frac{\text{Solute transfer rate by intraparticle surface diffusion}}{\text{Solute transfer rate by advection}}$
$Ed_p^a$	$\frac{D_p \tau (1 - \epsilon) \epsilon_p}{R^2 \epsilon}$	$\frac{\text{Solute transfer rate by intraparticle pore diffusion}}{\text{Solute transfer rate by advection}}$

<sup>a</sup> $Ed_p$  is a dimensionless intraparticle mass transfer group that characterizes pore diffusion contribution for the pore surface diffusion model (PSDM).

The Peclet number,  $Pe$ , is a measure of the amount of dispersion present in the fixed bed and the Stanton number,  $St$ , is a measure of the film mass transfer rate as compared to the rate by advection. Insight into the physical meaning of these and other dimensionless groups is summarized in Table 15-15.

The initial condition for Eq. 15-157 was given by Eq. 15-137. Converting to dimensionless terms yields

$$\bar{C}(0 \leq \bar{z} \leq 1, T = 0) = 0 \quad (15-160)$$

Substituting the dimensionless positions and Eqs. 15-153, 15-155, 15-156, and 15-157 into Eq. 15-143 results in the final form of the first boundary condition:

$$1 - \bar{C}(\bar{z} = 1, T) = \frac{1}{D_g} \frac{\partial}{\partial T} \left[ \int_0^1 \left( \bar{C} + 3D_g \int_0^1 \bar{q} r^2 d\bar{r} \right) d\bar{z} \right] \quad (15-161)$$

The second boundary condition was given by the system of Eq. 15-145 and 15-146. Converting to dimensionless form yields

$$\frac{\partial^2 \bar{C}(\bar{z} = 1, T)}{\partial T \partial \bar{z}} = 0 \quad (15-162)$$

$$\frac{\partial \bar{C}(\bar{z}, T = 0)}{\partial \bar{z}} = 0 \quad (15-163)$$

The solid-phase mass balance was given in Eq. 15-147. Converting to dimensionless form yields this expression and one dimensionless group,  $Ed_s$ ,

$$\frac{Ed_s}{\bar{r}^2} \frac{\partial}{\partial \bar{r}} \left( \bar{r}^2 \frac{\partial \bar{q}}{\partial \bar{r}} \right) = \frac{\partial \bar{q}}{\partial T} \quad (15-164)$$

The dimensionless group, the surface diffusion modulus,  $Ed_s$ , is defined by (see Table 15-15)

$$Ed_s = \frac{D_s D_g \tau}{R^2} \quad (15-165)$$

The initial condition for Eq. 15-164 was given in Eq. 15-148. Converting to dimensionless terms yields

$$\bar{q}(0 \leq \bar{r} \leq 1, 0 \leq \bar{z} \leq 1, T = 0) = 0 \quad (15-166)$$

The first boundary condition for Eq. 15-164 was given in Eq. 15-148. Substituting in dimensionless groups in this expression, and the Biot number (see Table 15-15) yields

$$Bi(\bar{C} - \bar{C}_s) = \frac{\partial \bar{q}}{\partial \bar{r}} \quad (15-167)$$

The Biot number based on surface diffusivity,  $Bi$ , is defined by

$$Bi = \frac{k_f R(1 - \varepsilon)}{D_s D_g \varepsilon} = \frac{k_f \tau(1 - \varepsilon)}{\frac{\varepsilon R}{D_s D_g \tau}} = \frac{St}{Ed_s} \quad (15-168)$$

The second boundary condition for Eq. 15-164 was given in Eq. 15-149. Converting to dimensionless variables yields

$$\frac{\partial \bar{q}_i}{\partial \bar{r}}(\bar{r} = 0, 0 \leq \bar{z} \leq 1, T \geq 0) = 0 \quad (15-169)$$

For convenience the final form of the dimensionless mass balances are reported in Table 15-16. The conversion of the equations into dimensionless form yields several important dimensionless parameters. The dimensionless group that would appear if pore diffusion were included are also shown in Table 15-15 (Crittenden et al., 1986).

For high  $Pe$  numbers, plug flow conditions exist and dispersion is negligible. For plug conditions, the Danckwerts boundary conditions are no longer necessary, and the boundary simply becomes the concentration at the entrance, which is equal to the influent concentration.

The asymptotic solutions for long fixed-bed adsorbers and linear adsorption can be used to develop relationships between the dimensionless groups and the controlling transport mechanism, as well as between the dimensionless groups and the relative size of the mass transfer zone due to each mass transfer mechanism. To produce the same size mass transfer zone, the following relationships between the  $Pe$  number,  $Ed_s$ ,  $Ed_p$ , and  $St$  can be derived from the analytical solutions to the plug flow pore and surface

**Table 15-16**

Dimensionless form of equations for dispersed-flow homogenous surface diffusion model (DFHSDM)

Phase	Equation	Initial condition	Boundary conditions
Liquid	$-\frac{\partial \bar{C}}{\partial \bar{z}} + \frac{1}{Pe} \frac{\partial^2 \bar{C}}{\partial \bar{z}^2}$ $= \frac{1}{D_g} \frac{\partial \bar{C}}{\partial T} + 3St(\bar{C} - \bar{C}_s)$	$\bar{C} \left( \begin{matrix} 0 \leq \bar{z} \leq 1, \\ T = 0 \end{matrix} \right) = 0$	$1 - \bar{C}(\bar{z} = 1, T)$ $= \frac{1}{D_g} \frac{\partial}{\partial T} \left[ \int_0^1 \left( \bar{C} + 3D_g \int_0^1 \bar{q} r^2 d\bar{r} \right) d\bar{z} \right]$ $\frac{\partial^2 \bar{C}(\bar{z} = 1, T)}{\partial T \partial \bar{z}} = 0$ $\frac{\partial \bar{C}(\bar{z}, T = 0)}{\partial \bar{z}} = 0$
Solid	$\frac{Ed_s}{\bar{r}^2} \frac{\partial}{\partial \bar{r}} \left( \bar{r}^2 \frac{\partial \bar{q}}{\partial \bar{r}} \right) = \frac{\partial \bar{q}}{\partial T}$	$\bar{q} \left( \begin{matrix} 0 \leq \bar{r} \leq 1, \\ 0 \leq \bar{z} \leq 1, \\ T = 0 \end{matrix} \right) = 0$	$Bi(\bar{C} - \bar{C}_s) = \frac{\partial \bar{q}}{\partial \bar{r}}$ $\frac{\partial \bar{q}_i \left( \begin{matrix} \bar{r} = 0, \\ 0 \leq \bar{z} \leq 1, \\ T \geq 0 \end{matrix} \right)}{\partial \bar{r}} = 0$

diffusion model by Rosen (1954), and to the dispersed flow model which was proposed by Dankwerts (1953) and includes only axial dispersion (Crittenden et al., 1986). The value of the dimensionless groups can be related such that equivalent amounts of spreading occurs in the mass transfer zone due to each of the various mass transport mechanisms:

$$Pe = 3 \cdot St = 15 \cdot Ed_s = 15 \cdot Ed_p \quad (15-170)$$

Accordingly, the mass transfer zone for a linear isotherm is similar in size if only dispersion, film transfer, or surface diffusion are the primary cause for spreading in the mass transfer zone, and the values of Pe, St, Ed<sub>s</sub>, and Ed<sub>p</sub> follow Eq. 15-170. For example, Pe, St, Ed<sub>s</sub>, and Ed<sub>p</sub> values equal to 45, 15, 3, and 3, respectively, would result in equal spreading of the mass transfer zone when the respective mechanism is controlling.

If surface diffusion controls the mass transfer rate, it is interesting to determine the controlling mechanism from the relative magnitudes of St and Ed<sub>s</sub>. As shown in Eq. 15-158, the Biot number compares the film transfer rate to the surface diffusion rate. For linear isotherms, as shown in Eq. 15-170, a Biot number of 5.0 indicates that both film transfer and surface diffusion have an equal impact on the breakthrough curve for a 1/n of 1.0. As far as when external mass transfer or intraparticle resistance is concerned, external mass transfer controls for Bi numbers less than 1 and intraparticle mass transfer controls for Bi greater than 20.

However, the Freundlich exponent,  $1/n$ , affects the shape of the breakthrough curve and influences the relative importance of the two mass transfer mechanisms with regard to control of the adsorption rate. For cases where external mass transfer had an equal importance, Hand et al. (1984) showed that Bi numbers of 3, 3.2, and 4 for  $1/n$  values of 0.2, 0.6 and 0.8, respectively, were required. For cases where intraparticle mass transfer controlled, Hand et al. (1984) showed that Bi numbers greater than 8, 16, and 20 for  $1/n$  values of 0.2, 0.6, and 0.8, respectively, were required. For cases where external mass transfer controlled, (Hand et al., 1984) Bi numbers less than 1.0 were required for all the  $1/n$  values 0 to 1.

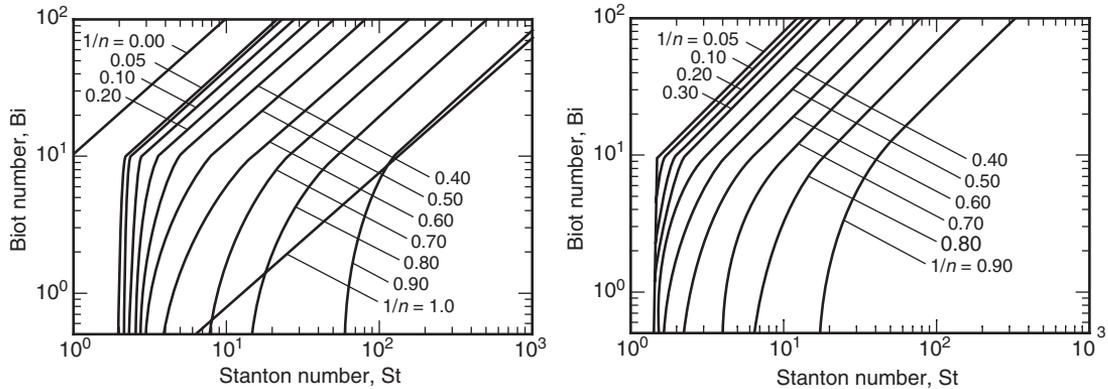

When an adsorbate enters a fresh GAC column, it establishes a mass transfer zone that spreads out to a constant shape. This shape is called a constant pattern. Hand et al. (1984) presented constant pattern solutions to the plug flow homogeneous surface diffusion model (PFHSDM), which can be used in many cases to obtain the identical results as given by the numerical solution of the PFHSDM. In this method, the solutions to the PFHSDM were fit by polynomials. The following four dimensionless groups and parameters characterize the constant pattern solutions to the PFHSDM: Solute distribution parameter,  $D_g$ ; Stanton number, St; Biot number, Bi; and Freundlich isotherm intensity constant,  $1/n$ . With these characteristic parameters, the breakthrough curve can be expressed in the generalized form:

$$\bar{C} = f\left(T, D_g, \text{St}, \text{Bi}, \frac{1}{n}\right) \quad (15-171)$$

According to Eq. 15-154, the throughput ratio,  $T$ , is linked to the  $D_g$ . Thus, the number of independent parameters in Eq. 15-171 is reduced to four. However, the multitude of possible solutions is nevertheless very great if all four parameters are considered. Therefore, two essential assumptions were made by Hand et al. (1984): (1) The isotherm can be described by a Freundlich equation over the whole concentration range, and the Freundlich  $1/n$  value is between 0 and 1; and (2) the constant pattern of the mass transfer zone is completely developed. Under these conditions, Hand et al. (1984) determined the minimum packed-bed residence time,  $\tau_{\min}$ , which is necessary to achieve constant pattern.

The minimum  $\tau_{\min}$  values are expressed as Stanton numbers,  $\text{St}_{\min}$ , on Fig. 15-28a for different Freundlich exponents and Bi numbers between 0.5 and 100 ( $0.5 \leq \text{Bi} \leq 100$ ). In the case of  $\text{Bi} < 0.5$ , the mass transfer rate is controlled by film diffusion, which allows the use of the analytical solution, which was proposed by Fleck et al. (1973). In the case of  $\text{Bi} > 100$ , surface diffusion controls the adsorption rate and identical constant pattern breakthrough curves are obtained for all Bi numbers  $> 100$  for a given  $1/n$  when they are expressed in terms of  $T$  for  $\text{St}_{\min}$ .

Using Fig. 15-28a, the minimum Stanton number can be determined in a simple and quick manner, if the Biot number is known. The equations corresponding to the curves in Fig. 15-28a are given in Table 15-17

**Figure 15-28**

(a) Minimum Stanton number necessary to reach a constant pattern for various Bi numbers and  $1/n$  values and (b) minimum Stanton number necessary to reach within 10 percent constant pattern for various Bi values (Hand et al., 1984).

**Table 15-17**

Minimum Stanton number required to achieve constant pattern conditions as function of Bi for various  $1/n$  values

Freundlich Isotherm Exponent Parameter $1/n$	Empirical Equation $St_{\min} = A_0 (Bi) + A_1$			
	$0.5 \leq Bi \leq 10$		$10 \leq Bi \leq \infty$	
	$A_0$	$A_1$	$A_0$	$A_1$
0.05	$2.10526 \times 10^{-2}$	1.98947	0.22	—
0.10	$2.10526 \times 10^{-2}$	2.18947	0.24	—
0.20	$4.21053 \times 10^{-2}$	2.37895	0.28	—
0.30	$1.05263 \times 10^{-1}$	2.54737	0.36	—
0.40	$2.31579 \times 10^{-1}$	2.68421	0.50	—
0.50	$5.26316 \times 10^{-1}$	2.73684	0.80	—
0.60	$1.15789 \times 10^0$	3.42105	1.50	—
0.70	$1.78947 \times 10^0$	7.10526	2.50	—
0.80	$3.68421 \times 10^0$	13.1579	5.00	—
0.90	$6.31579 \times 10^0$	56.8421	12.00	—

Adapted from Hand et al. (1984).

(Hand et al., 1984). If  $St > St_{\min}$ , the shape of the breakthrough curve is no longer dependent on the residence time or on the adsorber length. Consequently, Eq. 15-171 reduces to this expression as only the solution at  $St_{\min}$  and all others may be derived from it:

$$\bar{C} = f(T_{\min}, St_{\min}, Bi, 1/n) \quad (15-172)$$

where  $T_{\min}$  is equal to the ratio of the adsorption time required to reach constant pattern;  $t_{\min}$  is the minimum packed-bed residence time in the fixed bed,  $\tau_{\min}$ ;  $\tau_{\min}$  is the packed-bed contact time required for constant pattern and is directly related to a measure of the minimum length of the fixed bed,  $L_{\min}$ , required to achieve constant pattern; and the corresponding St value is equal to  $St_{\min}$ , which is the minimum Stanton number required to achieve constant pattern.

According to Eq. 15-172, Bi and  $1/n$  are the only two parameters necessary for all possible solutions to the PFHSDM under constant pattern conditions. Accordingly, Hand et al. (1984) has provided all solutions to Eq. 15-172 for  $Bi \geq 0.5$  and Freundlich exponents  $0.05 \leq 1/n \leq 0.90$  in the form of the following empirical equation:

$$T_{\min} \left( St_{\min}, Bi, \frac{1}{n} \right) = A_0 + A_1 \left( \frac{C}{C_0} \right)^{A_2} + \frac{A_3}{1.01 - (C/C_0)^{A_4}} \quad (15-173)$$

The coefficients,  $A_0$  through  $A_4$ , and the validity range of Eq. 15-173 for a  $1/n$  value of 0.5 are given in Table 15-18 [constants for additional values of  $1/n$  are provided in Hand et al. (1984) and the electronic Table E-7 at the website listed in App. E]. Thus, for each given effluent concentration,  $C/C_0$ , the respective throughput,  $T_{\min}$ , can be calculated.

The breakthrough curve, which is given by Eq. 15-173, can be used to calculate breakthroughs for any residence time,  $\tau > \tau_{\min}$ , because it remains constant in shape and travels at a constant velocity. Since the breakthrough curves are parallel, the operation time  $t$  for other residence times can be calculated from  $T_{\min}$  and  $\tau_{\min}$  according to

$$t = \tau_{\min} D_g T_{\min} + (\tau - \tau_{\min}) D_g \quad (15-174)$$

Substituting the expression  $T = t/\tau D_g$  into Eq. 15-174 yields

$$T = 1 + (T_{\min} - 1) \cdot \frac{\tau_{\min}}{\tau} \quad (15-175)$$

**Table 15-18**

Parameter values used in Eq. 15-173 for constant pattern solutions to the plug flow homogeneous surface diffusion model for  $1/n = 0.5$

Bi	$A_0$	$A_1$	$A_2$	$A_3$	$A_4$	$\left(\frac{C}{C_0}\right)_{\min}$	$\left(\frac{C}{C_0}\right)_{\max}$
0.5	-0.040800	1.099652	0.158995	0.005467	0.139116	0.01	0.99
4.0	-0.040800	0.982757	0.111618	0.008072	0.111404	0.01	0.99
10.0	0.094602	0.754878	0.092069	0.009877	0.090763	0.01	0.99

$\geq 100.0$	0.529213	0.291801	0.082428	0.008317	0.075461	0.01	0.99

Adapted from Hand et al. (1984). Parameters for other values of  $1/n$  are available in the electronic Table E-7 at the website listed in App. E.

$St_{\min}$  is calculated using the equation in Table 15-17 (Hand et al., 1984) and  $\tau_{\min}$  and  $L_{\min}$  can then be calculated from  $St_{\min}$  using the following equation:

$$\tau_{\min} = \frac{St_{\min} \varepsilon R}{k_f(1 - \varepsilon)} \quad (15-176)$$

$$L_{\min} = v \times \frac{\tau_{\min}}{\varepsilon} = v \times EBCT_{\min} \quad (15-177)$$

Finally, Eq. 15-173 and 15-176 can be substituted into Eq. 15-175 and an expression for  $T$  can be derived for specified Bi and  $1/n$  values:

$$T = 1 + \left[ A_0 + A_1 \left( \frac{C}{C_0} \right)^{A_2} + \frac{A_3}{1.01 - (C/C_0)^{A_4}} - 1 \right] \cdot \frac{St_{\min} \varepsilon R}{k_f(1 - \varepsilon) \tau} \quad (15-178)$$

Equation 15-178 can be used to calculate the value of  $T$  for each given value of  $C/C_0$  if the Biot number and  $1/n$  value are known. The parameters  $A_0$  through  $A_4$  for every Bi and  $1/n$  combination are reported by Hand et al. (1984) and the electronic Table E-7 at the website listed in App. E. It is recommended to use the  $A_0$  through  $A_4$  parameters for a larger Biot number and/or  $1/n$  values because this will give the largest mass transfer zone and result in the most conservative design. For example, if  $1/n$  is 0.245, use the solution for a  $1/n$  value of 0.3. For the parameters  $A_0$  through  $A_4$  interpolation is not possible because significant errors would result with respect to determining  $St_{\min}$ . The equations for higher and lower  $1/n$  values could also be used and the two values for  $St_{\min}$  should be interpolated.

Equation 15-178 can also be used for adsorbers with a length smaller than the length required to establish constant pattern,  $L_{\min}$ . When the adsorbate first enters the bed, a very steep mass transfer zone is established. As it migrates into the bed, the mass transfer zone expands until it reaches the constant pattern shape. Consequently, the breakthrough profile expands as bed length increases. Accordingly, if breakthrough curves are desired for residence times less than  $\tau_{\min}$ , the constant pattern solution, given by Eq. 15-178 is conservative because the constant pattern breakthrough profile and mass transfer zone would be broader than the actual profile. If a 10 percent error in  $T$  can be tolerated using the constant pattern solution, then the smallest  $St$  that can be used is given in Fig. 15-28b. To determine  $St$  for a 10 percent error in  $T$ , the equations are given in Hand et al. (1984) or Table E-8 at the website listed in App. E can be considered.

To complete the presentation and provide all solutions to the PFHSDM, the analytical solution to the PFHSDM for liquid-phase mass transfer controls the adsorption rate ( $Bi < 1.0$ ) and  $1/n$  is less than 1.0 is presented. Fleck et al. (1973) has provided the following analytical solution to the PFHSDM for this situation:

$$T = \frac{1}{3St} \left\{ 1 + \ln \left( \frac{C}{C_0} \right) - \frac{1}{n-1} \ln \left[ 1 - \left( \frac{C}{C_0} \right)^{n-1} \right] + \gamma \right\} + 1 \quad (15-179)$$

$$\gamma = \frac{1/n}{(1/n - 1)} \sum_{k=1}^{\infty} \frac{1/n}{k [k(1 - 1/n) + 1/n]} \quad (15-180)$$

The series given by Eq. 15-180 does not converge very rapidly so the computed values of  $\gamma$  can be obtained for a given  $1/n$  from the electronic Table E-9 at the website listed in App. E and Hand et al. (1984). Fleck et al. (1973) assumed constant pattern conditions exist, and this can be guaranteed for the various  $1/n$  values by examining Fig. 15-28a.

Intraparticle mass transfer will control the adsorption rate for  $1/n$  equal to 0.0 (irreversible adsorption). Wicke (1939) provided the following PFHSDM solution for the effluent concentration in the case of irreversible adsorption and constant pattern conditions:

$$\bar{C}(\bar{z} = 1, T) = 1 - \frac{6}{\pi^2} \sum_{k=1}^{\infty} \frac{1}{k^2} \exp \left\{ -k^2 \left[ \pi^2 \text{Ed}_s \left( \frac{TD_g - 1}{D_g} - 1 \right) + 0.64 \right] \right\} \quad (15-181)$$

Constant pattern conditions require that  $\text{Ed}_s$  must be greater than 0.101, which is located to the right of the line drawn on Fig. 15-28a for  $n = 0.0$ . By examining Eq. 15-181, it can be demonstrated that as  $\text{Ed}_s$  increases, the mass transfer zone occupies a smaller fraction of the bed. To obtain a convergent solution,  $T$  must be greater than the following:

$$T \geq \frac{1}{D_g} \left[ 1 + D_g \left( 1 - \frac{0.64}{\pi^2 \text{Ed}_s} \right) \right] \quad (15-182)$$

Usually, no more than three to six terms in the infinite series are needed to obtain an accurate solution for Eq. 15-181. The only exceptions are when the adsorbate first begins to appear in the effluent and when the exponential argument in the series does not vanish very rapidly with increasing  $k$ .

To decide how many terms in Eq. 15-181 are needed, the following equation can be used to evaluate the error associated with ignoring higher order terms,  $\text{Err.} (k < N_0)$ :

$$\text{Err.} (k < N_0) \leq \left( \frac{1}{N_0^2} + \frac{1}{N_0} \right) \exp \left\{ -N_0^2 \left[ \pi^2 \text{Ed}_s \left( \frac{TD_g - 1}{D_g} - 1 \right) + 0.64 \right] \right\} \quad (15-183)$$

Rosen (1954) has provided the following solution to PFHSDM for linear adsorption isotherm ( $1/n = 1.0$ ), which expresses the effluent concentration as a function of time:

$$\bar{C}(\bar{z} = 1, T) = \frac{1}{2} \left\{ 1 + \text{erf} \left[ \frac{(TD_g - 1)/D_g - 1}{2\sqrt{(1 + 5 \text{Bi})/(15 \text{Ed}_s)}} \right] \right\} \quad (15-184)$$

This solution requires  $\text{Ed}_s$  to be greater than 13.33, and this region is located to the right of the line for  $1/n = 1.0$  in Fig. 15-28a.

The surface diffusion coefficient can be obtained by relating the surface diffusion flux to the pore diffusion flux. This results in following correlation, which may be used to calculate the surface diffusion coefficient (Crittenden et al., 1987a):

$$D_s = (\text{SPDFR}) (\text{PDFC}) \quad (15-185)$$

$$\text{PDFC} = \left( \frac{\varepsilon_P C_0 D}{\rho_A q_0 \tau_P} \right) \quad (15-186)$$

where SPDFR = surface-to-pore diffusion flux ratio, dimensionless

PDFC = pore diffusion flux,  $\text{m}^2/\text{s}$

The SPDFR is the correlating parameter for determining  $D_s$ , and, for single solutes, Crittenden et al. (1987a) has found that it is between 4 and 9 using the maximum PDFC ( $\tau_p = 1.0$ ). To be conservative, a value of 4 may be used as long as there is no impact of background DOC on the breakthrough of the single component. (Single-solute SOC concentration > 5 times DOC concentration.)

However, it is rare to encounter situations where the background DOC does not have an impact on SOC removal with the possible exception of industrial waste treatment. Most often the presence of DOC has a tremendous impact on SOC removal in drinking water applications, and it usually blocks surface diffusion and intraparticle transport occurs only by pore diffusion. Experience has shown that one can use SPDFR values of 0.4 to 1 with the maximum PDFC in order to perform hand calculations using the CPHSDM (Hand et al., 1989). Crittenden et al. (1987a) and Sontheimer et al. (1988) have shown that good comparisons with data can be obtained using this approach. More complex protocols have been developed when using the pore surface diffusion model, and this protocol and the pore surface diffusion model have been built into AdDesignS software, which is currently commercially available (<http://cpas.mtu.edu/etdot/>).

### Procedure for Application of CPHSDM Solutions

1. Calculate  $D_g$  and Bi from the following equations:

$$D_g = \frac{\rho_a q_e (1 - \varepsilon)}{\varepsilon C_0} \quad (15-187)$$

where  $q_e = KC_0^{1/n}$

$$\text{Bi} = \frac{k_f R (1 - \varepsilon)}{D_s D_g \varepsilon} \quad (15-188)$$

2. Using the appropriate equation relating  $\text{St}_{\min}$  to Bi from Table 15-17 (Hand et al., 1984), calculate  $\text{St}_{\min}$  for the observed Bi and  $1/n$ , and

then calculate  $EBCT_{\min}$  or  $\tau_{\min}$ :

$$St_{\min} = A_0 (Bi) + A_1 \quad (15-189)$$

$$EBCT_{\min} = \frac{\tau_{\min}}{\varepsilon} = \frac{St_{\min} R}{k_f (1 - \varepsilon)} \quad (15-190)$$

3. Obtain the constant pattern solution in terms of  $C/C_0$  versus  $T$  using the parameters that are given in Table 15-18 for a  $1/n$  value of 0.5 (or the electronic Table E-7 at the website listed in App. E for other values of  $1/n$ ).

$$T \left( St_{\min}, Bi, \frac{1}{n} \right) = A_0 + A_1 \left( \frac{C}{C_0} \right)^{A_2} + \frac{A_3}{1.01 - (C/C_0)^{A_4}} \quad (15-191)$$

4. Convert the  $T$  values obtained for constant pattern solution to elapsed time using the following equation:

$$t_{\min} = \tau_{\min} (D_g + 1) T \quad (15-192)$$

This is the constant pattern solution that corresponds to an adsorber with  $EBCT_{\min}$ .

5. To convert elapsed time corresponding to the  $EBCT_{\min}$  to the desired  $EBCT$ , the travel time of the wave is added or subtracted according to the following equation:

$$t = t_{\min} + (\tau - \tau_{\min}) (D_g + 1) \quad (15-193)$$

6. Convert the time values to usage rates.

$$\left\{ \begin{array}{c} \text{Adsorbent} \\ \text{usage} \\ \text{rate} \end{array} \right\} = \frac{M_{\text{Adsorbent}}}{Qt} \quad (15-194)$$

7. The predicted breakthrough profiles can be use for GAC beds with shorter lengths than  $L_{\min}$ . The length that corresponds to an error of 10 percent of the breakthrough time can be estimate using the parameters that are given in the electronic Table E-8 at the website listed in App. E and Hand et al. (1984).
8. The  $EBCT$  of the mass transfer zone can be estimated using the following equation:

$$EBCT_{\text{MTZ}} = \left[ T \left( \frac{c}{c_0} = 0.95 \right) - T \left( \frac{c}{c_0} = \text{treatment objective} \right) \right] EBCT_{\min} \quad (15-195)$$

This length corresponds to a breakthrough that corresponds to the treatment objective, for example, 5 percent of the influent and a saturation of 95 percent because as stated above it can be shown that  $C/C_0 = q/q_e$  so the upstream end of the MTZ for this calculation is 95 percent saturated.

### Example 15-12 Using the constant pattern HSDM

GAC is being used to treat a groundwater containing 500  $\mu\text{g/L}$  of trichloroethene (TCE). The design flow is 0.89  $\text{m}^3/\text{min}$  and the treatment objective is 5  $\mu\text{g/L}$ . Calculate the size of the adsorber,  $\text{EBCT}_{\text{min}}$ , constant pattern solution, GAC usage rate, and  $\text{EBCT}_{\text{MTZ}}$  using the CPHSDM. The properties of the GAC and water are provided below.

GAC Properties:

Calgon Filtrasorb F-400 (12  $\times$  40 mesh),  $\rho_F = 0.45 \text{ g/cm}^3$ ,  $\rho_a = 0.8034 \text{ g/cm}^3$

$d_p = 0.1026 \text{ cm}$  particle porosity  $\varepsilon_p = 0.641$ ,  $\text{EBCT} = 10 \text{ min}$ ,  $\varepsilon = 0.44$   
Single-solute Freundlich  $K = 2030 (\mu\text{g/g})(\text{L}/\mu\text{g})^{1/n}$ , Freundlich  $1/n = 0.48$

Assume the TCE Freundlich  $K$  is reduced from 2030  $(\mu\text{g/g})(\text{L}/\mu\text{g})^{1/n}$  to 1062  $(\mu\text{g/g})(\text{L}/\mu\text{g})^{1/n}$  due to background organic compounds in the groundwater.

Water Properties:  $T = 10^\circ\text{C}$ ,  $\rho_w = 99.7 \text{ kg/m}^3$ ,  $1.307 \times 10^{-3} \text{ N}\cdot\text{s/m}^2$ .

1. Calculate  $\text{Bi}$  using Eq. 15-158:

$$\text{Bi} = \frac{k_f R (1 - \varepsilon)}{D_s D_g \varepsilon}$$

The film transfer rate is estimated using Gnielinski correlation from Table 7-5:

$$k_f = \frac{[1 + 1.5(1 - \varepsilon)] D_l}{d_p} \left[ 2 + 0.644 \text{Re}^{1/2} \text{Sc}^{1/3} \right]$$

See Table 7-5 to calculate  $k_f$ ,  $\text{Re}$ , and  $\text{Sc}$ , and Table 7-2 to calculate  $D_l$ . Typical superficial fluid velocities in GAC fixed beds are from 5.0 to 10  $\text{m/h}$ . For this problem assume 5.0  $\text{m/h}$ :

$$v_s = 5 \text{ m/h}, \text{ the interstitial velocity } v_i = \frac{v_s}{\varepsilon} = \frac{5 \text{ m/h}}{0.44} = 11.36 \text{ m/h}$$

$$\begin{aligned} \text{Re} &= \frac{\rho_w d_p v_i}{\mu} \\ &= \frac{(999.7 \text{ kg/m}^3) (0.001026 \text{ m}) [(11.36 \text{ m/h})(1 \text{ h}/3600 \text{ s})]}{(0.44)(1.3097 \times 10^{-3} \text{ N}\cdot\text{s/m})} \\ &= 5.63 \end{aligned}$$

For TCE, molal volume  $V_b$  is calculated using the values in Table 7-3:

$$V_b = 2(14.8) + 3(21.6) + 3.7 = 98.1 \frac{\text{cm}^3}{\text{mol}}$$

$$D_l = \frac{13.26 \times 10^{-9}}{(\mu_w)^{1.14} (V_b)^{0.589}} = \frac{13.26 \times 10^{-9}}{(1.3097)^{1.14} (98.1)^{0.589}}$$

$$= 6.54 \times 10^{-10} \frac{\text{m}^2}{\text{s}}$$

$$Sc = \frac{\mu}{\rho D_l} = \frac{1.3097 \times 10^{-3} \text{ N} \cdot \text{s/m}}{(999.7 \text{ kg/m}^3) (6.54 \times 10^{-10} \text{ m}^2/\text{s})} = 2000$$

$$k_f = \frac{[1 + 1.5(1 - 0.44)] (6.54 \times 10^{-10} \text{ m}^2/\text{s})}{0.001026 \text{ m}}$$

$$\times [2 + 0.644(5.63)^{1/2}(2000)^{1/3}] = 2.49 \times 10^{-5} \text{ m/s}$$

Apply shape correction factor to  $k_f$ :

$$k_f = SCF \times k_f = (1.5)(2.49 \times 10^{-5} \text{ m/s}) = 3.73 \times 10^{-5} \text{ m/s}$$

Use Eqs. 15-185 and 15-186 to calculate  $D_s$  and PDFC, respectively:

$$D_s = \text{PDFC} \times \text{SPDFR}$$

$$\text{PDFC} = \frac{D_l \varepsilon_P C_0}{\tau_P K C_0^{1/n} \rho_a} \quad \text{where } \tau_P = 1.0$$

$$\text{PDFC} = \frac{(6.54 \times 10^{-10} \text{ m}^2/\text{s})(0.641)(500 \mu\text{g/L})}{(1.0)(1062 \mu\text{g/g(L}/\mu\text{g})^{0.48})(500 \mu\text{g/L})^{0.48}(803.4 \text{ g/L})}$$

$$= 1.24 \times 10^{-14} \text{ m}^2/\text{s}$$

As we will see later in the chapter, the background organic matter can reduce surface diffusion, and in this case we will assume that the SPDFR is 1.0:

$$D_s = (1.24 \times 10^{-14} \text{ m}^2/\text{s})(1.0) = 1.24 \times 10^{-14} \text{ m}^2/\text{s}$$

$$Bi = \frac{(3.73 \times 10^{-5} \text{ m/s}) \left( \frac{0.001026 \text{ m}}{2} \right) (1 - 0.44)}{(1.24 \times 10^{-14} \text{ m}^2/\text{s}) (42,870) (0.44) (1.0)} = 45.7$$

2. Calculate  $St_{\min}$  from Eq. 15-189:

From Table 15-17, the coefficient  $A_0$  for  $1/n = 0.48$  and  $Bi = 45.7$  can be interpolated between  $A_0 = 0.5$  ( $1/n = 0.4$ ) and  $A_0 = 0.8$  ( $1/n = 0.5$ ). Since  $0.48 \cong 0.5$ , use  $A_0 = 0.8$  and calculate  $St_{\min}$  using Eq. 15-189.

$$St_{\min} = A_0 (Bi) = 0.8 (45.7) = 36.5$$

Calculate  $EBCT_{\min}$  required for constant pattern using Eq. 15-190:

$$EBCT_{\min} = \frac{St_{\min} R}{k_f (1 - \varepsilon)} = \frac{(36.5) \left( \frac{0.001026 \text{ m}}{2} \right)}{(3.73 \times 10^{-5} \text{ m/s}) (1 - 0.44)} = 897 \text{ s}$$

$$= 14.95 \text{ min}$$

$$\tau_{\min} = (0.44)(14.95 \text{ min}) = 6.58 \text{ min}$$

3. Calculation of constant pattern solution using Eq. 15-191:

$$T \left( Bi_s, \frac{1}{n}, St_{\min} \right) = A_0 + A_1 \left( \frac{C}{C_0} \right)^{A_2} + \frac{A_3}{1.01 - (C/C_0)^{A_4}}$$

In Table 15-18, the closest values to  $1/n = 0.48$  and  $Bi = 38.8$  are used. These are the values for  $1/n = 0.5$  and  $Bi = 25$ :  $A_0 = 0.023000$ ,  $A_1 = 0.793673$ ,  $A_2 = 0.039324$ ,  $A_3 = 0.009326$ , and  $A_4 = 0.08275$ . Calculate  $T$ ,  $t_{\min}$ , and  $t$  for  $C/C_0$  values from 0.01 to 0.95 as shown in the table below using Eqs. 15-191, 15-192, and 15-193; respectively.

$$T = 0.023 + 0.793673 \left( \frac{C}{C_0} \right)^{0.039324} + \frac{0.009326}{1.01 - (C/C_0)^{0.08275}}$$

$$t_{\min}(\text{d}) = \tau_{\min} (D_g + 1) T = \frac{(6.58 \text{ min}) (42,870 + 1) (T)}{1440 \text{ min/d}} = 196 \times T$$

$$t(\text{d}) = t_{\min} + (\tau - \tau_{\min}) (D_g + 1)$$

$$= t_{\min} + \frac{(4.4 - 6.58) (\text{min}) (42,870 + 1)}{1440 \text{ min/d}} = t_{\min} - 65$$

**HSDM solution using constant pattern**

$C/C_0$	$T$	$t_{\min}$ (days)	$t$ (days)
0.01	0.71	140	75
0.05	0.77	151	86
0.10	0.80	156	92
0.20	0.84	164	99
0.30	0.87	170	105
0.40	0.90	176	112
0.50	0.94	184	119
0.60	0.98	192	128
0.70	1.04	205	140
0.80	1.14	223	158
0.90	1.31	257	192
0.95	1.47	288	223

4. Calculate GAC usage rate using Eq. 15-194:  
For treatment objective  $C/C_0 = 5 \mu\text{g/L}/500 \mu\text{g/L} = 0.01$ :

$$T = 0.71, t_{\min} = 140 \text{ days}, t = 75 \text{ days}$$

After 75 days of operation the effluent will reach or exceed the MCL of  $5 \mu\text{g/L}$ :

$$\left\{ \begin{array}{l} \text{Bed} \\ \text{volumes} \\ \text{treated} \end{array} \right\} = \text{BVT} = \frac{t_{\epsilon}}{\tau} = \frac{(75 \text{ d})(0.44)}{\frac{4.4 \text{ min}}{1440 \text{ min/d}}} = 10,800$$

$$\left\{ \begin{array}{l} \text{Usage} \\ \text{rate} \\ \text{m}^3/\text{kg} \end{array} \right\} = \frac{\text{BVT}}{\rho_F} = \frac{10,800}{450 \text{ kg/m}^3} = 24 \frac{\text{m}^3 \text{ water treated}}{\text{kg GAC}}$$

5. Calculate the  $\text{EBCT}_{\text{MTZ}}$  using Eq. 15-195:

$$\begin{aligned} \text{EBCT}_{\text{MTZ}} &= [T(C/C_0 = 0.95) - T(C/C_0 = 0.01)] \times \text{EBCT}_{\min} \\ &= [1.47 - 0.71] \times 14.95 \text{ min} = 11.4 \text{ min} \end{aligned}$$

The MTZ for TCE should (almost) be contained in the adsorber with an adsorber EBCT of 10 min.

6. Calculate the size of the adsorber. The diameter of the adsorber can be calculated by dividing the flow rate by the superficial velocity:

$$A_{\text{Adsorber}} = \frac{Q}{v} = \frac{0.89 \text{ m}^3/\text{min}}{(5.0 \text{ m/h})(\text{h}/60 \text{ min})} = 10.68 \text{ m}^2$$

$$D_{\text{Adsorber}} = \sqrt{\left(\frac{4}{\pi}\right)(10.68 \text{ m}^2)} = 3.68 \text{ m} = 12 \text{ ft}$$

**Comment**

The adsorption capacity for TCE is reduced from 2030 ( $\mu\text{g/g})(\text{L}/\mu\text{g})^{1/n}$  to 1062 ( $\mu\text{g/g})(\text{L}/\mu\text{g})^{1/n}$  due to background organic compounds. This corresponds to the worst case where GAC is preloaded with background organic compounds.

**Evaluating the Impact of Natural Organic Matter on GAC Performance**

One of the most crucial applications of GAC in drinking water treatment is the removal of micropollutants. Most waters have concentrations of micropollutants that are only 0.5 to 5 percent of the concentration of the NOM with which they compete for the adsorption sites on the carbon surface. In addition to the NOM, which is comprised mainly of humic substances, there can be many unidentified synthetic organic chemicals that compete for adsorption sites with micropollutants.

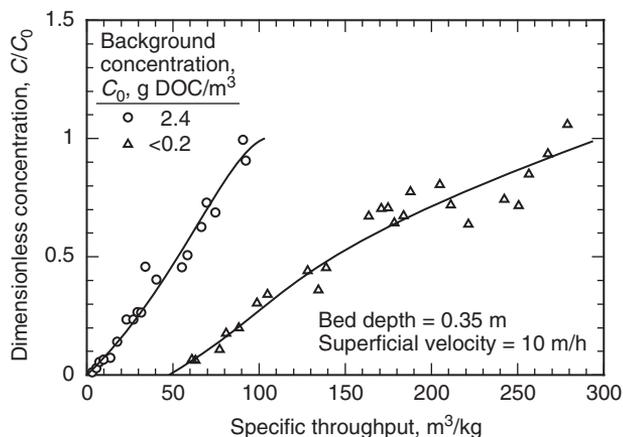

Methods have yet to be determined to predict the competitive interactions between the organic background and micropollutants, even when kinetic and equilibrium data for the unknown background and the micropollutants are available. Moreover, the competitive interactions between the organic background and micropollutants are not completely understood, and this section reviews the empirical evidence of the phenomena.

Pilot plant studies have been the only reliable method of obtaining design data for GAC adsorbers. But these studies are very time consuming and expensive. To reduce the time for the column tests, columns of small particle sizes known as rapid small-scale column tests have been utilized (see discussion later in this section). Very often, a correct simulation of large adsorbers using mathematical models has not been possible for the removal of micropollutants, unless they have been calibrated with field experience.

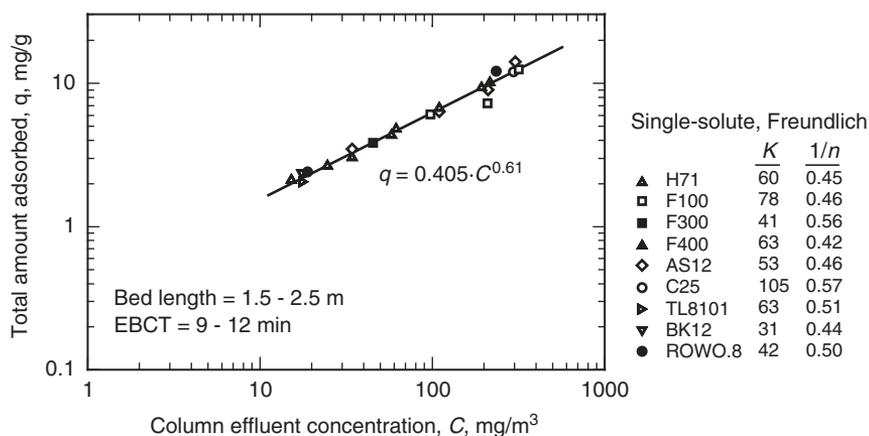

This section presents calibrated models that can describe micropollutant removal in the presence of unknown and adsorbing organics. The model draws upon many years of experience of using GAC columns treating polluted waters. This experience includes observations from these full-scale columns, and when combined with some specific laboratory studies, it has clearly shown that the presence of NOM decreases the adsorption capacity and kinetics of micropollutants in a GAC column (Jarvi et al. 2005).

An example of the reduction in the adsorption capacity and kinetics in a GAC column in the presence of NOM is shown in Fig. 15-29 (Baldauf, 1986). The breakthrough curve of groundwater that is spiked with trichloroethene (open circles) yields a capacity at complete breakthrough of about 35 percent of the single-solute expected isotherm value.

In a study based on much data from full-scale and pilot columns, Baldauf and Zimmer (1985) compared the adsorption capacities in GAC columns of different waterworks, utilizing different groundwater sources

**Figure 15-29**  
Breakthrough curves of trichloroethene in the presence of DOC (Adapted from Baldauf, 1986).

**Figure 15-30**  
Solid-phase concentration, at complete breakthrough, as a function of influent concentration for several groundwater sources and nine activated carbon (Adapted from Baldauf and Zimmer, 1985).

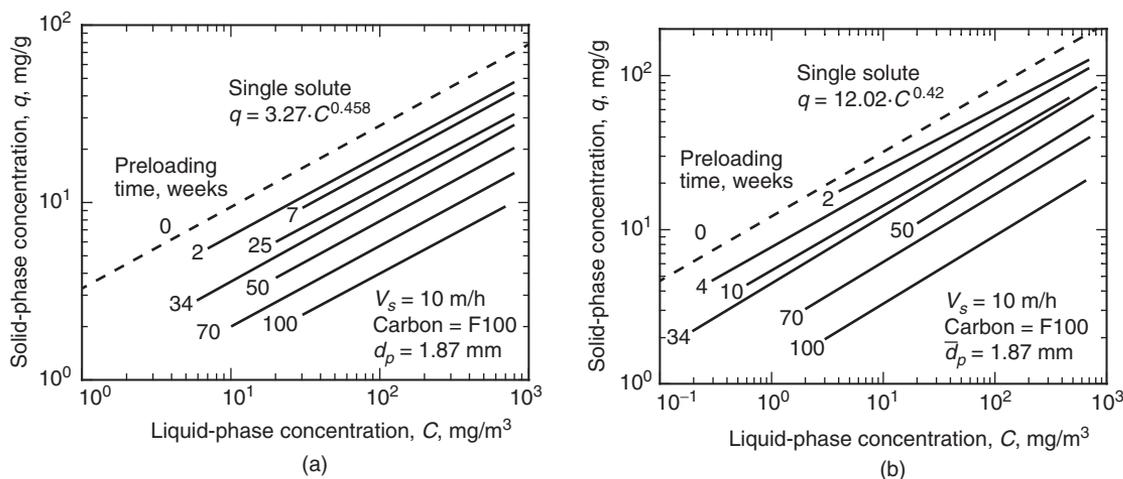

and activated carbons. The solid-phase concentration was calculated by integrating the complete breakthrough curve to determine the column capacity at exhaustion. The column capacities found for trichloroethene are shown in Fig. 15-30 as a function of the influent concentration and EBCT values between 9 and 12 min.

Figure 15-30, termed an adsorber correlation curve, yielded an unexpected result. Despite the different single-solute capacities of the diverse activated carbon types and different concentrations and adsorbability of the groundwater organic matter, a single adsorption relationship for trichloroethene was found adequate for all activated carbon and groundwater sources examined. This filter correlation provides a connection between the influent concentration and the maximum solid-phase concentration of the carbon at total breakthrough for GAC columns with EBCTs of 9 to 12 min.

Filter correlations with major reductions in capacity were also found for tetrachloroethene and 1,1,1-trichloroethane (Baldauf and Zimmer, 1985). The column adsorption capacity of the strongly adsorbing tetrachloroethene was effected the most by the presence of NOM with a 90 percent reduction in its single-solute capacity, while the capacity of the weakly adsorbing 1,1,1-trichloroethane was reduced by about 50 percent. The additional intriguing result is that higher influent concentrations have less impact due to the organic matter.

The differences in the diffusivity of humic substances versus micropollutants cause very different breakthrough behavior of micropollutants and humic substances. Within a fixed bed, micropollutants build up a well-defined mass transfer zone, which migrates slowly through the column with increasing elapsed time. The large humic molecules have slow adsorption kinetics, which leads to a long mass transfer zone. This, in turn, yields a faster breakthrough of the NOM. Thus, deep in the bed only NOM is present and adsorbing, which is termed preadsorption.

Consequently, humics have a greater preadsorption time for micropollutants that have lower concentrations or are more strongly adsorbed because low concentrations or strongly adsorbing components take much longer to move through the bed. As a result, the bed has a greater exposure to NOM before the micropollutant arrives at a given bed depth. The impact of the preadsorption of NOM on the adsorption behavior of micropollutants was shown by preadsorbing an activated carbon in fixed-bed columns with organic matter from Karlsruhe (West Germany) tap water. The results for the different preloading times are displayed in Fig. 15-31. This groundwater

**Figure 15-31**

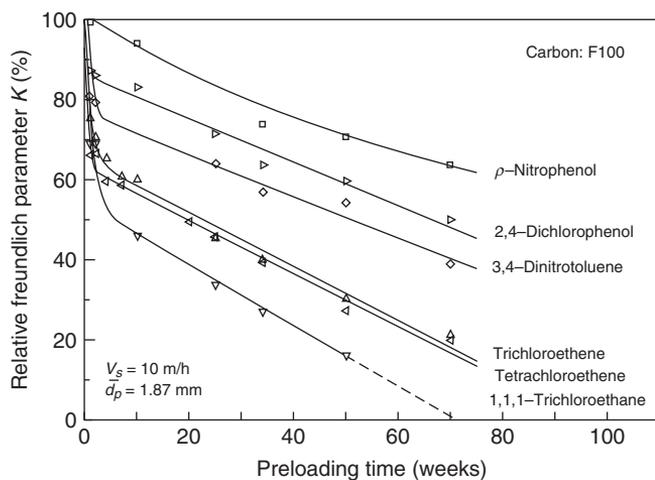

Influence of preloading time with NOM on adsorption isotherms for (a) trichloroethene and (b) tetrachloroethene (Adapted from Zimmer et al., 1987).

had an average DOC value of 0.8 mg/L and no detectable concentrations of chlorinated hydrocarbons as measured by total organic halides (TOX). At time intervals over the course of 2 years, carbon samples from the top of the column were taken and isotherm measurements for the chlorinated hydrocarbons were conducted.

For trichloroethene and tetrachloroethene, the isotherms show a parallel shift with time, compared to the isotherm of organic-free water (dashed line). After a great initial decrease in the first weeks, a further steady reduction is still observed after 2 years exposure to the tap water organic matter. In addition, the capacity of trichloroethene and tetrachloroethene, despite their different adsorbability in humic-free water, is reduced by 70 percent after 50 weeks of preloading and by 80 to 85 percent after 100 weeks preloading as compared to the single-solute isotherm value. Similar results were found for other organic substances. Consequently, the impact of preloading time on adsorption equilibrium can be expressed as a reduction in the Freundlich  $K$  as a function of time.

Figure 15-32 displays the reduction in the adsorption capacity as measured by the Freundlich capacity parameter  $K$  for other organic substances. Comparisons of the adsorption capacities with time can be made with the Freundlich capacity parameter  $K$  because all isotherms that were preloaded with tap water had a constant Freundlich  $1/n$  value. Thus, the adsorption capacity at any concentration is equally reduced. According to Eq. 15-33, the capacity for the chlorinated aliphatic hydrocarbons is significantly reduced after a few weeks preloading as compared to aromatic compounds, which have lower  $1/n$  values. After the initial rapid decrease, all substances have about the same linear reduction in capacity.

The results in Fig. 15-32 demonstrate that carbon fouling is greater for substances that have the lowest adsorbability, that is, low  $K$  and high

**Figure 15-32**  
Relative Freundlich  $K$  parameter in percent of the value (Adapted from Sontheimer et al., 1988).

$n$  values. However, it must also be remembered that weakly adsorbable substances such as 1,1,1-trichloroethane have relatively short breakthrough times, and shorter breakthrough times result in shorter preloading times and less fouling than is observed for strongly adsorbing substances.

In order to describe the changing Freundlich  $K$  values with time, a function, which has an exponential portion for the initial rapid decrease and a linear portion for the long-term slow decrease, was used. The coefficients for that function, which follow, have been determined for various raw waters and trichloroethene and are reported in Table 15-19.

$$\frac{K(t)}{K} = 0.01 [A_1 - A_2 t + A_3 e^{-A_4 t}] \quad (15-196)$$

In order to estimate the reduction in the Freundlich  $K$  values for other compound, the correction factors given in Table 15-20 are used. The reduction in Freundlich  $K$  values that are reported in Tables 15-19 and 15-20 have been incorporated into commercially available software that has been compared to numerous data sets, and so it can give preliminary design information (Hand et al., 1997).

NOM or background organic matter has an impact on the adsorption kinetics. It was found that surface diffusion is eliminated. The CPHSDM can still be used to simulate the impact of NOM by reducing the surface diffusion coefficient to a point that only pore diffusion is included.

**Table 15-19**

Empirical kinetic constants describing reduction in Freundlich isotherm capacity parameter for TCE in presence of various background water matrices

Background Water Matrix	Empirical Kinetic Constants			
	$A_1$ (—)	$A_2$ ( $d^{-1}$ )	$A_3$ (—)	$A_4$ ( $d^{-1}$ )
Surface water with significant anthropogenic input (Rhine River, Germany) <sup>a</sup>	35.0	$8.86 \times 10^{-4}$	65.0	$1.29 \times 10^{-1}$
Surface water with a small amount of anthropogenic input (Portage Lake, Michigan) <sup>b</sup>	51.0	$1.33 \times 10^{-1}$	49.0	$4.03 \times 10^{-2}$
Groundwater in Germany that caused reduction in capacity similar to six other German groundwaters (Karlsruhe, Germany) <sup>a</sup>	65.0	$9.66 \times 10^{-2}$	35.0	$1.44 \times 10^{-1}$
Rural Midwestern groundwater (Wausau, Wisconsin) <sup>b</sup>	83.0	$1.31 \times 10^{-1}$	17.0	$3.82 \times 10^{-1}$
Rural northern groundwater (Houghton, Michigan) <sup>b</sup>	66.0	$2.23 \times 10^{-2}$	34.0	$1.05 \times 10^{-1}$

<sup>a</sup>Calgon F100 GAC.

<sup>b</sup>Calgon F400 GAC.

**Table 15-20**

Correction factors for reduction in Freundlich isotherm capacity parameter for different classes of compounds

Class	Group	Surrogate Compound	Equation Relative to the Reference Compound—TCE
Purgeables	Halogenated alkanes	1,1,1-Trichloroethane	$K(t)/K = 1.2[K(t)/K]_{TCE} - 0.2$
	Halogenated alkenes	Trichloroethene	$K(t)/K = [K(t)/K]_{TCE}$
	Trihalomethanes	Chloroform	$K(t)/K = [K(t)/K]_{TCE}$
	Aromatics	Toluene	$K(t)/K = 0.9[K(t)/K]_{TCE} + 0.1$
Base Neutrals	Nitro compounds	3,4-Dinitrotoluene	$K(t)/K = 0.75[K(t)/K]_{TCE} + 0.25$
	Chlorinated	1,4-Dichlorobenzene	$K(t)/K = 0.59[K(t)/K]_{TCE} + 0.41$
	Hydrocarbons		
Acids	Phenols	2,4-Dichlorophenol	$K(t)/K = 0.65[K(t)/K]_{TCE} + 0.35$
Polynuclear aromatics (PNAs)		Methylene blue	$K(t)/K = 0.32[K(t)/K]_{TCE} + 0.68$
Pesticides		Atrazine	$K(t)/K = 0.05$

### Example 15-13 Using the constant pattern HSDM to simulate the impact of NOM

Evaluate the efficacy of using GAC to treat a groundwater containing 50  $\mu\text{g/L}$  of tetrachloroethylene (PCE) to a treatment objective of 5  $\mu\text{g/L}$ . Assume the groundwater is similar to Karlsruhe groundwater. Given a design EBCT of 10 min and superficial water velocity of 5.0 m/h, and GAC properties and water properties below, calculate  $\text{EBCT}_{\min}$ , constant pattern solution, GAC usage rate, and  $\text{EBCT}_{\text{MTZ}}$  using the CPHSDM.

GAC Properties:

Calgon Filtrasorb F-400 (12  $\times$  40 mesh),  $\rho_f = 0.45 \text{ g/cm}^3$ ,  $\rho_a = 0.8034 \text{ g/cm}^3$

$d_p = 0.1026 \text{ cm}$  particle porosity  $\epsilon_p = 0.641$ , EBCT = 10 min,  $\epsilon = 0.44$ ,  $\phi = 1.5$ , single-solute Freundlich  $K = 200 \text{ (mg/g)(L/mg)}^{1/n}$ , Freundlich  $1/n = 0.50$

Water properties:  $T = 10^\circ\text{C}$ ,  $\rho_w = 999.7 \text{ kg/m}^3$ ,  $\mu_w = 1.307 \times 10^{-3} \text{ kg/m} \cdot \text{s}$

**Solution:**

1. Determine the reduced Freundlich  $K$  due to the background and the solute distribution parameter  $D_g$ .

The correction factor for the reduction in the Freundlich  $K$  is obtained from Table 15-20 for halogenated alkenes because PCE belongs to this group.

$$\left(\frac{K}{K_0}\right)_{\text{PCE}} = \left(\frac{K}{K_0}\right)_{\text{TCE}}$$

For the groundwater similar to Karlsruhe groundwater using Eq. 15-196 and the values from Table 15-19, Convert the units on the coefficients for Karlsruhe groundwater as follows:

$$A1 = 65.0$$

$$A2 = 9.66 \times 10^{-2} \text{ d}^{-1} = 6.71 \times 10^{-5} \text{ min}^{-1}$$

$$A3 = 35.0$$

$$A4 = 1.44 \times 10^{-1} \text{ d}^{-1} = 1.0 \times 10^{-4} \text{ min}^{-1}$$

$$\begin{aligned} \left(\frac{K}{K_0}\right)_{\text{PCE}} = \left(\frac{K}{K_0}\right)_{\text{TCE}} = & 0.01 \left\{ 65 - 6.71 \times 10^{-5} (t) \right. \\ & \left. + 35 \exp \left[ -1.0 \times 10^{-4} (t) \right] \right\} \end{aligned}$$

Assume  $T = 1$ , and negative values for  $K$  and  $D_g$  will occur using trial-and-error method. Substituting in

$$t = T\tau(D_g + 1) = \tau(D_g + 1) \quad \text{and} \quad D_g = \frac{\rho_a K C_0^{0.5} (1 - \epsilon)}{\epsilon C_0}$$

yields a nonlinear equation:

$$\left(\frac{K}{K_0}\right)_{\text{PCE}} = 0.01 \left( \begin{aligned} & 65 - 6.71 \times 10^{-5} \times T\tau \left( \frac{\rho_a K C_0^{0.5} (1 - \epsilon)}{\epsilon C_0} + 1 \right) \\ & + 35 \exp \left\{ -1.0 \times 10^{-4} \times T\tau \left[ \frac{\rho_a K C_0^{0.5} (1 - \epsilon)}{\epsilon C_0} + 1 \right] \right\} \end{aligned} \right)$$

where  $\tau = (\text{EBCT}) (\epsilon) = (10 \text{ min}) (0.44) = 4.4 \text{ min}$

Use  $K = 200 \text{ (mg/g)(L/mg)}^{0.5} = 6325 \text{ (\mu g/g)(L/\mu g)}^{0.5}$  to obtain the initial guess for  $K$ . MathCAD is used to solve the above equation,  $K = 1111 \text{ (\mu g/g)(L/\mu g)}^{0.5}$ .

$$D_g = \frac{(803.4 \text{ g/L})[1111 \text{ } \mu\text{g/g(L/}\mu\text{g)}^{0.5}](50 \text{ } \mu\text{g/L)}^{0.5}(1 - 0.44)}{(0.44)(50 \text{ } \mu\text{g/L})}$$

$$= 160,662$$

2. Calculate Bi using Eq. 15-168 as

$$\text{Bi} = \frac{k_f R (1 - \epsilon)}{D_s D_g \epsilon}$$

The film transfer rate is estimated using Gnielinski correlation (see Table 7-5):

$$k_f = \frac{[1 + 1.5(1 - \epsilon)] D_l}{d_p} (2 + 0.644 \text{ Re}^{1/2} \text{ Sc}^{1/3})$$

To calculate  $k_f$ , Re, liquid diffusivity  $D_l$  and Sc has to be determined first.

$$v_s = 5 \text{ m/h, the interstitial velocity } v_i = \frac{v_s}{\epsilon} = \frac{5 \text{ m/h}}{0.44} = 11.36 \text{ m/h}$$

$$\text{Re} = \frac{\rho_w d_p v_i}{\mu}$$

$$= \frac{(999.7 \text{ kg/m}^3) (0.1026 \text{ cm}) (11.36 \text{ m/h})}{(0.44) (1.307 \times 10^{-3} \text{ kg/m} \cdot \text{s}) (3600 \text{ s/h}) (100 \text{ cm/m})}$$

$$= 5.61$$

For PCE, Table 7-3 is used to calculate the molar volume  $V_b$  as

$$V_b = 2(14.8) + 4(21.6) = 116 \text{ cm}^3/\text{mol}$$

The Hayduk–Laudie correlation shown in Table 7-2 can be used to calculate the liquid-phase diffusion coefficient for PCE as

$$D_l = \frac{13.26 \times 10^{-9}}{(\mu_w)^{1.14} (V_b)^{0.589}} = \frac{13.26 \times 10^{-9}}{(1.307)^{1.14} (116)^{0.589}} = 5.93 \times 10^{-10} \text{ m}^2/\text{s}$$

$$\text{Sc} = \frac{\mu}{\rho D_l} = \frac{1.307 \times 10^{-3} \text{ kg/m} \cdot \text{s}}{(999.7 \text{ kg/m}^3) (5.93 \times 10^{-10} \text{ m}^2/\text{s})} = 2209$$

$$k_f = \frac{[1 + 1.5(1 - 0.44)] (5.93 \times 10^{-10} \text{ m}^2/\text{s})}{(0.1026 \text{ cm}) (0.01 \text{ m/cm})}$$

$$\times [2 + 0.644 (5.61)^{1/2} (2209)^{1/3}] = 2.33 \times 10^{-5} \text{ m/s}$$

Apply sphericity correction factor to  $k_f$ :

$$k_f = (\phi) (k_f) = (1.5) (2.33 \times 10^{-5} \text{ m/s}) = 3.49 \times 10^{-5} \text{ m/s}$$

Equations 15-185 and 15-186 can be used to calculate  $D_s$  and PDFC, respectively, as

$$D_s = (\text{PDFC}) (\text{SPDFR})$$

$$\text{PDFC} = \frac{D_s \varepsilon_P C_0}{\tau_P K C_0^{1/n} \rho_a} \quad \text{where } \tau_P = 1.0$$

$$\begin{aligned} \text{PDFC} &= \frac{(5.93 \times 10^{-10} \text{ m}^2/\text{s}) (0.641) (50 \text{ } \mu\text{g/L})}{(1.0) \left( 1111 \frac{\mu\text{g}}{\text{g}} \left( \frac{\text{L}}{\mu\text{g}} \right)^{0.5} \right) (50 \text{ } \mu\text{g/L})^{0.5} (803.4 \text{ g/L})} \\ &= 3.01 \times 10^{-15} \text{ m}^2/\text{s} \end{aligned}$$

Assume an SPDFR = 1.0 for NOM fouling:

$$\begin{aligned} D_s &= (3.01 \times 10^{-15} \text{ m}^2/\text{s}) (1.0) = 3.01 \times 10^{-15} \text{ m}^2/\text{s} \\ \text{Bi} &= \frac{(2.33 \times 10^{-5} \text{ m/s}) \left( \frac{0.001026 \text{ m}}{2} \right) (1 - 0.44)}{(3.01 \times 10^{-15} \text{ m}^2/\text{s}) (160,662) (0.44) (1.0)} = 31.4 \end{aligned}$$

3. Calculate  $St_{\min}$  from Eq. 15-189:

From Table 15-17, for  $1/n = 0.5$  the coefficient  $A_0 = 0.8$  ( $1/n = 0.5$ ):

$$St_{\min} = A_0 (\text{Bi}) = 0.8 (31.4) = 25.2$$

Calculate  $EBCT_{\min}$  required for constant pattern using Eq. 15-190:

$$\begin{aligned} EBCT_{\min} &= \frac{St_{\min} R}{k_f (1 - \varepsilon)} = \frac{(25.2) \left( \frac{0.001026 \text{ m}}{2} \right)}{(2.33 \times 10^{-5} \text{ m/s}) (1 - 0.44)} \\ &= 991 \text{ s} = 16.52 \text{ min} \end{aligned}$$

$$\tau_{\min} = (0.44) (16.52 \text{ min}) = 7.27 \text{ min}$$

4. Calculation of constant pattern solution using Eq. 15-191:

$$T \left( \text{Bi}_s, \frac{1}{n}, St_{\min} \right) = A_0 + A_1 \left( \frac{C}{C_0} \right)^{A_2} + \frac{A_3}{1.01 - (C/C_0)^{A_4}}$$

From Table 15-18, use the values closest to  $1/n = 0.5$  and  $\text{Bi} = 31.5$ , the appropriate values are for  $1/n = 0.5$  and  $\text{Bi} = 25$ :  $A_0 = 0.023000$ ,  $A_1 = 0.793673$ ,  $A_2 = 0.039324$ ,  $A_3 = 0.009326$ ,  $A_4 = 0.08275$ .

Calculate  $T$ ,  $t_{\min}$ , and  $t$  for various values of reduced concentration as shown in the table below:

$$T = 0.023 + 0.793673 \left( \frac{C}{C_0} \right)^{0.039324} + \frac{0.009326}{1.01 - (C/C_0)^{0.08275}}$$

$$t_{\min} \text{ (d)} = \tau_{\min} (D_g + 1) T = \frac{(7.27 \text{ min}) (160,662 + 1) (T)}{1440 \text{ min/d}} = 811 \times T$$

$$t \text{ (d)} = t_{\min} + (\tau - \tau_{\min}) (D_g + 1)$$

$$= t_{\min} + \frac{(4.4 - 7.27) \text{ (min)} (160,662 + 1)}{1400 \text{ min/d}} = t_{\min} - 320$$

#### HSDM solution using constant pattern

$C/C_0$	$T$	$t_{\min} \text{ (d)}$	$t \text{ (d)}$
0.01	0.71	579	259
0.05	0.77	624	304
0.10	0.80	648	328
0.20	0.84	679	359
0.30	0.87	705	385
0.40	0.90	731	411
0.50	0.94	760	440
0.60	0.98	797	477
0.70	1.04	847	527
0.80	1.14	924	604
0.90	1.31	1065	744
0.95	1.47	1193	872

5. Calculate GAC usage rate using Eq. 15-194:

For treatment objective  $C/C_0 = 5 \mu\text{g/L}/50 \mu\text{g/L} = 0.1$ ,  $T = 0.80$ ,  $t_{\min} = 648$  days,  $t = 328$  days.

After around 328 days of column operation, the effluent will reach or exceed the MCL of  $5 \mu\text{g/L}$ .

$$\left\{ \begin{array}{l} \text{Bed} \\ \text{volumes} \\ \text{treated} \end{array} \right\} = \text{BVT} = \frac{t_{\epsilon}}{\tau} = \frac{(328 \text{ d}) (0.44)}{\left( \frac{4.4 \text{ min}}{1440 \text{ min/d}} \right)} = 47,232$$

$$\left\{ \begin{array}{l} \text{Usage} \\ \text{rate} \\ \text{m}^3/\text{kg} \end{array} \right\} = \frac{\text{BVT}}{\rho_F} = \frac{47,232}{450 \text{ kg/m}^3} = 105 \frac{\text{m}^3 \text{ water treated}}{\text{kgGAC}}$$

6. Calculate the  $EBCT_{MTZ}$  using Eq. 15-195:

The MTZ for PCE will be contained in the adsorber with an EBCT of 10 min:

$$EBCT_{MTZ} = [T (C/C_0 = 0.95) - T (C/C_0 = 0.1)] \times EBCT_{min}$$

$$EBCT_{MTZ} = [1.47 - 0.80] \times 16.52 \text{ min} = 11.1 \text{ min}$$

The MTZ for PCE should almost be contained in the adsorber with an EBCT of 10 min.

### Comment

The adsorption capacity parameter  $K$  for PCE is reduced from 6325  $(\mu\text{g/g})(\text{L}/\mu\text{g})^{1/n}$  to 1111  $(\mu\text{g/g})(\text{L}/\mu\text{g})^{1/n}$  due to background organic compounds. The reduction of the adsorption capacity is approximately 82 percent compared with 50 percent for TCE for a similar calculation. Therefore, the NOM has much greater influence on PCE removal by adsorption than TCE removal. Again, this corresponds to the worst case where GAC is preloaded with background organic compounds. The CPHSDM was used for a length shorter than the minimum value required to establish constant pattern. This would provide a conservative approach because this would be the longest the MTZ would be. We could calculate the length that compares to the 10 percent breakthrough error criteria to get an idea of the error that is committed using this approach.

### Rapid Small-Scale Column Tests

Design of GAC systems using single, parallel, and series beds was illustrated earlier using pilot plant studies. Rapid small-scale column tests (RSSCTs) may be used to determine GAC performance, and these are discussed in this section. The advantages and disadvantages of the various methods for predicting GAC performance are reported in Table 15-21.

Mathematical models of the GAC process are not completely accurate because the organic matter present in water has an impact on the intraparticle diffusion and adsorption capacity that is not completely understood. However, a smaller, scaled-down fixed bed that utilizes the actual raw water can be used to predict the performance of full-scale adsorbers if the transport processes scale according to the dimensionless groups that appear in the fixed-bed models. Such tests are called RSSCTs. The three primary advantages of using RSSCTs to predict performance are (1) the RSSCT may be conducted in a fraction of the time required to conduct pilot studies; (2) unlike predictive mathematical models, extensive isotherm or kinetic studies are not required; and (3) a small volume of water is required to conduct the RSSCT, which can be transported to a central laboratory for

**Table 15-21**

Methods for estimating full-scale GAC performance

Method	Reliability	Advantages	Disadvantages
Pilot studies	Excellent	<ol style="list-style-type: none"> <li>1. Can predict full-scale GAC performance very accurately.</li> </ol>	<ol style="list-style-type: none"> <li>1. Can take a very long time to obtain results.</li> <li>2. Expensive and must be conducted onsite.</li> </ol>
RSSCTs	Good if scaling factor is known	<ol style="list-style-type: none"> <li>1. Can predict full-scale GAC performance accurately.</li> <li>2. Small volume of water is required for the test, which can be transported to a central laboratory for evaluation.</li> <li>3. Can be conducted in a fraction of the time and cost required to conduct pilot studies.</li> </ol>	<ol style="list-style-type: none"> <li>1. Cannot predict GAC performance for different concentrations.</li> <li>2. Biological degradation that may prolong GAC bed life is not considered.</li> <li>3. The impact of NOM on micropollutant removal is less than is observed in full-scale plants.</li> </ol>
Models	Good if calibrated; fair if not calibrated	<ol style="list-style-type: none"> <li>1. Once calibrated, models can be used to predict impact of EBCT and changes in influent concentration.</li> <li>2. Can predict breakthrough of SOCs with 20–50% error.</li> </ol>	<ol style="list-style-type: none"> <li>1. Cannot predict TOC breakthrough and must be used in conjunction with pilot or RSSCT data.</li> <li>2. Accurate prediction of SOC removal requires calibration with pilot or RSSCT data.</li> </ol>

evaluation. Consequently, replacing a pilot study with an RSSCT significantly reduces the time and cost of a full-scale design. However, the results from a RSSCT are site specific and only valid for the raw-water conditions that are tested. Unfortunately, even RSSCTs seem to show less impact of TOC than is observed in pilot-scale plants (Corwin and Summers, 2010).

#### SCALING DOWN A FULL-SCALE ADSORBER TO RSSCT

In the RSSCT method, mathematical models are used to scale down the full-scale adsorber to an RSSCT and maintain perfect similarity between the RSSCT and full-scale performance. Perfect similarity is obtained by setting the dimensionless groups that describe adsorbate transport in a small-scale RSSCT adsorber (SC) equal to those for a large-scale column (LC). In principle, if perfect similarity is maintained, the RSSCT, which uses a smaller adsorbent particle size than the full-scale adsorber, will have identical breakthrough profiles as the full-scale process. Accordingly, a number of RSSCTs could be used to evaluate important design variables such as GAC selection, EBCT, or bed operations such as beds in series or in parallel.

The scaling procedure was developed using the dispersed-flow pore and surface diffusion model (DFPSDM) (Crittenden et al., 1986, 1987a, 1991). To derive the scaling equations, one only equates the dimensionless groups that characterize the large column to those that characterize the small column. The independent dimensionless groups that characterize the DFPSDM are defined in Table 15-15. Three independent dimensionless groups, used to describe adsorbate transport, appear in the dispersed-flow homogeneous pore surface diffusion model: (1) Peclet number,  $Pe$ ; (2) surface diffusion modulus,  $Ed_s$ , pore diffusion modulus,  $Ed_p$ , and (3) the Stanton number,  $St$ .

#### SCALING EBCT

The relationship between the empty-bed contact time of the full-scale column ( $EBCT_{LC}$ ) and the empty-bed contact time of the rapid small-scale column ( $EBCT_{SC}$ ) is obtained by equating the surface and pore diffusion modulus of the full-scale column and the RSSCT:

$$Ed_{s,SC} = Ed_{s,LC} \quad (15-197)$$

$$\frac{D_{s,SC} \tau_{SC} D_g}{R_{SC}^2} = \frac{D_{s,LC} \tau_{LC} D_g}{R_{LC}^2} \quad (15-198)$$

where  $D_{s,SC}$  = effective intraparticle surface diffusion coefficient in small-scale column,  $m^2/s$

$\tau_{SC}$  = small-scale column packed-bed contact time ( $EBCT_{SC} \cdot \epsilon$ ,  $\epsilon$  is bed porosity), s

$R_{SC}$  = particle radius of adsorbent in small-scale column, mm

$D_g$  = solute distribution parameter defined in Table 15-15, dimensionless

$D_{s,LC}$  = effective intraparticle surface diffusion coefficient in full-scale column,  $m^2/s$

$\tau_{LC}$  = full-scale column packed-bed contact time ( $EBCT_{LC} \cdot \epsilon$ ), s

$R_{LC}$  = particle radius of adsorbent in full-scale column, m

Solving for the ratio  $\tau_{SC}/\tau_{LC}$  yields

$$\frac{\tau_{SC}}{\tau_{LC}} = \left(\frac{R_{SC}}{R_{LC}}\right)^2 \left(\frac{D_{s,LC}}{D_{s,SC}}\right) = \left(\frac{d_{SC}}{d_{LC}}\right)^2 \left(\frac{D_{s,LC}}{D_{s,SC}}\right) \quad (15-199)$$

where  $d_{SC}$  = particle diameter of adsorbent in small-scale column, mm

$d_{LC}$  = particle diameter of adsorbent in full-scale column, mm

The same result can be obtained by equating  $Ed_p$  for both the small-scale and full-scale columns as shown:

$$\frac{\tau_{SC}}{\tau_{LC}} = \left(\frac{R_{SC}}{R_{LC}}\right)^2 \left(\frac{D_{p,LC}}{D_{p,SC}}\right) = \left(\frac{d_{SC}}{d_{LC}}\right)^2 \left(\frac{D_{p,LC}}{D_{p,SC}}\right) \quad (15-200)$$

where  $D_{p,SC}$  = pore diffusion coefficient in small-scale column,  $m^2/s$   
 $D_{p,LC}$  = pore diffusion coefficient in full-scale column,  $m^2/s$

In Eqs. 15-199 and 15-200 it is assumed that the adsorption capacity and physical properties of the adsorbents and bed do not depend on particle size. If the intraparticle pore and surface diffusivities of the small and large GAC are identical, then the following expression may be obtained:

$$\frac{EBCT_{SC}}{EBCT_{LC}} = \frac{\tau_{SC}/\varepsilon}{\tau_{LC}/\varepsilon} = \left(\frac{d_{SC}}{d_{LC}}\right)^2 = \left(\frac{R_{SC}}{R_{LC}}\right)^2 \quad (15-201)$$

However, the diffusivity has been observed to depend on particle size as shown in this equation:

$$\frac{D_{p,SC}}{D_{p,LC}} = \left(\frac{d_{SC}}{d_{LC}}\right)^x \quad \text{or} \quad \frac{D_{p,SC}}{D_{p,LC}} = \left(\frac{d_{SC}}{d_{LC}}\right)^x \quad (15-202)$$

where  $x$  = power dependency of the diffusivity

If the controlling intraparticle diffusivity is dependent on particle size, then the ratio of the EBCTs are given by this equation:

$$\frac{EBCT_{SC}}{EBCT_{LC}} = \left(\frac{d_{SC}}{d_{LC}}\right)^{2-x} \quad (15-203)$$

If the diffusivity is linearly dependent on the diffusivity, then the ration of the EBCTs are given by this equation:

$$\frac{EBCT_{SC}}{EBCT_{LC}} = \left(\frac{d_{SC}}{d_{LC}}\right) \quad (15-204)$$

To minimize the impact of bulk density and void fraction differences between the pilot and RSSCT columns, the following equation should be used to calculate the mass of adsorbent in the RSSCT:

$$M_{SC} = EBCT_{LC} \left[\frac{R_{SC}}{R_{LC}}\right]^{2-x} Q_{SC} \rho_{F,SC} \quad (15-205)$$

where  $M_{SC}$  = mass of adsorbent in small-scale column, kg  
 $Q_{SC}$  = water flow rate in small-scale column, L/s  
 $\rho_{F,SC}$  = bulk density of small-scale column, g/mL

#### SCALING OPERATION TIME

The duration of the RSSCT as compared to a full-scale column test is determined by noting that the mass throughput (Eq. 15-152) of the RSSCT must be equal to that of the full-scale column:

$$T_{SC} = \frac{C_0 t_{SC}}{EBCT_{SC}(1-\varepsilon)q_e \rho_a} = T_{LC} = \frac{C_0 t_{LC}}{EBCT_{LC}(1-\varepsilon)q_e \rho_a} \quad (15-206)$$

$$\frac{t_{SC}}{t_{LC}} = \frac{EBCT_{SC}}{EBCT_{LC}} = \left[\frac{d_{SC}}{d_{LC}}\right]^2 \quad (15-207)$$

where  $T_{SC}$  = mass throughput for small-scale column, dimensionless  
 $t_{SC}$  = small-scale column operation time, d  
 $T_{LC}$  = mass throughput for full-scale column, dimensionless  
 $t_{LC}$  = full-scale column operation time, d  
 $C_0$  = average influent to GAC column, mg/L  
 $q_e$  = column adsorbent capacity evaluated at  $C_0$ , mg/g

Or it is given by this equation if the diffusivity depends on particle size:

$$\frac{t_{SC}}{t_{LC}} = \frac{EBCT_{SC}}{EBCT_{LC}} = \left[ \frac{d_{SC}}{d_{LC}} \right]^{2-x} \quad (15-208)$$

#### SCALING HYDRAULIC LOADING

The relationship between the hydraulic loading of the full-scale column and the hydraulic loading of the RSSCT is obtained by equating the Stanton numbers of the full-scale column and the RSSCT:

$$St_{SC} = St_{LC} \quad (15-209)$$

$$\frac{k_{f,SC} \tau_{SC} (1 - \varepsilon)}{\varepsilon R_{SC}} = \frac{k_{f,LC} \tau_{LC} (1 - \varepsilon)}{\varepsilon R_{LC}} \quad (15-210)$$

$$\frac{k_{f,SC} \tau_{SC} / \varepsilon}{R_{SC}} = \frac{k_{f,LC} \tau_{LC} / \varepsilon}{R_{LC}} \quad (15-211)$$

$$\frac{k_{f,SC} EBCT_{SC}}{R_{SC}} = \frac{k_{f,LC} EBCT_{LC}}{R_{LC}} \quad (15-212)$$

where  $St_{SC}$  = Stanton number of small-scale column, dimensionless  
 $k_{f,SC}$  = film transfer coefficient of small-scale column, m/s  
 $St_{LC}$  = Stanton number of full-scale column, dimensionless  
 $k_{f,LC}$  = film transfer coefficient of full-scale column, m/s  
 $\varepsilon$  = adsorber bed void fraction, dimensionless

Substituting Eq. 15-201 into 15-212, the following expression is obtained:

$$k_{f,SC} R_{SC} = k_{f,LC} R_{LC} \quad (15-213)$$

As given by Eq. 15-213, the Sherwood numbers for the small-scale column ( $Sh_{SC}$ ) and full-scale column ( $Sh_{LC}$ ) (see Chap. 7) are identical:

$$\frac{k_{f,SC} d_{SC}}{D_l} = \frac{k_{f,LC} d_{LC}}{D_l} \quad (15-214)$$

where  $D_l$  = liquid diffusivity of adsorbate, m<sup>2</sup>/s

$$Sh_{SC} = Sh_{LC} \quad (15-215)$$

The Sherwood number depends on the Reynolds number (Re) and Schmidt number (Sc) as shown in the following:

$$\text{Sh} = f(\text{Re}, \text{Sc}) \quad (15-216)$$

$$\text{Sc} = \frac{\mu_l}{\rho_l D_l} \quad (15-217)$$

where  $\rho_l$  = liquid density of adsorbate, g/L  
 $\mu_l$  = dynamic viscosity of liquid, g/m · s

Accordingly, if the Reynolds numbers of the small and large columns are identical, then the Sherwood numbers of the large and small columns are identical. Consequently, the interstitial and approach velocity of the RSSCT can be determined from the full-scale column by equating the Reynolds numbers:

$$\text{Re}_{\text{SC}} = \text{Re}_{\text{LC}} \quad (15-218)$$

$$\frac{\rho_l v_{i,\text{SC}} d_{\text{SC}}}{\mu_l} = \frac{\rho_l v_{i,\text{LC}} d_{\text{LC}}}{\mu_l} \quad (15-219)$$

$$\frac{v_{i,\text{SC}}}{v_{i,\text{LC}}} = \frac{v_{\text{SC}}/\varepsilon}{v_{\text{LC}}/\varepsilon} = \frac{v_{\text{SC}}}{v_{\text{LC}}} = \frac{d_{\text{LC}}}{d_{\text{SC}}} \quad (15-220)$$

where  $v_{i,\text{SC}}$  = interstitial velocity of small-scale column, m/h  
 $v_{i,\text{LC}}$  = interstitial velocity of full-scale column, m/h  
 $v_{\text{SC}}$  = superficial velocity (hydraulic loading) of small-scale column, m/h  
 $v_{\text{LC}}$  = superficial velocity (hydraulic loading) of full-scale column, m/h

Because Pe depends upon Re and Sc, Eq. 15-220 will also guarantee that  $\text{Pe}_{\text{SC}} = \text{Pe}_{\text{LC}}$ .

Granular activated carbon particle size distributions have been shown to be a lognormal distribution, and the log mean of the diameters should be used for scaling. In general, the scaling relationships should be verified by comparing RSSCTs to pilot- or full-scale tests or by conducting batch tests to determine how the intraparticle rate is influenced by particle size (Crittenden et al., 1986, 1987a, 1991).

Sometimes using Eq. 15-220 leads to a design with a high head loss, which increases dramatically with operation time, as the GAC is crushed due to a large pressure drop across the RSSCT. In general, intraparticle diffusion causes most of the spreading in the MTZ, and the main factors that need to remain the same are the surface and pore diffusion modulus and the Re for the RSSCT, and large columns do not have to be the same.

Consequently, the high head loss may be avoided by lowering the superficial velocity as long as dispersion does not become the dominant transport mechanism and intraparticle mass transfer is limiting the adsorption rate.

It has been reported that the Peclet number based on diameter can be estimated from the following equation (Fried, 1975):

$$Pe_d = 0.334 \text{ for } 160 \leq Re \times Sc \leq 40,000 \quad (15-221)$$

When the velocity is reduced below what is given in Eq. 15-221, axial dispersion, which is caused by molecular diffusion, can be more important in the RSSCT than in the full-scale process. Consequently, Eq. 15-221 can be used to check whether dispersion becomes important as the velocity of the RSSCT is reduced in an effort to reduce the head loss. A typical Sc value for SOCs is  $\sim 2000$ ; consequently, Re for the RSSCT must be kept greater than  $\sim 0.1$  and the  $Pe_{MTZ}$  must be kept above 50 for the length of the mass transfer zone:

$$Pe_{MTZ} = \frac{L_{MTZ}}{d_p} Pe_d \quad (15-222)$$

$$Re_{SC, \min} = 0.1 = \frac{\rho_l v_i 2 R_{sc}}{\mu} \quad (15-223)$$

$$v_{sc} = v_i \varepsilon = 0.1 \frac{\mu_l}{\rho_l 2 R_{sc}} \varepsilon \quad (15-224)$$

where  $Pe_{MTZ}$  = Peclet number based on mass transfer zone length, dimensionless

$L_{MTZ}$  = length of the mass transfer zone, m

$d_p$  = diameter of the adsorbent particle, m

$Pe_d$  = Peclet number based on particle diameter, dimensionless

$Re_{SC, \min}$  = minimum Re number for RSSCT, dimensionless

$v_i$  = interstitial velocity, m/h

A larger  $v_{sc}$  can be chosen if the column is too short and it can be increased until the head loss is too large.

Because the EBCT of the MTZ is typically between 5 and 10 min, the Peclet number,  $Pe_{MTZ}$ , is greater than 50, and the  $Pe_d$  of the RSSCT is equal to  $0.334(L_{MTZ}/d_p)$ . For example, if the MTZ of the LC is 5 min (which would be short), then the MTZ would be 4150 and the  $Pe_{MTZ}$  would be 1390. Obviously, axial dispersion can be ignored in nearly all cases.

#### CONSTANT-DIFFUSIVITY RSSCT DESIGN

The final set of design equations for a constant-diffusivity RSSCT design is given as

$$\frac{EBCT_{SC}}{EBCT_{LC}} = \frac{d_{SC}^2}{d_{LC}^2} = \frac{t_{SC}}{t_{LC}} \quad (15-225)$$

$$\frac{v_{SC}}{v_{LC}} = \frac{d_{LC}}{d_{SC}} \quad (15-226)$$

Or for a reduced head loss the superficial velocity would be given by this equation as long as the  $Pe_{MTZ} \gg 50$ , which can be calculated from the experimental results. (This criteria also ensures that intraparticle diffusion resistance is the most significant transport process.)

$$v_{sc} = 0.1 \frac{\mu_l}{\rho_l 2R_{sc}} \varepsilon \quad (15-227)$$

#### NONCONSTANT-DIFFUSIVITY RSSCT DESIGN

The final set of design equations for a nonconstant-diffusivity RSSCT design is given as

$$\frac{t_{SC}}{t_{LC}} = \frac{EBCT_{SC}}{EBCT_{LC}} = \left( \frac{d_{SC}}{d_{LC}} \right)^{2-x} \quad (15-228)$$

The  $St$ ,  $Pe$ , and  $Re$  cannot be matched unless  $x = 0$ , and we can use this equation to determine the  $v_{sc}$ :

$$v_{sc} = 0.1 \frac{\mu_l}{\rho_l 2R_{sc}} \varepsilon \quad (15-229)$$

A larger  $v_{sc}$  can be chosen if the column is too short and it can be increased until the head loss is too large.

#### CARBON PREPARATION FOR USE IN RSSCT

Preparation of the GAC for the RSSCT is important because a representative sample is required for good results. Mixing and splitting the  $GAC_{LC}$  must first be performed on a bag of GAC that is used in the full-scale columns to obtain a representative sample. The smaller GAC used in RSSCT studies,  $GAC_{SC}$ , is obtained by crushing a representative sample of  $GAC_{LC}$ . The crushed carbon is then sieved, retaining the desired sieve fraction. The crushing of the  $GAC_{LC}$  should be done carefully so that a lot of carbon fines are not generated, which will increase the yield of  $GAC_{SC}$ . The crushing and sieving must be continued until all the crushed carbon from the  $GAC_{LC}$  sample passes through the largest sieve used to obtain  $GAC_{SC}$ . If care is used in grinding the  $GAC_{LC}$ , then the yield of  $GAC_{SC}$  can be more than 40 percent of the  $GAC_{LC}$  by weight.

The direct scaling of the full-scale column to a small column is demonstrated in Example 15-14. However, as discussed above, sometimes the RSSCT design does not work well because of excessive pressure drop caused by the small particle size coupled with a high velocity. Using a smaller RSSCT column length and a lower velocity will produce a manageable pressure drop, and still provide RSSCT predictive capabilities.

A study summarizing 22 case studies in which RSSCTs are compared to pilot columns that involved 12 SOCs, including weakly adsorbing trihalomethanes and strongly adsorbing pesticides, was performed (Critenden et al., 1991). The background water matrices included water that

### Example 15-14 Development of the design and operating parameters of an RSSCT

Calculate the design and operating parameters of an RSSCT that has a particle diameter of 0.21 mm compared to a full-scale unit that has a particle diameter of 1.0 mm. The RSSCT is to be designed assuming that the intraparticle diffusivities do not change with particle size. The RSSCT column diameter is 1.10 cm. Typical operating conditions for pilot-scale columns are given in the following table:

Design Parameters	Unit	Pilot Scale
Particle diameter	mm	1.0 (12 × 40)
Bulk density	g/mL	0.49 (F-400)
EBCT	min	10.0
Loading rate	m/h	5.0
Flow rate	mL/min	170.1
Column diameter	cm	5.1
Column length	cm	83.3
Mass of adsorbent	g	833.8
Time of operation	d	100.0
Water volume required	L	24,501

#### Solution

1. Calculate the  $EBCT_{SC}$  using Eq. 15-225:

$$EBCT_{SC} = EBCT_{LC} \frac{d_{SC}^2}{d_{LC}^2} = 10 \left( \frac{0.21^2}{1.0^2} \right) = 0.44 \text{ min}$$

2. Calculate the hydraulic loading rate using Eq. 15-226:

$$v_{SC} = v_{LC} \frac{d_{LC}}{d_{SC}} = 5.0 \left( \frac{1.0}{0.21} \right) = 23.8 \text{ m/h}$$

3. Calculate the run time using Eq. 15-225:

$$t_{SC} = t_{LC} \frac{d_{SC}^2}{d_{LC}^2} = 100 \left( \frac{0.21}{1.0} \right)^2 = 4.4 \text{ d}$$

4. Calculate the bed length, flow rate, and mass of carbon using the RSSCT column diameter, hydraulic loading rate and EBCT:

$$L_{SC} = v_{SC} EBCT_{SC} = \frac{(23.8 \text{ m/h})(100 \text{ cm/m})(0.44 \text{ min})}{60 \text{ min/h}} = 17.4 \text{ cm}$$

$$Q_{SC} = v_{SC}A_{SC} = v_{SC} \left( \frac{\pi D_{SC}^2}{4} \right) = \frac{(23.8 \text{ m/h})\pi(1.10 \text{ cm})^2(100 \text{ cm/m})}{(4)(60 \text{ min/h})}$$

$$= 37.7 \text{ cm}^3/\text{min} \text{ (37.7 mL/min)}$$

$$M_{SC} = Q_{SC} \text{ EBCT}_{SC} \rho_{SC} = (37.7 \text{ mL/min})(0.44 \text{ min})(0.49 \text{ g/mL}) = 8.1 \text{ g}$$

5. Calculate the volume of water required to run the RSSCT

$$V_W = Q_{SC} t_{SC} = \frac{(37.7 \text{ mL/min})(4.4 \text{ d})(1440 \text{ min/d})}{10^3 \text{ mL/L}} = 239 \text{ L}$$

The design parameters for the RSSCT are:

$D = 1.1 \text{ cm}$	$v = 23.4 \text{ m/h}$
$L = 17.4 \text{ cm}$	$Q = 37.7 \text{ mL/min}$
$d = 0.21 \text{ mm}$	$M = 8.1 \text{ g}$
$\text{EBCT} = 0.44 \text{ min}$	$V = 239 \text{ L}$
$t = 4.4 \text{ d}$	

### Comment

The quantity of water required to simulate 100 days of pilot column operation is 239 L, which can be transported to an off-site laboratory to conduct the test.

## Example 15-15 Using a RSSCT to predict full-scale performance

A proportional diffusivity RSSCT was performed to evaluate the removal of 1,2-dichloropropane from a groundwater supply using GAC adsorption. The RSSCT was designed to mimic a full-scale adsorber with an EBCT of 4.9 min and a superficial velocity of 8.75 m/h (0.243 cm/s). Based on the RSSCT results shown in the following table, scale up the data and plot the expected full-scale performance in terms of GAC specific throughput. From the predicted full-scale performance, determine the GAC specific throughput for a treatment objective of 5  $\mu\text{g/L}$  and the annual GAC usage (kg/yr).

**Table of bed parameters**

Item	Unit	Full-Scale Column	RSSCT
Apparent particle density	g/cm <sup>3</sup>	0.759	0.759
Bulk or bed density	g/cm <sup>3</sup>	0.44	0.5067
Bed porosity	—	0.42	0.33
Particle radius	mm	0.81	0.106
Column diameter	mm		11
Column length	mm	714	94.1
Bed volume	cm <sup>3</sup>	92,618	8.94
GAC mass (dry)	g		4.53
Flow rate	L/min	6,940	0.1043
Superficial velocity	cm/s	0.243	1.83
EBCT	s	294	5.16
Operating temperature	°C	13.0±2	13.0±2
Operating time	d	288	5.05

**Table of RSSCT column results**

Elapsed Time, min	Concentration, µg/L	
	Influent	Effluent
0.0	19.0	0.0
79.0	19.0	0.0
128.0	18.0	0.0
1023.0	19.0	5.0
1174.0	18.0	6.0
1409.0	19.0	8.0
1551.0	19.0	8.0
1826.0	19.0	10.0
1876.0	19.0	10.0
2474.0	19.0	12.0
2612.0	19.0	10.0
2851.0	18.0	13.0
3007.0	18.0	11.0
3287.0	18.0	13.0

**Solution**

1. Determine the full-scale time based on RSSCT data. The RSSCT effluent time scale can be converted to the full-scale time using Eq. 15-225:

$$\begin{aligned}
 t_{LC} &= t_{SC} \left( \frac{EBCT_{LC}}{EBCT_{SC}} \right) = t_{SC} \left( \frac{294 \text{ s}}{5.16 \text{ s}} \right) = \frac{57.0}{1440 \text{ min/d}} t_{SC} \\
 &= (0.0396 \text{ d/min}) t_{SC}(\text{min})
 \end{aligned}$$

2. Predict full-scale performance. Multiplying the RSSCT time scale by 0.0396 will scale up the RSSCT to predict the full-scale performance as shown in the following table. In addition, the following table shows the specific throughput for each time as determined using Eq. 15-102:

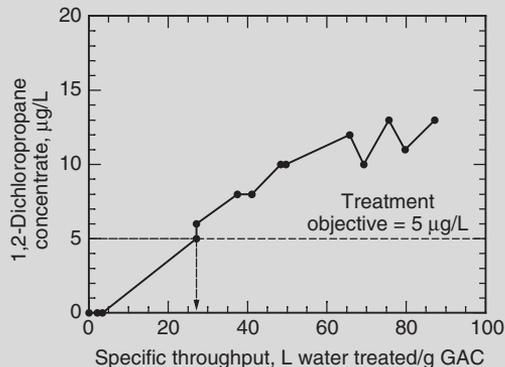

$$\text{Specific throughput} = \frac{t_{LC}}{\text{EBCT}_{LC} \rho_{FLC}} = \frac{t_{LC}(1440 \text{ min/d})}{(4.90 \text{ min})(0.44 \text{ g/cm}^3)(1000 \text{ cm}^3/\text{L})}$$

$$= (0.67 \text{ L/g} \cdot \text{d})(t_{LC})$$

### Full-scale column prediction based on the RSSCT data

RSSCT Elapsed Time, $t_{SC}$ (min)	Predicted Full-Scale Elapsed Time, $t_{LC}$ (d)	Predicted Specific Throughput (L/g)	Effluent Concentration ( $\mu\text{g/L}$ )
0.0	0.0	0.0	0.0
79.0	3.12	2.1	0.0
128.0	5.07	3.4	0.0
1023.0	40.5	27.1	5.0
1174.0	46.5	27.1	6.0
1409.0	55.8	37.4	8.0
1551.0	61.4	41.1	8.0
1826.0	72.3	48.4	10.0
1876.0	74.2	49.7	10.0
2474.0	98.0	65.7	12.0
2612.0	103.4	69.3	10.0
2851.0	112.9	75.6	13.0
3007.0	119.0	79.7	11.0
3287.0	130.1	87.2	13.0

3. Plot the effluent concentration versus specific throughput from the data in the table above.

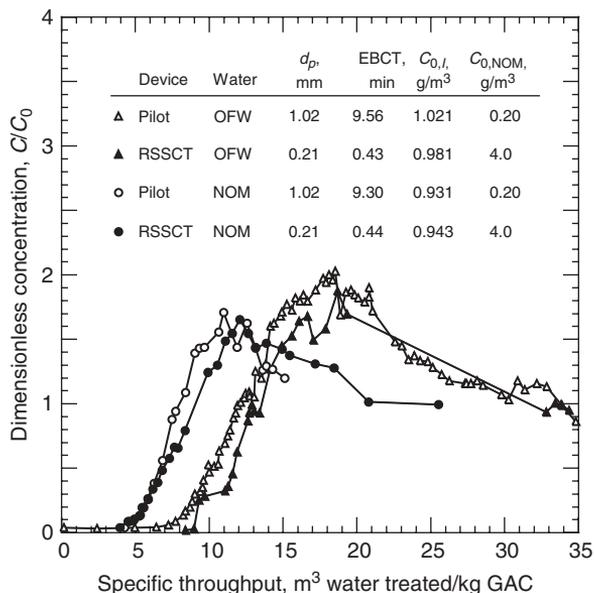

Based on a treatment objective of 5  $\mu\text{g/L}$ , as shown in the figure, the specific throughput is 27.1 L of water treated per gram of GAC. If the flow rate is 10 ML/d, the annual GAC consumption is calculated as

$$\begin{aligned}\text{Annual GAC consumption} &= \frac{(10 \times 10^6 \text{ L/d})(365 \text{ d/yr})}{(27.1 \text{ L/g})(1000 \text{ g/kg})} \\ &= 134,700 \text{ kg GAC/yr}\end{aligned}$$

had been distilled, deionized, and GAC filtered, four groundwaters, lake water, and river water. Three scenarios were represented: (1) a low concentration of background organic matter and a relatively high concentration of the SOC > 1.0 mg/L, (2) adsorbable background organic matter and a relatively high concentration of the SOC, and (3) adsorbable background organic matter and a relatively low concentration of SOCs < 0.38 mg/L.

The pilot and RSSCTs data for organic-free water and surface water containing approximately 4.0 mg DOC/L are compared on Fig. 15-33. The RSSCTs were designed using Eqs. 15-225 and 15-226 [the analysis is called a constant-diffusivity (CD) design]. The influent concentrations and operational parameters for this study are reported in Table 15-22. The source of organic matter was drainage from a swamp in Lake Superior basin (Houghton, Michigan). Based on the data presented on Fig. 15-33, the

**Figure 15-33**

Comparison of RSSCTs and pilot column data for chloroform that were collected in organic-free water (OFW) and surface water (NOM). (Adapted from Sontheimer et al., 1988.)

<sup>a</sup>DBCM = dibromochloromethane, EDB = ethylene dibromide, TCE = trichloroethylene, PCE = tetrachloroethylene.<sup>b</sup>The column capacity was determined by extrapolating the effluent concentration profiles.<sup>c</sup>The column capacity was determined by extrapolating the effluent concentration profiles; however, the profiles were too short to extrapolate with precision.  
Source: Adapted from Crittenden et al. (1991).

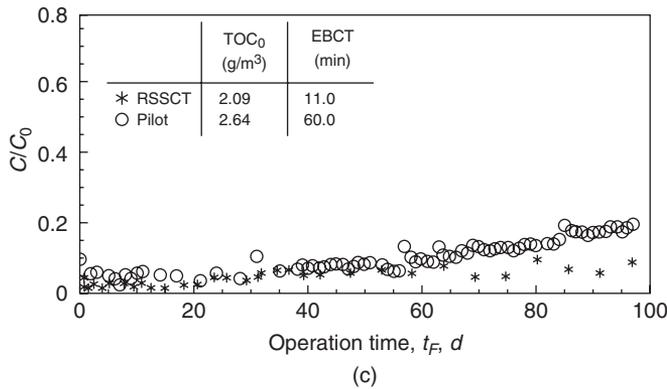

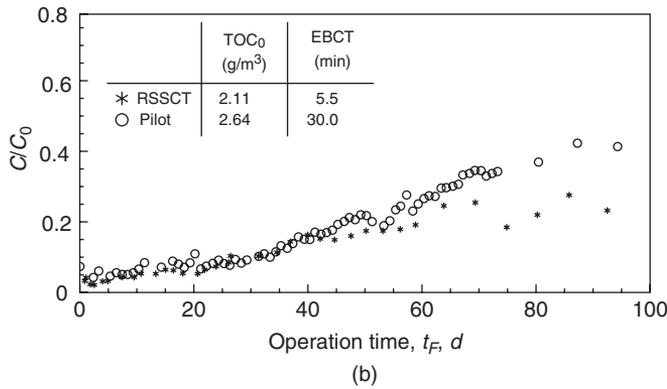

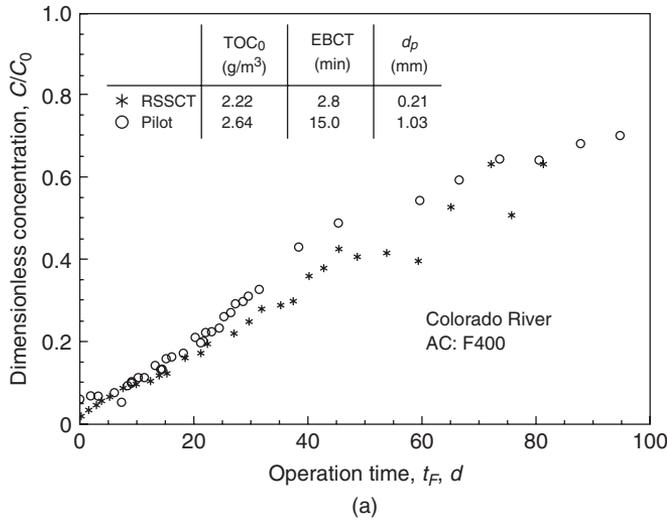

pilot and RSSCT data for the low-DOC water have higher capacity than the data for a high-DOC background. The RSSCT data for organic-free water agrees well with the pilot column data. The comparisons between RSSCTs and pilot data for the SOCs in the presence of high DOC are very good, but the RSSCTs exhibit slightly higher capacity.

The results obtained by assuming that the intraparticle diffusivity is constant for SOCs ( $MW < 300$ ) are reasonable for preliminary design. Typically, using this type of design will give a column capacity that is 20 to 40 percent larger than those observed for pilot columns. Greater precision will require comparisons between RSSCT and pilot- or full-scale data. Alternatively, batch isotherm and rate data conducted on carbon exposed to the water matrix could be used to properly select the best RSSCT design (Sontheimer et al., 1988). Recently, ASTM (2000) accepted the RSSCT method as a standard test using a constant diffusivity design. Corwin and Summers (2010) examined the precision of RSSCTs and made recommendations for designing RSSCTs ( $x$  values) for several SOCs. Their findings show that proportional diffusivity may yield better results. It appears that using small GAC in the RSSCT reduces the impact of NOM on GAC capacity because there are more pore openings on the outside of the GAC that is used in RSSCTs. Accordingly, the GAC that is used in full-scale plants has fewer pore openings and NOM can plug or foul the GAC in full-scale plants more easily than GAC that is used in RSSCTs.

Studies have evaluated using RSSCTs to predict DOC removal (Crittenden et al., 1991). The studies included the following water sources: (1) Colorado River water (CRW), (2) California State Project water (SPW), from Northern California, (3) Ohio River water, (4) Mississippi River water, and (5) Delaware River water. It was determined that the intraparticle diffusivity was proportional to particle size for CRW and SPW; consequently, the RSSCTs with proportional diffusivity (PD) designs were compared to RSSCTs with CD designs. In all cases, a good comparison was reported between PD RSSCTs and pilot column results. The results for CRW and a PD design are presented on Fig. 15-34. Breakthrough time is expressed as the equivalent operation time in the pilot column, as given by Eq. 15-225; the RSSCT (using a  $60 \times 80$ -mesh GAC) can be conducted in 20 percent of the time of the pilot test. Comparisons of the breakthrough of the RSSCTs and pilot columns for 30 and 60 min EBCT show that the RSSCT breakthroughs appeared slightly after the pilot breakthrough profiles. However, the PD RSSCT design yielded good comparisons between the results of the RSSCT and the pilot columns for the other sites. However, if biodegradation of the DOC occurs in the full-scale process, it will not be reflected in the RSSCT predictions.

### **Factors That Impact Adsorber Performance**

The three main factors that impact adsorber performance, as discussed below, are particle size, backwashing, and hydraulic loading.

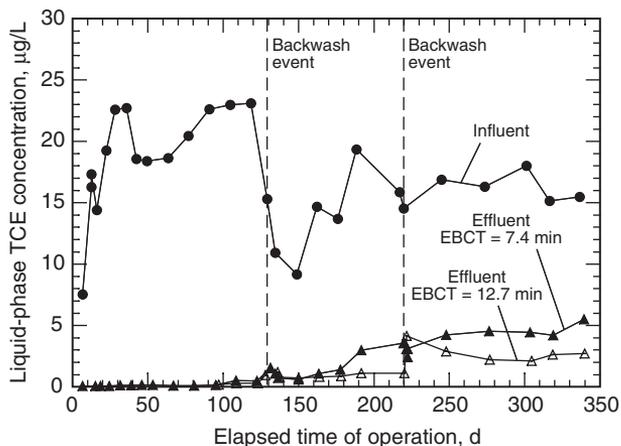

**Figure 15-34**  
Comparison of TOC breakthrough curves for pilot columns and RSSCTs designed based on proportional diffusivity for full-scale column EBCTs of (a) 15 min, (b) 30 min, and (c) 60 min. (Adapted from Sontheimer et al., 1988.)

**PARTICLE SIZE**

Particle size influences the rate of adsorption and head loss in GAC columns. As particle size decreases, the length of the MTZ decreases. The head loss across a GAC bed will vary with particle size. For deeper beds and longer absorber runs, the particle size is typically 0.6 to 2.36 mm (U.S. sieve sizes of  $8 \times 30$ ). For lower hydraulic loading rates, particle size will typically vary from 0.425 to 1.7 mm (U.S. sieve sizes of  $12 \times 40$ ).

**BACKWASHING**

To obtain the best performance for SOCs, GAC contactors should be operated in the postfiltration mode or receive low-turbidity water because backwashing will greatly reduce their performance. The mass transfer zone will be disrupted due to backwashing, which in turn causes premature breakthrough of contaminants. Backwashing decreases adsorber performance, as shown on Fig. 15-35. The profile for the 7.4-min EBCT decreases because during backwashing exhausted GAC is mixed up into the bed and less exhausted carbon is mixed in this section of the bed. Backwashing is usually not needed for treatment of groundwater from deep wells as long as there is no potential for precipitation of calcium carbonate or metals. Care must be taken not to introduce oxygen or other gases that may cause precipitation or significant biological growth. In cases where there is precipitation potential, dissolved species that may precipitate must be removed prior to the GAC process. When treating turbid surface waters, turbidity must be removed prior to the GAC process, otherwise backwashing will be required and the GAC cannot achieve a high degree of removal of SOCs. Based on operating experience, it has been found that backwashing does not appear to affect DOC removal because high degrees of removal cannot be achieved with reasonable EBCTs.

**Figure 15-35**  
Impact of backwashing on full-scale pressure GAC contactor.

**HYDRAULIC LOADING**

The review of Cover and Pieroni (1969) reported that hydraulic loading does not influence the performance of adsorbers with the same EBCT. However, increasing hydraulic loading will increase head loss. One common mistake for pressure GAC contactors is to use too few GAC beds, operated in parallel, in an effort to reduce capital expense. The larger hydraulic loading can cause a high pressure drop, which can increase dramatically over time. Because GAC can be crushed by the high pressure, the bed void fraction will be reduced with a concomitant increase in pressure. The problem can be exacerbated to a point where the bed must be backwashed.

## Problems and Discussion Topics

---

- 15-1 Compare chemisorption and physical adsorption.
- 15-2 List the types of commercially available adsorbents in water treatment. Which type is the most commonly used and why?
- 15-3 Describe the production method of activated carbon and list the methods of regeneration and reactivation of spent GAC.
- 15-4 List the forces that may be operative during adsorption. Discuss the origin of each force, and the properties of the adsorbate and adsorbent that influence the force.
- 15-5 Derive the Langmuir equation from the elementary reaction rate steps. List the assumptions that are required to derive the Langmuir equation and the Freundlich isotherm equations.
- 15-6 Determine the Freundlich and Langmuir parameters for the data given below. You may use linear regression, and plot  $C/Q$  versus  $C$  for the Langmuir equation and  $\log Q$  versus  $\log C$  for the Freundlich equation.

Adsorption isotherm data: Carbon type, F-400; chemical, tetrachloroethene; temperature, 13.8°C.

Isotherm Data:

$C_e, \mu\text{mol/L}$	$q_e, \mu\text{mol/g}$
15.7	1,246
1.27	489
0.396	298
0.225	250
0.161	213

- 15-7 Determine the Freundlich isotherm parameters for tetrachloroethene (PCE) using Polanyi potential theory and compare the parameters with those determined in Problem 15-6. Use Cargon

F-400 GAC and a water treatment temperature of 13.8°. For PCE, the following properties at 13.8°C are given:  $V_m = 102.4$  mL/mol,  $\rho_l = 1620$  kg/m<sup>3</sup>, and  $C_s = 347.0$  mg/L.

- 15-8 Compare the GAC usage rates for TCE concentrations of 100, 50, and 25 µg/L in water and compare the gas phase usage rate to the usage rate in water. Assume the GAC is completely saturated at the influent concentration. Use the Freundlich parameters in Table 15-6. From Chapter 14, assume a stripper with an air-to-water ratio of  $3.5/H$  is used to strip out all TCE and transfer it to the air.  $T = 10^\circ\text{C}$  and the following properties at 10°C for TCE are given: solubility = 821 mg/L, vapor pressure = 36.7 mm Hg, refractive index = 1.4773,  $\rho_l = 1620$  kg/m<sup>3</sup>. Use Calgon BPL (4 × 6) for gas-phase adsorption. Hint: ideal gas law can be used to calculate partial pressure of TCE from the TCE concentration.
- 15-9 Derive the expression of adsorption potential ( $\epsilon$ ) in the Polanyi and DR equations for water and air. The adsorption in water can be described using the following reaction.

Assume adsorbed state is a saturated solution. Hint:  $\epsilon = \Delta G$ .

- 15-10 Using TOC data for Colorado River water in Fig. 15-25 and a treatment objective of 1.0 mg/L of TOC (trihalomethane formation potential is 50 µg/L), calculate the volume of water treated per gram GAC for the following: (a)  $2 \times 7.5$ -min EBCT columns in series, (b) 2 columns in parallel with EBCT = 15 min, (c) single contactor with 7.5- and 15-min EBCT. The filter density is 0.457 g/mL, the average TOC influent concentration is 2.52 mg/L.
- 15-11 Calculate the dosage of activated carbon to reduce an influent concentration of 300 µg/L of chloroform to 100 µg/L (treatment objective) using powdered (PAC) and granular activated carbon (GAC). Assume for the GAC and PAC process that the carbons are saturated at the influent concentration and treatment objective, respectively. *Given:*  $Q = 10$  mgd.

$$K = 159 \frac{\mu\text{g of chloroform}}{\text{g of activated carbon}} \left( \frac{L}{\mu\text{g}} \right)^{0.625}$$

How long will the GAC last if the filter density  $\rho_f = 0.37$  g/cm<sup>3</sup> and EBCT = 15 min?

- 15-12 Derive the scaling equations (Eqs. 15-225 and 15-226) needed to simulate a full-scale adsorber by a constant diffusivity RSSCT.
- 15-13 Design a RSSCT from the pilot plant data for the removal of methyl-*tert*-butyl ether (MTBE) from a raw-water source obtained from a reservoir based on constant diffusivity design. The design should

include the column length, EBCT, time of operation, hydraulic loading rate, flow rate, mass of carbon, and volume of water needed.

Pilot Data	RSSCT
$d_p = 1.026$ mm	$d_p = 0.1643$ mm
$\rho_a = 0.803$ g/cm <sup>3</sup>	$\rho_a = 0.803$ g/cm <sup>3</sup>
$\rho_F = 0.480$ g/cm <sup>3</sup>	$\rho_F = 0.480$ g/cm <sup>3</sup>
$\varepsilon = 0.40$	$\varepsilon = 0.40$
Column diameter = 5.1 cm	Column diameter = 1.1 cm
EBCT = 10.0 min	
$v_S = 10$ m/h	
$t$ (time of operation) = 10 wk	

- 15-14 Design an RSSCT from the pilot plant data for the removal of DOC (molecular weight = 10,000) from a raw-water source obtained from a reservoir based on  $D_s$  varying linearly with  $d_p$ : The design should include the column length, EBCT, time of operation, hydraulic loading rate, flow rate, mass of carbon, and volume of water needed.

Pilot Data	RSSCT
$d_p = 1.026$ mm	$d_p = 0.1643$ mm
$\rho_a = 0.803$ g/cm <sup>3</sup>	$\rho_a = 0.803$ gm/cm <sup>3</sup>
$\rho_F = 0.480$ g/cm <sup>3</sup>	$\rho_F = 0.480$ gm/cm <sup>3</sup>
$\varepsilon = 0.40$	$\varepsilon = 0.40$
Column diameter = 5.1 cm	Column diameter = 1.1 cm
EBCT = 10.0 min	
$v_S = 10$ m/h	
$t$ (time of operation) = 10 wk	

- 15-15 Derive the expression comparing PAC/GAC usage rates.
- 15-16 For the GAC pilot plant data plotted in Example 15-10, calculate the specific volume for two beds in series with the first bed having a 10-min EBCT and the second bed a 22-min EBCT. The flow rate is 161 mL/min, and  $\rho_f = 0.457$  g/mL. The treatment objective is 5  $\mu$ g/L. The average DCE influent concentration is 80  $\mu$ g/L. The effluent from the first bed is 64  $\mu$ g/L when the treatment objective from the second column is exceeded.
- Column data:

EBCT, min	$M$ , g	$T$ , d	$Q_t$ , L	L/g
10	791.1	75	17400	22.0
32	2373.3	290	67280	29.0

- 15-17 Calculate removal in a flocculent blanket reactor (FBR) for 25, 50, 100, and 500 ng/L MIB and PAC dosages of 5, 10, 25, 50, and 75 mg/L for a CMFR that considers the influence of NOM. Redo this for a CMFR that does not consider the presence of NOM. Given the following single-solute adsorption isotherm parameters:  $K = 9.56$  (ng/mg)(L/ng) $^{1/n}$ ,  $1/n = 0.492$ . Laboratory studies determined that the adsorption capacity for MIB was reduced by 25 percent due to NOM adsorption. For simplification, assume that the adsorption of MIB reaches equilibrium in the CMFR. [Comments: Adsorption equilibrium is rarely reached in real practice. A longer carbon retention time (CRT) can cause the adsorption closer to equilibrium. See Example 15-6.]
- 15-18 Isotherm experiments were conducted in bottles with two different initial concentrations to measure the adsorption isotherm of MIB on PAC in a natural water and the following data were obtained (Gillogly et al., 1998). Plot the percentage of MIB remaining in the solution as a function of PAC dosage, and determine the PAC dosage corresponding to 90 percent removal of MIB in a batch reactor for an initial concentration of 200 ng/L.

$C_0$ , ng/L	PAC Dosage, mg/L	$C_e$ , ng/L
150	2.2	137.7
	4.1	122.7
	9.9	81.6
	32.4	16.2
	45.7	5.85
1245	2.1	1088.13
	4	949.94
	14.6	329.68
	40.2	51.04
	60.3	14.94

- 15-19 A municipality wants to treat 2.7 ML/d of a groundwater that contains 85  $\mu\text{g/L}$  of 1,1-dichloroethylene (DCE) using granular activated carbon (GAC) adsorption. It is recommended that a 3.66-m diameter pressure vessel containing 9000 kg of Calgon F-400 GAC be used to treat the DCE from the water. Using the constant pattern solutions, calculate the time it will take to reach the treatment objective of 5  $\mu\text{g/L}$  assuming continuous pumping, the specific throughput in  $\text{m}^3$  water treated per kg of GAC, and the mass transfer zone length. Assume no NOM fouling is important and  $\text{SPDFR} = 4$ . The properties of the GAC and water are as follows: GAC properties: Calgon Filtrasorb F-400 (12  $\times$  40 mesh),  $\rho_f = 0.45 \text{ g/cm}^3$ ,  $\rho_a = 0.8034 \text{ g/cm}^3$ ;  $d_p = 0.1026 \text{ cm}$ , particle porosity  $\epsilon_p = 0.641$ ,

- EBCT = 10 min,  $\varepsilon = 0.44$ , temperature = 14°C; single-solute Freundlich parameters are  $K = 470 (\mu\text{g/g})(\text{L}/\mu\text{g})^{1/n}$ ,  $1/n = 0.515$ .
- 15-20 Redo Problem 15-19 assuming NOM fouling of the GAC using Karlsruhe groundwater correlation and compare your answer to the case of no NOM fouling. Assume SPDFR = 1 when NOM is present.
- 15-21 Redo Problem 15-19 assuming there is 30  $\mu\text{g/L}$  of methyl-*tert*-butyl ether (MTBE) and a treatment objective of 5  $\mu\text{g/L}$ . Apply each NOM fouling correlations listed in Table 15-20 and compare the results. Assume MTBE behaves like a halogenated alkene and SPDFR = 1 when NOM is present.
- 15-22 If packed-tower air stripping is used to treat DCE in Problem 15-19, design a gas-phase GAC contactor to treat the off-gas from the packed tower. Assume the optimum air-to-water ratio is equal to 3.5 times the minimum air-to-water ratio required for stripping (you do not need to design the air stripper). Assume a typical superficial gas velocity of 0.8 m/s, EBCT of 40 s, and a treatment objective of <1  $\mu\text{g/L}$ . Determine the dimensions of the fixed bed, mass of GAC required, GAC usage rate in  $\text{m}^3/\text{kg}$ , and time to breakthrough in days. Use Calgon BPL GAC with the following properties:  $\rho_F = 0.525 \text{ g/cm}^3$ ;  $\rho_a = 0.525 \text{ g/cm}^3$ ;  $\varepsilon_p = 0.595$ ;  $D_p = 0.3715 \text{ cm}$ , Freundlich  $K = 1111 (\mu\text{g/g})(\text{L}/\mu\text{g})^{1/n}$ , and  $1/n = 0.838$ . Assume SPDFR = 16.0 for gas-phase operation.

## Terminology for Ion Exchange

---

<b>Term</b>	<b>Definition</b>
Counterion	Ion in solution that can exchange with an ion attached to a stationary functional group.
Empty-bed contact time	Volume of the resin in the bed including pore volume divided by the volumetric flow rate to the fixed bed.
Film diffusion	Effective rate at which ions migrate across the stagnant film surrounding the resin particles in the fixed bed.
Gel-type resin	Translucent polymeric resin with low degree of crosslinking and a high water content with an open matrix.
Helfferich number	Ratio of the rate of mass transfer by film diffusion to the rate of mass transfer by intraparticle diffusion.
Intraparticle diffusion	Effective rate at which ions migrate inside the resin particles.
Ion exchange	Process in which ions attached to a stationary functional group exchange for ions in a solution. Ions are exchanged on an equivalence basis.
Macroreticular resin	Opaque polymeric resin having a high degree of crosslinking and low water content with a closed matrix.
Presaturant ion	Ion that comes attached to the virgin resin or is exchanged onto the resin during the regeneration process.
Regeneration curves	Breakthrough curves obtained from a fixed-bed ion exchange operation during the regeneration cycle.
Resin swelling	Enlarging of an ion exchange resin due to the exchange of a larger preferred ion over a smaller less preferred ion.
Saturation loading curves	Breakthrough curves obtained from a fixed-bed ion exchange operation during the loading cycle.

<b>Term</b>	<b>Definition</b>
Selectivity	Preference of one ion over another for exchange onto an ion exchange site on a resin.
Separation factor	Quantitative description of the preference of one ion over another for a given ion exchange resin.
Service flow rate	Volumetric flow rate to the ion exchange column divided by the volume of the resin in the bed including pore volume.
Strong acid cation resin	Ion exchange resin that will readily give up a proton over a wide pH range.
Strong base anion resin	Ion exchange resin that will readily give up a hydroxide ion if the pH is less 13.
Synthetic resins	Spherical beads that contain a network of crosslinked polymers containing functional groups.
Total ion exchange capacity	Total amount of chemical equivalents available for exchange per unit weight or unit volume of resin.

Ion exchange is a process used to remove dissolved ionic constituents that can cause aesthetic and health issues. The ion exchange process for water treatment is considered to be a nonconventional process because it is not widely used in large-scale plants. The types of ion exchange materials used in water treatment, basic mechanisms involved in the ion exchange process, process design considerations, and example problems that apply ion exchange fundamentals to system design and operation are discussed in this chapter.

## 16-1 Evolution of Ion Exchange Technology

In drinking water treatment applications, ion exchange is primarily used for water softening and demineralization (e.g., removal of  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ). The vast majority of ion exchange installations in the United States are small, point-of-use devices at individual households. The application of ion exchange to municipal systems has been limited. Applications include the removal of hardness (softening), nitrate, barium, radium, arsenic, perchlorate, and chromate. There have been several full-scale systems designed for industrial applications, such as the demineralization of water for prevention of scale formation in power plant boilers, removal of calcium and magnesium in car-washing facilities, and production of ultrapure water for making pharmaceuticals and semiconductor materials.

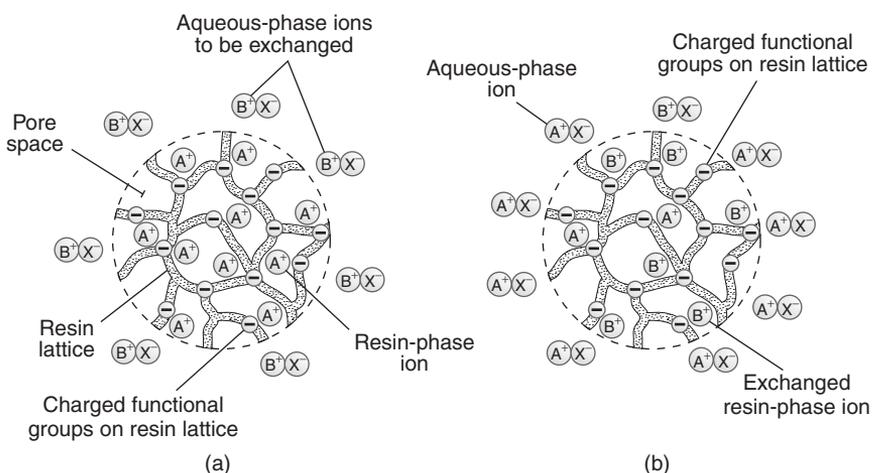

With increased concern for the health effects of other contaminant ions such as barium, radium, fluoride, nitrate, arsenate, perchlorate, and

uranium, the use of ion exchange and inorganic adsorbents for full-scale applications in water treatment has increased. While much attention has been placed on the use of conventional synthetic ion exchange resins, research is ongoing to develop specialty resins that are selective for some contaminant ions. Natural and synthetic inorganic materials (e.g., zeolites) that have adsorption properties and exhibit favorable capacities for contaminant ions are also being developed and evaluated.

### Natural Exchange Materials

In water treatment applications, ion exchange involves the exchange of an ion in the aqueous phase for an ion in the solid phase. The solid phase or ion exchanger is insoluble and can be of natural origin such as kaolinite and montmorillonite minerals or a synthetic material such as a polymeric resin. These exchangers have fixed charged functional groups located on their external and/or internal surface, and associated with these groups are ions of opposite charge called “counterions” (see Fig. 16-1a). These mobile counterions are associated by electrostatic attraction to each of the charged functional groups to satisfy the criterion that electroneutrality is maintained at all times within the exchange material as well as in the bulk aqueous solution. Depending on the charge of the functional group on the exchanger, the counterion can either be a cation if the functional group is negative or an anion if the functional group is positive and can exchange with another counterion in the aqueous phase.

The application of natural ion exchange materials for water treatment may have been used as far back as biblical times when Moses sweetened the waters of Mariah (Exodus 15:23–25). In approximately 320 BC, Aristotle

**Figure 16-1**

Schematic framework of functional cation exchange resin: (a) resin initially immersed in an aqueous solution containing  $B^+$  cations and  $X^-$  anions and (b) cation exchange resin in equilibrium with aqueous solution of  $B^+$  cations and  $X^-$  anions.

used 20 earthen containers containing a material with ion exchange properties to produce freshwater from seawater (Wachinski and Etzel, 1997). It was not until 1854 that the first reported systematic study of the ion exchange phenomenon was reported by Thompson and Way (Kunin and Myers, 1950). They observed ammonium ions adsorbing onto soils, releasing calcium ions in equivalent amounts, and the aluminum silicates present in the soils were responsible for the exchange. In 1876, Lemberg observed that the mineral leucite ( $K_2O \cdot Al_2O_3 \cdot 4SiO_2$ ) could be transformed into analcite ( $Na_2O \cdot Al_2O_3 \cdot 4SiO_2 \cdot 2H_2O$ ) by leaching the mineral with a solution of sodium chloride (Kunin and Myers, 1950).

In the early twentieth century, many contributions were made in the understanding of the ion exchange phenomenon in clays, peat, charred bone, soils, and other silicates. In fact, one of the first known synthetic mineral ion exchange materials was developed and composed of processed natural greensand, which is referred to as a natural zeolite material. Although these zeolite materials exhibited low capacities and poor abrasion characteristics, they were the first exchangers used in large quantities for water treatment application.

In 1935, development of sulfonated coal exchangers by Leibknecht in Germany and synthetic phenol–formaldehyde exchangers by Adams and Holmes in England led to the discovery of the first synthetic resin materials that were stable and had high anion exchange capacities (Kunin and Meyers, 1950). Unlike aluminosilicate zeolites, these materials were highly resistant to regenerant solutions of mineral acids. The discoveries of these researchers led D’Alelio to develop and patent sulfonated, crosslinked polystyrene resins in 1945 (Kunin and Meyers, 1950). The work of Leibknecht, Adams, Holmes, and D’Alelio forms the basis of modern-day synthetic organic ion exchangers. The first large domestic ion exchange facility was a softening plant (756 ML/d or 20 mgd) built by the Metropolitan Water District of Southern California (Streicher et al., 1947). The plant was first built in 1946 using silica-based synthetic media but was later converted to modern polystyrene divinyl benzene resin. It was operated until the early 1970s.

For most ion exchange applications in water treatment, synthetic organic resins are utilized because of their relatively large available exchange capacities and ease of regeneration. The schematic framework of a synthetic organic cation ion exchange resin initially immersed in an aqueous solution containing cation  $B^+$  with its coion  $X^-$  is illustrated on Fig. 16-1a. The resins are spherical beads consisting of a network of crosslinked polymers containing functional groups with fixed coions, which are negative ( $-$ ) charges located on each functional group along the polymer matrix. Associated with these fixed coions are  $A^+$  cations, which are mobile and free to move in the pores of the polymer matrix. Cation  $A^+$  is referred to as the presaturant ion.

### Synthetic Exchange Materials

### Exchange Mechanisms for Synthetic Resins

When the cation exchange resin (saturated with  $A^+$ ) is immersed in solution, there is a tendency for  $A^+$  to diffuse into the bulk solution and  $X^-$  into the resin because of the concentration differences between the solution and resin phases. If these ions carried no charge, then their concentration differences would equalize by diffusion, and equilibrium would be obtained. However, because the ions are charged and electroneutrality is maintained, initially there is a small migration of  $A^+$  into the bulk solution and  $X^-$  into the resin, causing a net positive charge in the bulk solution and a net negative charge in the ion exchanger. The first few  $A^+$  ions diffusing into the bulk solution and  $X^-$  ion diffusing into the resin establish an electric potential difference between the bulk solution and the resin phase. This potential difference, called the *Donnan potential*, causes a small shortage of anions in the bulk solution and cations within the resin phase, which acts to maintain electroneutrality. The Donnan theory was developed to explain the equilibrium behavior of ion distributions across membranes (Helfferich, 1995; Weber, 1972). Consequently, counterion  $B^+$  can diffuse into the negatively charged resin phase and replace  $A^+$  stoichiometrically while  $X^-$  anions are repelled back into the positively charged bulk solution due to this Donnan exclusion potential. As shown on Fig. 16-1b, equilibrium is established eventually where the concentration differences of the ions are balanced by the electric field. In other words, the electrical potentials are equal in both phases because the voltage difference is balanced by the concentration difference. At equilibrium, the resin phase will still contain a higher concentration of counterions  $A^+$  and  $B^+$  than in the bulk solution, and electroneutrality will be maintained between the bulk solution and the resin phase. A similar explanation can be made for a strong-base anion exchange resin with the exception being the charges are reversed.

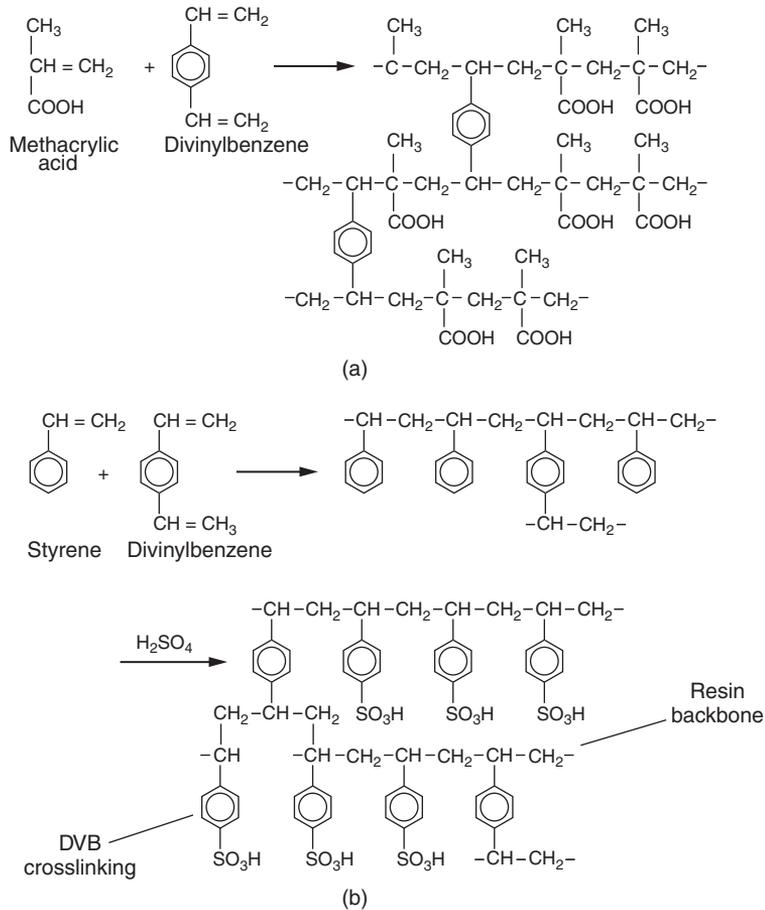

## 16-2 Synthetic Ion Exchange Media

---

Synthetic ion exchange resins are almost always used in water treatment practices. Synthetic polymeric resins are very durable and their properties can be modified to selectively remove both anions and cations. The resins can be regenerated using various salt or acid solutions depending upon the particular application. A discussion of the structure, manufacturing process, and various types of synthetic resins is presented below.

### Resin Structure

Ion exchange polymeric resin is composed of a three-dimensional, crosslinked polymer matrix that contains covalently bonded functional groups with fixed ionic charges. Vinyl polymers (typically, polystyrene and polyacrylic) are used for the resin matrix backbone. Divinylbenzene (DVB) is used to crosslink the polymer backbone. The overall steps involved in making both polyacrylic and polystyrene cation exchange resins are displayed on Fig. 16-2.

**Figure 16-2**

Major steps involved in synthesis of cation ion exchange resin by polymerization of (a) methacrylic acid with divinylbenzene crosslinking and (b) styrene with divinylbenzene crosslinking followed by sulfonation. (Adapted from Weber, 1972)

An important distinction for resins, with respect to their polymeric backbone, is whether the resin is a microreticular (gel) or macroreticular resin, which depends upon the degree of crosslinking within the resin's polymer backbone. Gel-type resins have about 4 to 10 percent DVB crosslinking with a typical value of 8 percent. The pore structure of a gel-type resin is determined by the distances between the polymer chains and crosslinking member that vary with (1) the exchanging ions, (2) ionic strength, (3) temperature, (4) the number of fixed ionic charges, and (5) the degree of crosslinking. Gel-type resins are translucent with high water content and can exhibit a significant amount of swelling or shrinking depending on the presaturant ion. Because gel-type resins lose their pore structure upon drying, they have very low Brunauer–Emmett–Teller (BET) nitrogen surface areas (see Chap. 15 for discussion of BET surface area), typically less than 2 m<sup>2</sup>/g. The ion exchange rate is very fast for a gel-type resin due to its rather open matrix (Kunin, 1979; Rohm and Haas, 1975).

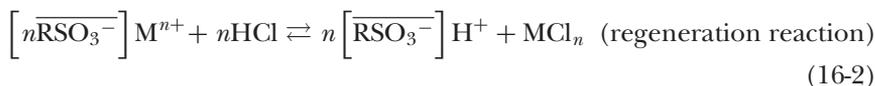

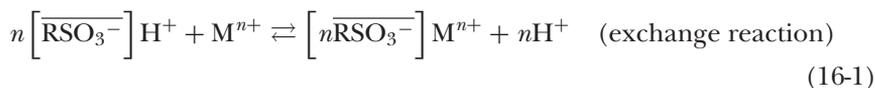

Macroreticular resins have approximately 20 to 25 percent DVB crosslinking and are opaque. Macroreticular resins are made up of microspheres linked together to form a resin bead (Kunin, 1979; Rohm and Haas, 1975). Macroreticular resins retain their structural integrity when dried, and as a result, they have BET surface areas of about 7 to 600 m<sup>2</sup>/g and particle porosities of 20 to 60 percent. In addition, macroreticular resins do not swell or shrink significantly due to ion exchange reactions.

### Classification of Resins by Functional Groups

Based on the functional groups bonded to the resin backbone, the four general types of exchange resins are (1) strong-acid cation (SAC), (2) weak-acid cation (WAC), (3) strong-base anion (SBA), and (4) weak-base anion (WBA). The distinctions are based on the p*K*<sub>a</sub> values of the functional groups as summarized in Table 16-1. These resin types are discussed in more detail in the following sections.

#### STRONG-ACID EXCHANGERS

In SAC exchange resins, a charged sulfonate group typically acts as the exchange site. The term “strong” in SAC has nothing to do with the physical strength of the resin but is derived from Arrhenius theory of electrolyte strength in which the functional group on the resin is dissociated completely in its ionic form at any pH. In other words, the resin’s low p*K*<sub>a</sub> (<0) implies SAC exchangers will readily give up a proton over a wide pH range (1 to 14). The general exchange and regeneration reactions for the hydrogen form can be written as

In Eq. 16-1, the overbar refers to the immobile resin phase, H<sup>+</sup> is the pre-saturant ion associated with the resin before exchange, M<sup>n+</sup> is the counterion in solution being exchanged out of solution, and *n* is the charge on the counterion in solution. For the reaction shown in Eq. 16-1, based on the p*K*<sub>a</sub> of SAC resins and the large hydrated radius of hydrogen, SAC resins have little affinity for hydrogen ion and will readily exchange it for another cation. Because the hydrated radius of the H<sup>+</sup> ion in a SAC exchanger is much larger than other cations, the resin will typically shrink upon exchange (≈7 percent for a gel-type resin, 3 to 5 percent for macroreticular type resin). The sodium form of a SAC will also behave in a similar manner, although the shrinkage will be less than observed for the hydrogen form. Equation 16-2 represents the regeneration expression for a strong-acid cation exchange resin using HCl as the regenerant solution.

**Table 16-1**  
 Characteristics of ion exchange resins used in water treatment processes

Resin Type	Acronym	Fundamental Reaction <sup>a</sup>	Regenerant Ions (X)	pK	Exchange Capacity, meq/mL	Constituents Removed
Strong-acid cation	SAC	$n [\text{RSO}_3^-]\text{X}^+ + \text{M}^{n+} \rightleftharpoons [n\text{RSO}_3^-]\text{M}^{n+} + n\text{X}^+$	H <sup>+</sup> or Na <sup>+</sup>	<0	1.7–2.1	H <sup>+</sup> form: any cation; Na <sup>+</sup> form: divalent cations
Weak-acid cation	WAC	$n [\text{RCOO}^-]\text{X}^+ + \text{M}^{n+} \rightleftharpoons [n\text{RCOO}^-]\text{M}^{n+} + n\text{X}^+$	H <sup>+</sup>	4–5	4–4.5	Divalent cations first, then monovalent cations until alkalinity is consumed
Strong-base anion (type 1)	SBA-1 <sup>b</sup>	$n [\text{R}(\text{CH}_2)_3 \text{N}^+\text{X}^- + \text{A}^{n-} \rightleftharpoons [n\text{R}(\text{CH}_2)_3 \text{N}^+\text{A}^{n-} + n\text{X}^-$	OH <sup>-</sup> or Cl <sup>-</sup>	>13	1–1.4	OH <sup>-</sup> form: any anion; Cl <sup>-</sup> form: sulfate, nitrate, perchlorate, etc.
Strong-base anion (type 2)	SBA-2 <sup>c</sup>	$n [\text{R}(\text{CH}_2)_2(\text{CH}_2\text{CH}_2\text{OH})\text{N}^+\text{X}^- + \text{A}^{n-} \rightleftharpoons [n\text{R}(\text{CH}_2)_2(\text{CH}_2\text{CH}_2\text{OH})\text{N}^+\text{A}^{n-} + n\text{X}^-$	OH <sup>-</sup> or Cl <sup>-</sup>	>13	2–2.5	OH <sup>-</sup> form: any anion; Cl <sup>-</sup> form: sulfate, nitrate, perchlorate, etc.
Weak-base anion	WBA	$[\text{R}(\text{CH}_2)_2\text{N}]\text{HX} + \text{HA} \rightleftharpoons [\text{R}(\text{CH}_2)_2\text{N}]\text{HA} + \text{HX}$	OH <sup>-</sup>	5.7–7.3	2–3	Divalent anions first, then monovalent anions until strong acid is consumed

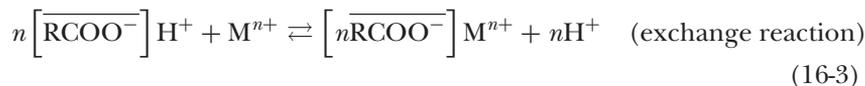

<sup>a</sup>Term within brackets represents the solid phase of the resin.

<sup>b</sup>Greater regeneration efficiency and capacity than SBA-2.

<sup>c</sup>Greater chemical stability than SBA-1.

**WEAK-ACID EXCHANGERS**

In WAC exchange resins the functional group on the resin is usually a carboxylate and the exchange reaction can be written as

Weak-acid cation resins have  $pK_a$  values in the range of 4 to 5 and thus will not readily give up a proton unless the pH is greater than 6. At a pH less than 6, WAC resins have a great affinity for hydrogen and will not exchange it for another cation; therefore, the apparent cation exchange capacity of a WAC exchanger is a function of pH. As the pH increases, the apparent capacity increases to a maximum total capacity between pH values of 10 and 11.

Weak-acid exchangers usually require alkaline species in the water to react with the more tightly bound hydrogen ions. Consider the following reaction between a weak-acid exchanger and alkalinity:

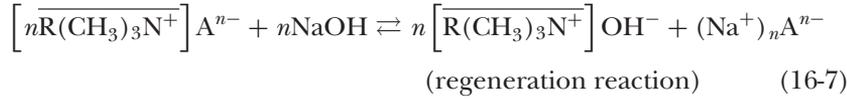

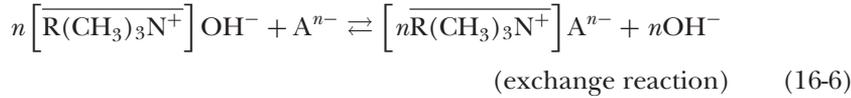

The exchange is essentially neutralization with bicarbonate alkalinity neutralizing the  $\text{H}^+$  on the resin. Weak acids will dissociate alkaline salts such as  $\text{NaHCO}_3$  but not nonalkaline salts like  $\text{NaCl}$  or  $\text{NaSO}_4$ . Because weak-acid exchangers exhibit a higher affinity for  $\text{H}^+$  than strong-acid exchangers do, they exhibit higher regeneration efficiencies. Weak-acid resins do not require as high a concentration of regenerant as required for regenerating strong-acid resins to the hydrogen form. The carboxylic functional groups will utilize up to 90 percent of the acid ( $\text{HCl}$  or  $\text{H}_2\text{SO}_4$ ) regenerant, even with low acid concentrations. By comparison, strong-acid resin regeneration requires a large excess of regenerant solution to provide the driving force for exchange to take place.

Weak-acid exchangers have been used in water treatment to remove cations in high-alkaline (e.g., high  $\text{CO}_3^{2-}$ ,  $\text{OH}^-$ , and  $\text{HCO}_3^-$  concentrations) waters with low dissolved carbon dioxide and sodium. Simultaneous softening and dealkalization can be accomplished with weak-acid exchangers. It has also been reported that sometimes WBA resins are used in conjunction with strong-acid exchangers to reduce regenerant requirements and produce treated water with the same quality as just using strong-acid exchangers alone.

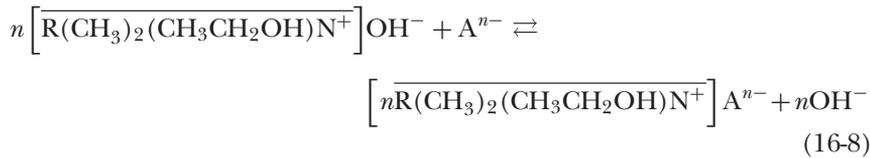

**STRONG-BASE EXCHANGERS**

Strong-base anion exchange resins typically have a quaternary amine group as the fixed positive charge. For a type 1 quaternary group, the exchange

reaction for a resin in the hydroxide form can be written as

For a type 2 quaternary group, the exchange reaction for a resin in the hydroxide form can be written as

As shown in Eqs. 16-6 and 16-8, the main difference between type 1 and type 2 resins is the ethanol group in the type 2 quaternary amine. The purpose of the ethanol group is to reduce the resin's affinity for hydroxide ions. Strong-base anion resins have  $pK_b$  values of 0 to 1, implying that they will readily give up a hydroxide ion if the pH value is less than 13. The operational pH of SBA resins ( $\text{pH} < 13$ ) makes the apparent anionic exchange capacity independent of pH. Strong-base anion exchangers in the hydroxide form will shrink upon exchange due to other anions typically having hydrated radii smaller than hydroxide. Type 1 has a slightly greater chemical stability, while type 2 has a slightly greater regeneration efficiency and capacity.

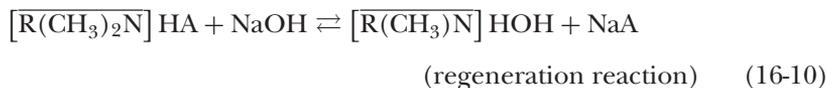

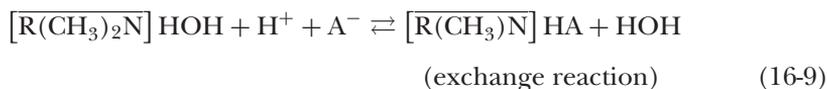

Strong-base anion resins are less stable than strong-acid resins and are characterized by the fishy odor of amines even at room temperature. Strong-base anion exchange resins will degrade to release both the tertiary amine and methanol at  $60^\circ\text{C}$  (Bolto and Pawlowski, 1987).

Strong-base exchangers traditionally have been used for many years to demineralize water. However, more recently SBA exchangers are increasingly being used to treat waters contaminated with nitrate, arsenic, and perchlorate ions and are usually operated in the chloride cycle, where the resin is regenerated with NaCl (Clifford and Weber, 1978; Clifford et al., 1987; Ghurye et al., 1999; Najm et al., 1999).

#### WEAK-BASE EXCHANGERS

In WBA exchange resins the exchange site is a tertiary amine group, which does not have a permanent fixed positive charge. Weak-base anion exchange resins are available in either chloride or freebase forms. The freebase designation indicates that the tertiary amine group is not ionized but has a water molecule (HOH) associated with it. The tertiary amine groups will adsorb ions without the exchange of an ion (Helfferich, 1995).

The exchange reaction for a WBA resin in the freebase form can be written as

The reaction in Eq. 16-9 can be viewed as the ionization of the resin by hydrogen and the consequent uptake of the anion.

Weak-base anion resin behavior can also be described as the adsorption of a weak acid with the tertiary amine group acting as a Lewis base and the release of HOH as shown:

The weak-base designation is derived from the WBA resin's  $pK_b$  values of 5.7 to 7.3. Weak-base anion resins will not readily give up hydroxide ion unless the  $p\text{OH}$  is greater than the  $pK_b$  of the resin ( $p\text{H}$  values less than 8.3 to 6.7 at 25°C). In many respects, the weak-base exchangers behave much like weak-acid exchangers. The weak-base resins remove free mineral acidity such as HCl or H<sub>2</sub>SO<sub>4</sub> but will not remove weakly ionized acids such as silicic and carbonic, which is why these resins are sometimes called "acid adsorbers."

Weak-base resins can be regenerated using NaOH, NH<sub>4</sub>OH, or Na<sub>2</sub>CO<sub>3</sub>. The regeneration efficiencies of these resins are much greater than for strong-base resins. Weak-base exchangers are used in conjunction with strong-base exchangers in demineralizing systems to reduce regenerant costs and to attract organics that might otherwise foul the strong-base resins. Where silica removal is not critical, weak-base resins may be used alone or in conjunction with an air stripper to remove CO<sub>2</sub>.

## 16-3 Properties of Ion Exchange Media

---

Two types of properties are important for ion exchange: (1) engineering properties and (2) physical properties. The engineering properties consist of the exchange capacity and selectivity of the resin. Engineers use exchange capacity and selectivity relationships to determine the performance of the resin under specific operating conditions. The physical properties consist of particle size, stability, swelling, moisture, and density of the resin. Physical properties are important in the selection of resins for specific water treatment applications. For example, the resin particle size must be large enough to minimize column pressure drop while in operation but small enough to enable fast mass transfer of the ions for exchange. The

resins must also be durable enough to undergo swelling and shrinking of the resin during regeneration and loading. All the properties described above and the forces that impact them are discussed below.

The exchange capacity and selectivity are two important engineering parameters when considering the column design and operation of the column. The exchange capacity allows the engineer to determine how much the ionic constituent can be retained by the resin for a given resin volume. The selectivity provides the engineer with information on which ionic constituents in the water are preferred by the resin.

### Engineering Properties of Resins

#### EXCHANGE CAPACITY

An important property of an ion exchange resin is the quantity of counterions that can be exchanged onto the resin. This exchange capacity can be expressed in terms of total (theoretical) capacity or effective capacity. The effective capacity is that part of the total capacity that can be utilized in a column operation, which is dependent on operating conditions such as service flow rate (SFR), regeneration level, regeneration flow rate, and water quality. Because the effective capacity is site specific, the total capacity is discussed here.

##### *Total exchange capacity*

The total capacity is dependent upon the quantity of functional groups in the copolymer bead. For SAC exchange resins, one sulfonate group, on average, can be attached to each benzene ring in the matrix. Hence, the dry-weight capacity of the resin can be determined and is usually expressed in terms of milliequivalents per gram of dry resin (meq/g). For example, if a gel-type SAC in the hydrogen form has a functional monomer with an empirical formula of  $C_8H_7 \cdot SO_3^-H$  (molecular weight 184) and 1 eq of exchangeable hydrogen ion, the theoretical capacity would be 1 eq per 184 g of dry resin or 5.4 meq/g dry resin (Harland and Prud'homme, 1992). Reported values are actually lower than the calculated values because some of the benzene rings are occupied by the DVB crosslinking and the materials are not homogeneous. Measurement of dry-weight capacities can be determined from direct titration of a known volume of resin. For sulfonated styrene-DVB resins, the reported dry-weight capacity is typically  $5.0 \pm 0.1$  meq/g (Anderson, 1979). For SBA exchange resins, more or less than one functional group can be attached to the benzene ring. Consequently, the dry-weight capacity is more variable than with strong-acid resins and can range from 2 to 5 meq/g.

##### *Expressions for exchange capacity*

In most ion exchange literature, the capacity is expressed in terms of a wet-volume capacity. The wet-volume capacity depends upon the moisture

**Table 16-2**

Properties of styrene–divinylbenzyl, gel-type strong-acid cation and strong-base anion resins

Parameter	Unit	Strong-Acid Cation Resin	Type I, Strong-Base Anion Resin
Screen size, U.S. mesh	—	16 × 50	16 × 50
Shipping weight	kg/m <sup>3</sup> (lb/ft <sup>3</sup> )	850 (53)	700 (44)
Moisture content	%	45–48	43–49
pH range	—	0–14	0–14
Maximum operating Temperature	°C	140	OH <sup>-</sup> form 60, Cl <sup>-</sup> form 100
Turbidity tolerance	NTU	5	5
Iron tolerance	mg/L as Fe	5	0.1
Chlorine tolerance	mg/L Cl <sub>2</sub>	1.0	0.1
Backwash rate	M/h (gal/min · ft <sup>2</sup> )	12–20 (5–8)	4.9–7.4 (2–3)
Backwash period	min	5–15	5–20
Expansion volume	%	50	50–75
Regenerant and concentration <sup>a</sup>	%	NaCl, 3.0–14	NaCl, 1.5–14
Regenerant dose	kg NaCl/m <sup>3</sup> resin (lb/ft <sup>3</sup> )	80–320 (5–20)	80–320 (5–20)
Regenerant rate	BV/min (gal/min ft <sup>3</sup> )	0.067 (0.5)	0.067 (0.5)
Rinse volume	BV (gal/ft <sup>3</sup> )	2–5 (15–35)	2–10 (15–75)
Exchange capacity	meq/mL as CaCO <sub>3</sub> , (kgr/ft <sup>3</sup> as CaCO <sub>3</sub> ) <sup>b</sup>	1.8–2.0 (39–41)	1–1.3 (22–28)
Operating capacity <sup>c</sup>	meq/mL as CaCO <sub>3</sub> , (kgr/ft <sup>3</sup> as CaCO <sub>3</sub> ) <sup>b</sup>	0.9–1.4 (20–30)	0.4–0.8 (12–16)
Service flow rate	BV/h (gal/min · ft <sup>3</sup> )	8–40 (1–5)	8–40 (1–5)

<sup>a</sup>Other regenerants such as H<sub>2</sub>SO<sub>4</sub>, HCl, and CaCl<sub>2</sub> can also be used for SAC resins while NaOH, KOH, and CaCl<sub>2</sub> can be used for SBA regeneration.

<sup>b</sup>Kilograins CaCO<sub>3</sub>/ft<sup>3</sup> are the units commonly reported in resin manufacturer literature. To convert kgr CaCO<sub>3</sub>/ft<sup>3</sup> to meq/mL, multiply by 0.0458.

<sup>c</sup>Operating capacity is based on Amberlite IR-120 SAC resin. Operating capacities depend on method of regeneration and amount of regenerant applied. Manufacturers should provide regeneration data in conjunction with operating capacities for their resins.

Source: Adapted from Clifford et al., (2011).

content of the resin, which is dependent upon the functional form of the resin and will vary for a given type of resin. The wet-volume capacity is commonly expressed in milliequivalents per milliliter of resin (meq/mL), although it may also be expressed in terms of kilograins as  $\text{CaCO}_3$  per cubic foot ( $\text{kgr}/\text{ft}^3$ ) of resin. There are 21.8 meq/mL in 1  $\text{kgr}/\text{ft}^3$ . As shown in Table 16-2, typical SAC exchange capacities are 1.8 to 2.0 meq/mL in the sodium form and SBA exchange capacities are 1.0 to 1.3 meq/mL in the chloride form. Weak-acid cation exchange capacities are about 4.0 meq/mL in the  $\text{H}^+$  form and WBA exchange capacities are around 1.0 to 1.8 meq/mL in the freebase form, although WAC and WBA resin capacities are variable due to their partially ionized conditions and because exchange capacity is also a function of pH.

Given two different ion forms of the same resin, the capacity on a volume basis will be different due to differences in water content. The same is true for the same resin but with different degrees of crosslinking. The volume capacity is inversely proportional to the swelling of the resin. The resin volume is determined in a column in the presence of excess water after tapping the column to settle the resin. This resin volume includes the volume of the water within the interstices between resin particles. In a backwashed and settled bed, this void volume is usually 35 to 40 percent of the total bed volume.

#### SELECTIVITY

Ion exchange resins have a certain affinity or preference for ions in aqueous solution. This affinity or preference for a given resin is called selectivity. The direction, forward or reverse, of the ion exchange reactions shown in Eqs. 16-1 to 16-11 will depend upon the resin selectivity for a particular ion system. Take, for example, the exchange reaction shown in Eq. 16-6 for an SBA. If a dilute aqueous solution containing  $\text{NO}_3^-$  and  $\text{Cl}^-$  ions are being treated with a type I SBA resin in the  $\text{OH}^-$  form, both  $\text{NO}_3^-$  and  $\text{Cl}^-$  ions will be exchanged over the presaturant ion  $\text{OH}^-$  because they are preferred by the resin. In this case the reaction proceeds in the forward direction. Type I SBA resins also have a higher selectivity for  $\text{NO}_3^-$  ions over  $\text{Cl}^-$  ions so  $\text{NO}_3^-$  will occupy more exchange sites in a dilute solution.

#### *Basis for selectivity*

Resin selectivity depends upon the physical and chemical characteristics of the exchanging ion and resins. Chemical properties of the ions that impact selectivity are the magnitude of the valence and the atomic number of the ion. The physical properties of the resins that influence selectivity include pore size distribution and the type of functional groups on the polymer chains. The following discussion provides insight into these properties.

### Example 16-1 Estimate resin requirements

A small public water system is considering removing nitrate from its water using ion exchange. The major ions contained in the well water are listed in the following table. The average daily flow rate is about 2000 m<sup>3</sup>/d. If an SBA exchange resin is used, estimate the minimum daily volume of resin that would be required assuming that nitrate is removed completely and is the only anion exchanging on the resin. Use the information provided in Table 16-2.

Cation	meq/L	Anion	meq/L
Ca <sup>2+</sup>	1.8	Cl <sup>-</sup>	3.5
Mg <sup>2+</sup>	1.0	NO <sub>3</sub> <sup>-</sup>	0.5
Na <sup>+</sup>	2.0		
Total	4.8	Total	4.8

#### Solution

1. Determine the minimum volume of resin required per day.
  - a. From Table 16-2 the typical exchange capacity for a type I SBA resin is about 1.2 meq/mL resin (1 to 1.3 meq/mL).
  - b. The required volume is

$$\left\{ \begin{array}{l} \text{Minimum} \\ \text{resin volume} \end{array} \right\} = (0.5 \text{ meq NO}_3^- \text{ N/L})(2.0 \times 10^6 \text{ L/d})$$

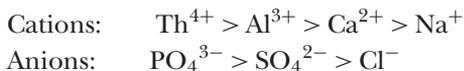

$$\text{(mL resin/1.2 meq)}$$

$$= 8.32 \times 10^5 \text{ mL/d} = 0.832 \text{ m}^3/\text{d}$$

#### Comment

This type of “back-of-the-envelope” calculation is valuable when a first estimate of the resin requirements is needed for a preliminary calculation. In most cases, the resin requirement will be higher due to the presence of other anions in the water (e.g., sulfate) that will compete with nitrate ions for exchange sites, as discussed in the section on ion exchange equilibrium.

For dilute aqueous-phase concentrations at temperatures encountered in water treatment, ion exchange resins prefer the counterion of higher valence, as shown below:

In the preference shown above, it is assumed that the spacing of the functional groups allow for the exchange of multivalent ions. Counterion preference increases with dilution of solution and is strongest with ion exchangers of high internal molality (Helfferrich, 1995). Although empirical, this rule of thumb can be explained using the Donnan potential theory. As explained earlier for a cation exchanger, when a resin comes in contact with a dilute aqueous solution, large concentration gradients exist between the ions in the aqueous phase and the resin phase. The tendency is for the aqueous cations and anions to migrate into the resin phase and cations in the resin phase to migrate into the aqueous phase. However, the initial migration of ions establishes the Donnan potential, which repels any further anions from entering the resin that would cause any significant deviation from electroneutrality.

The potential attracts aqueous-phase cations into the resin to balance the diffusion of the resin-phase cations entering the aqueous solution and approaches zero when equilibrium is established. The force exerted by the Donnan potential on an ion is proportional to the ionic charge of the ion (Helfferrich, 1995). A counterion with a higher charge is attracted more strongly and is preferred by the resin phase. The Donnan potential increases as the aqueous-phase concentration becomes more dilute and the molality of the fixed ionogenic groups on the resin increases. For large aqueous-phase ion concentrations, the exchange potentials of ions of different charge become negligible and ions of lower valence can sometimes be preferred over ions of higher valence.

There are some exceptions to the above general rule. For example, divalent  $\text{CrO}_4^{2-}$  has a lower preference than monovalent  $\text{I}^-$  and  $\text{NO}_3^-$  ions, as shown in the following series:

#### *Effect of physical properties on selectivity*

Resin selectivity can also be influenced by the degree of swelling or pressure within the resin bead. In an aqueous solution, both resin-phase ions and ions in aqueous solution have water molecules that surround them. The group of water molecules surrounding each ion is called the radius of hydration and is different for different ions. Typically, the radius of hydration becomes larger as the size of the ion decreases (see Table 16-3). When these ions diffuse in solution, the water molecules associated with them move as well. The crosslinking bonds that hold the resin matrix together oppose the osmotic forces exerted by these exchanged ions. These opposing forces cause the swelling pressure. In a dilute aqueous phase containing ion exchange resins, the ions with a smaller hydrated radius are preferred because they reduce the swelling pressure of the resin and are more tightly bound to the resin. As shown in Table 16-3 for a series of ions of equal charge, the hydrated radius is inversely proportional to the unhydrated

**Table 16-3**

Comparison of ionic, hydrated radii, molecular weight, and atomic number for a number of cations

Ion	Ionic Radii, <sup>a</sup> Å	Hydrated Radii, <sup>b</sup> Å	Molecular Weight	Atomic Number
Li <sup>+</sup>	0.60	10.0	6.941	3
Na <sup>+</sup>	0.95	7.9	22.98977	11
K <sup>+</sup>	1.33	5.3	39.0983	19
Rb <sup>+</sup>	1.48	5.09	85.4678	37
Cs <sup>+</sup>	1.69	5.05	132.9054	55
Mg <sup>2+</sup>	0.65	10.8	24.305	12
Ca <sup>2+</sup>	0.99	9.6	40.08	20
Sr <sup>2+</sup>	1.13	9.6	87.62	38
Ba <sup>2+</sup>	1.35	8.8	137.33	56

<sup>a</sup>From Mortimer (1975).

<sup>b</sup>From Kunin and Myers (1950).

ionic radius (Weber, 1972). For some alkali metals the order of preference for exchange is

For alkaline earth metals the preference for exchange is

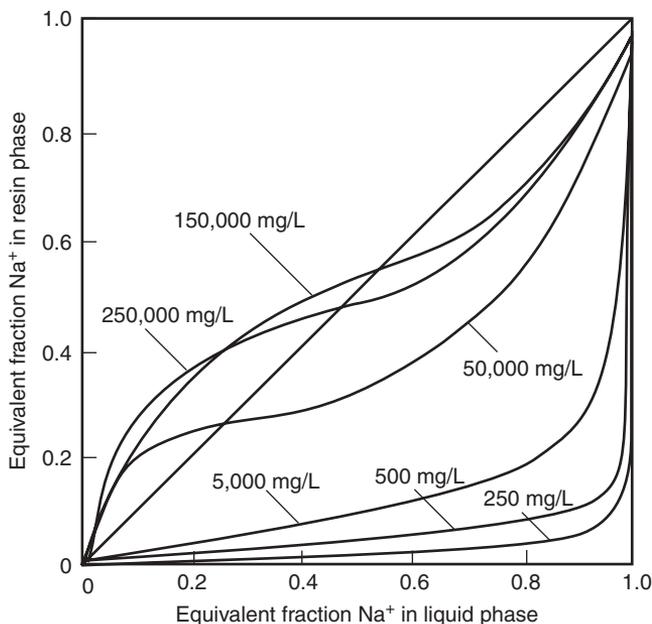

For a given series, anion exchange follows the same selectivity relationship with respect to ionic and hydrated radii as cations:

Consequently, for a given series of ions, the resin selectivity for ions increases with increasing atomic number, increasing ionic radius, and decreasing hydrated radius.

With the exception of specialty resins, WAC resins with carboxylic functional groups behave similar in preference to SAC resins with the exception that hydrogen is the most preferred ion. In a similar manner, the preference of anions for WBA resins is the same as for SBA resins with the exception that the hydroxide ion is the most preferred ion.

The above general rules for order of selectivity apply to ions in waters that have total dissolved solids (TDS) values less than approximately 1000 mg/L. The preference for divalent ions over monovalent ions diminishes as the ionic strength of a solution increases. For example, consider a sulfonic cation exchange resin operating on the sodium cycle. In dilute concentrations, calcium ion is much preferred over sodium; hence calcium will replace sodium on the resin structure. However, at high salt concentrations ( $\approx 100,000$  mg/L TDS), the preference reverses and this enhances

**Figure 16-3**  
The Na<sup>+</sup>–Ca<sup>2+</sup> equilibria for sulfonic acid cation exchange resin. (Courtesy of Rohm and Haas.)

regeneration efficiency. Equilibrium isotherms for Na<sup>+</sup>–Ca<sup>2+</sup> exchange are shown on Fig. 16-3. As the TDS concentration increases, a higher concentration of sodium can be found in the resin phase. This is because as the salt concentration increases, the sodium concentration increases, and the activity coefficient for calcium decreases such that sodium is preferred over calcium.

Another important factor to consider in determining selectivity is the size of organic ions or inorganic complexes. A resin will exclude some of these ions by screening or sieving. Resins that exhibit this phenomenon are called molecular sieves. Ions too large to penetrate the resin matrix can be specifically excluded by proper selection of the resin properties. Increasing the crosslinking in the resin will produce a greater screening effect.

Most synthetic ion exchange resin materials have physical properties that make them ideal for water treatment applications such as softening, demineralization, and removal of potentially toxic ionic contaminants. For example, polystyrene and polyacrylic resins are highly stable, are very durable, and retain their predictable capacities over many years of operation. In fact, some of these resins have been in use for over 15 years. Physical properties such as mechanical, chemical, and thermal stability, water content or swelling potential, total and apparent capacities, ion exchange equilibrium, and kinetics are influenced by the resin polymeric structure.

### Physical Properties of Resins

**SWELLING, MOISTURE CONTENT, AND DENSITY**

When resins exchange ions, the volume of the resin beads can change to reflect the differing magnitude of resin-counterion interactions, degree of resin crosslinking, and hydration. The swelling, moisture content, and density for several SAC, WAC, SBA, and WBA resins are summarized in Table 16-4. For all the resin types, the percentage of swelling decreases as the degree of crosslinking increases. Swelling of a resin due to exchange of ions can be reversible or irreversible. Reversible swelling is when the resin beads undergo a reversible volume change between one ionic form and another. The internal osmotic pressure of the resin bead increases when the resin swells and decreases when the beads shrink. Over time, the osmotic pressure swings can cause the beads to fracture, which is more likely to occur on macroporous resins than on gels. Swelling should be considered in the design of the ion exchange columns.

**Table 16-4**

Physical properties of several ion exchange resins

Resin	Bulk Wet Density, kg/m <sup>3</sup>	Moisture Content Drained, % by Weight	Swelling Due to Exchange, %
SAC resins—sulfonated polystyrene			
2% crosslinked	720	72–82	12–15
5–6% crosslinked	769–849	58–65	5–10
12% crosslinked	753–929	37–49	4–9
Sulfonated phenolic	640–961	44–68	7
WAC resins—acrylic or methacrylic			
Weakly crosslinked	800	51–75	60–90
Medium crosslinked	721–800	46–62	10–90
Macroporous	688–800	56	5–10
SBA resins—polystyrene matrix, trimethyl benzyl ammonium			
2% crosslinked	705	70–78	20
4% crosslinked	673	60	14
8% crosslinked	720	34–56	15–20
WBA resins			
Aminopolystyrene	640–720	25–45	5–30
Aminated acrylic polymers	240–304	1–5	3
Epoxy-polyamine	689	50–62	6–25

Source: Adapted from Perry and Chilton (1973).

Irreversible swelling is observed with acrylic SBA resins where during the first few regeneration cycles the resins can irreversibly swell 7 to 10 percent over and above the reversible volume changes (Harland, 1994).

Because the water content of a resin can vary, the resin densities of different forms of the resin can also vary. The density will depend upon the quantity of water and the ionic form of the resin. The specific gravity of wet SAC resins will vary from 1.10 to 1.35, while the wet specific gravity of SBA resins vary from 1.05 to 1.15. The bulk or shipping weight of most wet strong-acid and strong-base resins vary from 675 to 900 kg/m<sup>3</sup> (42 to 56 lb/ft<sup>3</sup>). Several physical properties of both strong-acid and strong-base resins are shown in Table 16-2.

#### PARTICLE SIZE

Ion exchange resin beads are spherical in shape and are commercially available in particle diameter sizes of 0.04 to 1.0 mm. In the United States, the particle sizes are listed according to standard screen sizes, or “mesh” values. A comparison of metric mesh sizes is given in Table 16-5. The most common size ranges used in large-scale applications are 16 to 50 and 50 to 100 mesh size.

Manufacturers usually provide three parameters related to particle size: (1) particle size range, (2) effective size (ES), and (3) uniformity coefficient (UC). The size range provides the minimum and maximum particle sizes for a given manufactured lot of resin beads. The ES is the mesh size in millimeters that passes 10 percent of a sieved sample,  $d_{10}$ . The UC is defined as the ratio of the  $d_{60}$  to the  $d_{10}$  resin sizes. For ion exchange resins UC values are usually in the range of 1.4 to 1.6; however, it is possible to obtain resins with smaller UCs required by kinetic or hydraulic restrictions. The ES and UC of resins can be obtained from the resin manufacturer.

Particle size has two major influences on ion exchange applications. First, the rate of ion exchange decreases with increasing particle size. An increase in resin particle size for the same mass of resin will decrease the film diffusion rate and increase the intraparticle diffusion path length. Second, the head loss through the bed increases with decreasing particle

**Table 16-5**  
Particle size in U.S. mesh and millimeters

U.S. Standard Screen Size	Particle Diameter, mm	Geometric Mean Size, mm
16–20	1.2–0.85	1.01 <sup>a</sup>
20–50	0.85–0.30	0.50
50–100	0.30–0.15	0.21
100–200	0.15–0.08	0.11
200–400	0.08–0.04	0.056

<sup>a</sup>Calculated as  $\sqrt{0.85 \times 1.2} = 1.01$  mm.

size, subjecting the beads to situations that could cause breakage. In many ion exchange applications, the design is based on hydraulic requirements of the resin beads and the vessel rather than on ion exchange kinetics.

#### **STABILITY**

The stability of an ion exchange resin can be an important process design consideration under certain physical, chemical, and/or radioactive conditions. Chemical reactions between the resin matrix and dissolved constituents in water, physical impairment of resin performance due to fouling by organic and inorganic constituents, and some process operating conditions can significantly affect the resin performance and cost. Consequently, it is important to understand these interactions and take steps in the design stages to identify and prevent conditions that would negatively alter the resin's performance and the possible release of material from the resin to the finished water.

#### *Effect of physical factors*

As stated above, the stability of the resin may be impacted by either chemical or physical means. Physical stresses such as excessive swelling and shrinking, mechanical compression due to large hydraulic pressure drops across the resin bed, and abrasion due to excessive backwashing can significantly reduce the structural integrity of the resin bead and thereby shorten the resin operating life. With respect to swelling and shrinking, the acrylic resin is particularly durable due to its more elastic properties compared to the more rigid polystyrene matrix. However, in column operations with high operating pressures, the elasticity of acrylic resins can cause the beads to compress and result in inadequate liquid distribution and reduced flow.

#### *Effect of chemical factors*

Strong-acid cation exchange resins, especially the sulfonated polystyrene-DVB type, can be susceptible to oxidation. For example, oxidation can occur from free-chlorine attack of the DVB crosslinking, causing increased moisture retention of the resin, weakening the resin structurally, leading to compression of the beads, and affecting the service cycle. In addition, the resin can also lose capacity and must eventually be replaced. If an oxidant in the process water is unavoidable, it may be beneficial to use a resin with higher DVB crosslinking. Strong-acid cations with higher crosslinking (10 to 15 percent) will last longer than a typical SAC with 8 percent crosslinking. Chloride-regenerated SBA (type II) resins used to treat groundwater have lasted for more than 8 years and have still maintained over 90 percent of their capacity. Strong-base anions resins are also susceptible to releasing amines, which can lead to the formation of *N*-nitrosodimethylamine (NDMA), which can be a health concern (Kimoto et al., 1979; Najm and Trussell, 2001).

Precipitates such as calcium sulfate and ferric hydroxide can foul SACs. If the resin contains a large quantity of exchanged calcium and is regenerated with sulfuric acid, calcium sulfate precipitate will form inside the resin particles and reduce its capacity. In addition, excessive quantities of iron and manganese, if oxidized, can form precipitates and foul the resin. Weak-acid cation exchange resins can be fouled by calcium sulfate, but are not as susceptible to oxidation as SACs.

#### *Effect of fouling*

Two major types of fouling can occur with SBA resins, silica fouling and organic fouling. When used in the hydroxide form in a demineralization process, silicic acid is concentrated at the exchange front within the bed. Silicic acid will polymerize into an inorganic solid that will not behave as an exchangeable anion. The silica can accumulate in the SBA resin until silica-free water cannot be produced.

Natural organic matter composed of humic and fulvic acids is negatively charged and can irreversibly exchange/adsorb onto SBA resins. Consequently, it usually requires large volumes of regenerant and rinses to bring the fouled resin back to its original capacity.

Weak-base resins are also subject to oxidation and fouling, depending on the type of resin. Special care should be taken with these resins prior to their use to ensure their stability will not be adversely affected. Manufacturers will normally provide a user guide to proper selection and use of these types of resins to prevent degradation.

## 16-4 Ion Exchange Equilibrium

---

As shown in Eqs. 16-1 through 16-11, the general equilibrium expressions for ion exchange are most often reversible. The reversibility implies that equilibrium is independent of the direction from which the equilibrium state is approached. Based on the previous discussion of selectivity (i.e., the inherent preference of a resin for one ion over another), the ratios of concentrations of various ions in solution will be different from the concentration ratios in the resin phase at equilibrium. In this section, methods for calculating ion exchange performance based on equilibrium expressions is presented for single (or binary) and multiple ions present in water.

Two methods have been used to develop ion exchange equilibrium expressions. One method treats ion exchange as a chemical reaction and applies the laws of mass action to obtain an equilibrium description. In the second method, the same equilibrium description can also be developed using the principles of Donnan exclusion theory. As mentioned above, the Donnan theory is used to describe the behavior of ions based on the unequal distribution of ions across a membrane when an electrolyte solution on one

side of the membrane contains ionic species that cannot diffuse through the membrane. The Donnan theory provides a more rigorous thermodynamic basis for ion exchange equilibrium description, which the mass action laws do not include. A more rigorous thermodynamic approach may be found in Helfferich (1995). Because both methods result in the same equilibrium expression, the equilibrium description based on the mass action laws will be used to develop an expression for the apparent equilibrium constant.

### Ion Exchange Selectivity

If it is assumed that ion exchange is a simple stoichiometric reaction, then the mass action laws can be applied to obtain an equilibrium expression. For simplification, a generalized form of the stoichiometric reaction for Eqs. 16-1 through 16-10 can be written as

where  $\overline{\text{R}^\pm}$  is the ionic group attached to an ion exchange resin, A and B are exchanging ions, and  $n$  is the valence of the exchanging ion. In water treatment, ion exchange applications most often involve dilute ionic solutions where the ions behave independently of one another and are treated as ideal solutions (i.e., activity coefficients are assumed to be unity). In the resin phase, the ion concentrations can be much larger (5 to 6 M, 10 percent DVB SAC; Weber, 1972) and the activity is not unity and will be a function of ionic strength. With respect to Eq. 16-12, all binary exchange reactions can be expressed as

$$K_A^B = \frac{[\text{A}^\pm]^n \left\{ \overline{\text{R}^\pm} \text{B}^{n\pm} \right\}}{\left\{ \overline{\text{R}^\pm} \text{A}^\pm \right\}^n [\text{B}^{n\pm}]} \quad (16-13)$$

where

$K_A^B$  = selectivity coefficient or apparent equilibrium constant for A exchanging with ion B onto resin

$[\text{A}^\pm]$  = aqueous-phase concentration of presaturant ion, mol/L

$[\text{B}^{n\pm}]$  = aqueous-phase concentration of counterion, mol/L

$\left\{ \overline{\text{R}^\pm} \text{A}^\pm \right\}, \left\{ \overline{\text{R}^\pm} \text{B}^{n\pm} \right\}$  = activities of resin-phase presaturant ion and counterion, respectively

Because concentrations are measured more easily than activities, the resin phase can be expressed in terms of concentrations, and Eq. 16-12 can be written in general terms as

$$K_j^i = \frac{C_j^n q_i}{q_j^n C_i} \quad (16-14)$$

where  $C_j$  = aqueous-phase concentration of presaturant ion, mol/L  
 $q_i$  = resin-phase concentration of counterion, mol/L  
 $q_j$  = resin-phase concentration of presaturant ion, mol/L  
 $C_i$  = aqueous-phase concentration of counterion, mol/L

Ion exchange resin manufacturers provide equilibrium data as selectivity coefficients. The selectivity coefficient can depend on the valence, the type of resin and its saturation, and the nature and concentration of the ion in the raw water.

Selectivity coefficients for SAC and SBA resins are presented in Table 16-6. For both SAC and SBA resins, the ion preference for the resin increases as the value of the selectivity coefficient increases. Generally, selectivity increases with increasing valence of both SAC and SBA resins.

### Example 16-2 Determination of selectivity expression

Write a selectivity expression for the exchange of calcium onto a SAC resin in the sodium form and for the exchange of nitrate onto an SBA resin in the chloride form.

#### Solution to Part A

1. For the exchange of calcium,  $\text{Ca}^{2+}$ , onto an SAC resin in the sodium,  $\text{Na}^+$ , form, the following stoichiometric expression can be written:

2. Using the general form of Eq. 16-14, the following selectivity expression can be written:

$$K_{\text{Na}^+}^{\text{Ca}^{2+}} = \frac{q_{\text{Ca}^{2+}} C_{\text{Na}^+}^2}{C_{\text{Ca}^{2+}} q_{\text{Na}^+}^2}$$

#### Solution to Part B

1. For the exchange of nitrate,  $\text{NO}_3^-$ , onto an SBA resin in the chloride,  $\text{Cl}^-$ , form, the following stoichiometric expression can be written:

2. Using the general form of Eq. 16-14, the following selectivity expression can be written:

$$K_{\text{Cl}^-}^{\text{NO}_3^-} = \frac{q_{\text{NO}_3^-} C_{\text{Cl}^-}}{C_{\text{NO}_3^-} q_{\text{Cl}^-}}$$

**Table 16-6**  
Selectivity coefficients for SAC and SBA resins

Source: Adapted, in part, from Weber (1972).

Ion exchange reactions with inorganic ions have a relatively constant free-energy change; thus equilibrium constants do not vary significantly with solution conditions. However, it has been reported that the equilibrium constants for organic ions do change with resin loading (Semmens, 1975). The concept of selectivity coefficients or apparent equilibrium constants is used primarily in the theoretical treatment of ion exchange equilibrium and in qualitatively assessing the ion exchange preference. For quantitative analysis or process design evaluation, separation factors are used more commonly than selectivity coefficients.

### Separation Factors

Equilibrium can be expressed in terms of equivalent fractions instead of concentration because equivalent charges are exchanged. The binary separation factor  $\alpha_j^i$  is a measure of the preference for one ion over another during ion exchange and can be expressed as

$$\alpha_j^i = \frac{Y_i X_j}{X_i Y_j} \quad (16-15)$$

where  $X_j$  = equivalent fraction or mole fraction of presaturant ion  
in aqueous phase  
 $X_i$  = equivalent fraction or mole fraction of counterion in aqueous  
phase  
 $Y_j$  = resin-phase equivalent fraction or mole fraction  
of presaturant ion  
 $Y_i$  = resin-phase equivalent fraction or mole fraction  
of counterions

The equivalent fraction in the aqueous phase is calculated from the following:

$$X_i = \frac{C_i}{C_T} \quad X_j = \frac{C_j}{C_T} \quad (16-16)$$

where  $C_T$  = total aqueous ion concentration, eq/L  
 $C_i$  = aqueous-phase concentration of counterion, eq/L  
 $C_j$  = aqueous-phase concentration of presaturant ion, eq/L

The equivalent fraction in the resin phase is expressed as

$$Y_i = \frac{q_i}{q_T} \quad Y_j = \frac{q_j}{q_T} \quad (16-17)$$

where  $q_T$  = total exchange capacity of resin, eq/L

For process design calculations, binary separation factors are primarily used in ion exchange calculations because they are experimentally determined and account for the solution concentration and the total ion exchange capacity.

Substituting Eqs. 16-16 and 16-17 into Eq. 16-15 yields

$$\alpha_j^i = \frac{q_i C_j}{C_i q_j} \quad (16-18)$$

where  $\alpha_j^i$  = separation factor of ion  $i$  with respect to ion  $j$ , unitless  
(concentrations are in eq/L)

For the special case of monovalent ion exchange with a monovalent presaturant ion (all ions are 1 eq/mol), the separation factor is constant and equal to the selectivity coefficient. For multivalent ion ( $i$ ) exchange with a resin having a monovalent presaturant ion ( $j$ ), the separation factor and selectivity coefficient are related by the ratio of presaturant ion concentrations in the liquid and resin phases (Harland, 1994):

$$K_j^i = \alpha_j^i \left( \frac{C_j}{q_j} \right)^{|\pm Z| - 1} \quad (16-19)$$

where  $Z$  = charge on ion, unitless (concentrations are in mol/L)

As shown in Eq. 16-19, for low multivalent ion concentrations the separation factor for multivalent/monovalent exchange is inversely proportional to the equivalent aqueous-phase concentration of ion  $j$  raised to the power  $|\pm Z| - 1$ . It is common to have sodium or chloride as the presaturant ion

for cationic or anionic resins, respectively. The separation factor is inversely proportional to the aqueous-phase sodium or chloride concentration for low concentrations of exchanging multivalent ions because the amount of resin in the sodium or chloride forms will not change significantly for small cation or anion concentrations. Accordingly, ion exchange resins are very efficient for scavenging low concentrations of multivalent cations and anions.

It is important to note that the separation factor may not be a constant but rather is influenced by various factors: exchangeable ions (size and charge), properties of the resins, including particle size, degree of crosslinking, capacity, and type of functional groups occupying the exchange sites; water matrix, which includes total concentration, type, and quantity of organic compounds present in solution; reaction period; and temperature. Because separation factors can be influenced by several factors, they are usually determined by performing an equilibrium experiment called a binary isotherm. A binary isotherm involves performing a batch equilibrium experiment for a binary system. Both binary component systems and isotherms are discussed in the following sections.

### Binary Component Systems

A binary component system involves the exchange of a presaturant ion with only one other component ion present in solution. For the binary system, the total aqueous-phase equivalent concentration can be expressed as

$$C_T = C_i + C_j \quad (16-20)$$

where  $C_T$  = total aqueous ion concentration, eq/L

$C_i$  = counterion concentration, eq/L

$C_j$  = presaturant ion concentration, eq/L

Total resin-phase equivalent concentration can be expressed as

$$q_T = q_i + q_j \quad (16-21)$$

where  $q_T$  = total resin-phase ion concentration, eq/L resin

$q_i$  = counterion concentration, eq/L resin

$q_j$  = presaturant ion concentration, eq/L resin

Consequently, substitution of the expression for  $q_T$  into Eq. 16-18 yields the following expression for calculating the resin-phase concentration of the counterion of interest:

$$q_i = \frac{C_i q_T}{C_i + C_j \alpha_i^j} \quad (16-22)$$

Note that  $\alpha_i^j = 1/\alpha_j^i$  in the above expression. For a given counterion concentration, Eq. 16-22 can be used to estimate the resin-phase concentration provided the binary separation factor and the total resin capacity are known. Similarly, the following equation can be used to calculate the aqueous-phase concentration of the counterion given the total aqueous-phase

concentration, binary separation factor, and the resin-phase concentrations of the counterion and presaturant ion:

$$C_i = \frac{q_i C_T}{q_i + \alpha_j^i q_j} \quad (16-23)$$

Separation factors for commercially available SAC and SBA exchange resins are given in Table 16-7. Based on the definition of Eq. 16-15, a separation factor greater than 1 means that ion  $i$  is preferred over ion  $j$ . For example, if  $\alpha_{\text{Cl}^-}^{\text{NO}_3^-} = 2.3$ , expressed in equivalents, at equal aqueous-phase concentrations,  $\text{NO}_3^-$  is preferred over chloride by 2.3 to 1.0. The magnitude of the separation factors is different for WAC and WBA resins from those shown in Table 16-7 for SAC and SBA resins. When separation factors for a given resin are unknown, they may be determined experimentally using binary isotherms. Clifford (1999) provides a detailed experimental procedure and example for determining separation factors.

**Table 16-7**

Separation factors for several commercially available cation and anion exchange resins<sup>a</sup>

Strong-Acid Cation Resins <sup>b</sup>		Strong-base Anion Resins <sup>c</sup>	
Cation	$\alpha_{\text{Na}^+}^i$	Anion	$\alpha_{\text{Cl}^-}^i$
Ra <sup>2+</sup>	13.0	UO <sub>2</sub> (CO <sub>3</sub> ) <sub>3</sub> <sup>4-</sup>	3200
Ba <sup>2+</sup>	5.8	ClO <sub>4</sub> <sup>-d</sup>	150
Pb <sup>2+</sup>	5.0	CrO <sub>4</sub> <sup>2-</sup>	100
Sr <sup>2+</sup>	4.8	SeO <sub>4</sub> <sup>2-</sup>	17
Cu <sup>2+</sup>	2.6	SO <sub>4</sub> <sup>2-</sup>	9.1
Ca <sup>2+</sup>	1.9	HAsO <sub>4</sub> <sup>2-</sup>	4.5
Zn <sup>2+</sup>	1.8	HSO <sub>4</sub> <sup>-</sup>	4.1
Fe <sup>2+</sup>	1.7	NO <sub>3</sub> <sup>-</sup>	3.2
Mg <sup>2+</sup>	1.7	Br <sup>-</sup>	2.3
K <sup>+</sup>	1.7	SeO <sub>3</sub> <sup>2-</sup>	1.3
Mn <sup>2+</sup>	1.6	HSO <sub>3</sub> <sup>-</sup>	1.2
NH <sub>4</sub> <sup>+</sup>	1.3	NO <sub>2</sub> <sup>-</sup>	1.1
Na <sup>+</sup>	1.0	Cl <sup>-</sup>	1.0
H <sup>+</sup>	0.67	BrO <sub>3</sub> <sup>-</sup>	0.9
		HCO <sub>3</sub> <sup>-</sup>	0.27
		CH <sub>3</sub> COO <sup>-</sup>	0.14
		F <sup>-</sup>	0.07

<sup>a</sup>Values are approximate separation factors for 0.005–0.010 N solutions (TDS = 250–500 mg/L as CaCO<sub>3</sub>).

<sup>b</sup>SAC resin is polystyrene divinylbenzene matrix with sulfonate functional groups.

<sup>c</sup>SBA resin is polystyrene divinylbenzene matrix with  $-\text{N}^+(\text{CH}_3)_3$  functional groups (i.e., a type 1 resin).

<sup>d</sup>ClO<sub>4</sub><sup>-</sup>/Cl<sup>-</sup> separation factor is for polystyrene SBA resins; on polyacrylic SBA resins, the ClO<sub>4</sub><sup>-</sup>/Cl<sup>-</sup> separation factor is approximately 5.0.

Source: Adapted From Clifford et al. (2011).

### Example 16-3 Binary exchange calculation

Nitrate is to be removed from water containing high chloride concentration. The chemical composition of the water is given below. The water contains some bicarbonate and sulfate, but for this calculation it is assumed they are negligible. Using an SBA resin with a total capacity of 1.4 eq/L, estimate the maximum volume of water that can be treated per liter of resin.

Cation	meq/L	Anion	meq/L
Ca <sup>2+</sup>	0.9	Cl <sup>-</sup>	2.5
Mg <sup>2+</sup>	0.8	SO <sub>4</sub> <sup>2-</sup>	0.0
Na <sup>+</sup>	2.6	HCO <sub>3</sub> <sup>-</sup>	0.0
		NO <sub>3</sub> <sup>-</sup>	1.8
Total	4.3	Total	4.3

#### Solution

- Estimate the maximum useful capacity of nitrate on the SBA resin in the chloride form using Eq. 16-22.
  - The separation factor for nitrate over chloride can be obtained from Table 16-7:

$$\alpha_j^i = \alpha_{\text{Cl}^-}^{\text{NO}_3^-} = 3.2$$

$$\alpha_i^j = \alpha_{\text{NO}_3^-}^{\text{Cl}^-} = \frac{1}{\alpha_j^i} = \frac{1}{\alpha_{\text{Cl}^-}^{\text{NO}_3^-}} = \frac{1}{3.2} = 0.3125$$

- The maximum useful capacity of the resin for nitrate using Eq. 16-22 is

$$\begin{aligned} q_{\text{NO}_3^-} &= \frac{C_{\text{NO}_3^-} q_T}{C_{\text{NO}_3^-} + C_{\text{Cl}^-} \alpha_{\text{NO}_3^-}^{\text{Cl}^-}} \\ &= \frac{(1.8 \text{ meq NO}_3^- / \text{L H}_2\text{O})(1.4 \text{ eq/L resin})(1000 \text{ meq/eq})}{(1.8 \text{ meq NO}_3^- / \text{L H}_2\text{O}) + (2.5 \text{ meq Cl}^- / \text{L H}_2\text{O})(0.3125)} \\ &= 976 \text{ meq NO}_3^- / \text{L resin} \end{aligned}$$

- The volume of water that can be treated per volume of resin per cycle is calculated by dividing the nitrate capacity by the influent nitrate concentration:

$$V = \frac{q_{\text{NO}_3^-}}{C_{\text{NO}_3^-}} = \frac{976 \text{ meq NO}_3^- / \text{L resin}}{1.8 \text{ meq NO}_3^- / \text{L H}_2\text{O}} = 542 \text{ L H}_2\text{O} / \text{L resin}$$

**Multicomponent  
Systems**

In water treatment, the application of ion exchange involves treatment of groundwaters containing multiple cations and anions (e.g.,  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Cl}^-$ ,  $\text{HCO}_3^-$ ,  $\text{SO}_4^{2-}$ ). Some waters may also contain ions of more significant health threat, such as  $\text{Ba}^{2+}$ ,  $\text{Ra}^{2+}$ ,  $\text{Pb}^{2+}$ ,  $\text{Cu}^{2+}$ ,  $\text{NO}_3^-$ ,  $\text{HAsO}_4^-$ ,  $\text{F}^-$ , and  $\text{ClO}_4^-$ . Consequently, a multicomponent expression is needed to describe the competitive interactions between the ions for the resin site at equilibrium. In a multicomponent system, the total capacity of the resin and the total concentration of exchanging ions in solution can be expressed as

$$q_T = q_i + q_j + \cdots + q_n \quad (16-24)$$

$$C_T = C_i + C_j + \cdots + C_n \quad (16-25)$$

where  $q_T$  = total resin-phase ion concentration, eq/L resin  
 $q_i$  = resin-phase concentration of counterion  $i$ , eq/L resin  
 $q_j$  = resin-phase concentration of presaturant  $j$ , eq/L resin  
 $q_n$  = resin-phase concentration of counterion  $n$ , eq/L resin  
 $C_T$  = total aqueous-phase ion concentration, eq/L  
 $C_i$  = aqueous-phase concentration of counterion  $i$ , eq/L  
 $C_j$  = aqueous-phase concentration of presaturant  $j$ , eq/L  
 $C_n$  = aqueous-phase concentration of counterion  $n$ , eq/L

Applying Eq. 16-24 to Eq. 16-22 yields the following expression for  $q_i$  in terms of  $n$  exchanging ions:

$$q_i = \frac{q_T C_i}{\sum_{k=1}^n \alpha_i^k C_k} \quad (16-26)$$

where  $C_k$  = aqueous-phase concentration for ion  $k$  (presaturant ion when  $k = j$ ), eq/L resin  
 $\alpha_i^k$  = separation factor for counterion  $i$  with respect to ion  $k$

Note that  $\alpha_i^k$  assumes the separation factors are known with respect to the ion concentrations being sought on the resin phase for ion  $i$ . Since the separation factors are reported in terms of the presaturant ion, Eq. 16-26 would be easier to use if the separation factors were with respect to the presaturant instead of the resin phase ion. If the subscript  $j$  is set equal to  $p$  where  $p$  is equal to the presaturant ion, the following expression for the separation factor in Eq. 16-26 can be obtained:

$$\alpha_i^k = \alpha_i^p \alpha_p^k = \frac{\alpha_p^k}{\alpha_p^i} \quad (16-27)$$

Substitution of Eq. 16-27 into Eq. 16-26 yields the following expression:

$$q_i = \frac{q_T C_i}{\sum_{k=1}^N \left( \frac{\alpha_p^k}{\alpha_p^i} C_k \right)} = \frac{q_T C_i}{\alpha_p^i \sum_{k=1}^N (\alpha_p^k C_k)} = \frac{q_T \alpha_p^i C_i}{\sum_{k=1}^N (\alpha_p^k C_k)} \quad (16-28)$$

If all the liquid-phase ion concentrations and the total resin capacity are known, the resin-phase concentrations can be calculated using the separation factors referenced to the presaturant ion as reported in Table 16-7. Similarly, Eq. 16-28 can be solved for  $C_i$  in terms of  $n$  exchanging ions:

$$C_i = \frac{C_T q_i}{\alpha_p^i \sum_{k=1}^n q_k / \alpha_p^k} \quad (16-29)$$

where  $q_k$  = resin-phase concentration of ion  $k$  (presaturant ion when  $k = j$ ), eq/L resin  
 $\alpha_k^i$  = separation factor for ion  $i$  with respect to ion  $k$   
 $\alpha_p^k$  = separation factor for ion  $k$  with respect to presaturant ion  $p$

### Example 16-4 Multicomponent equilibrium calculation

Consider the removal of nitrate from well water using an SBA exchange resin in the chloride form. The major ions contained in the well water are given below. Assuming nitrate is removed completely from solution, calculate the maximum volume of water that can be treated per liter of resin assuming equilibrium conditions. Assume total resin capacity of the SBA is 1.4 eq/L.

Cation	meq/L	Anion	meq/L
Ca <sup>2+</sup>	0.9	Cl <sup>-</sup>	1.0
Mg <sup>2+</sup>	0.8	SO <sub>4</sub> <sup>2-</sup>	1.5
Na <sup>+</sup>	2.6	NO <sub>3</sub> <sup>-</sup>	1.8
Total	4.3	Total	4.3

#### Solution

- Applying Eq. 16-28 with the use of the separation factors provided in Table 16-7, the summation term in the denominator can be calculated.

$$\sum_{k=1}^N (\alpha_p^k C_k) = (1.0) (1 \text{ meq/L}) + (9.1) (1.5 \text{ meq/L}) \\ + (3.2) (1.8 \text{ meq/L}) = 20.41 \text{ meq/L}$$

- Calculate  $q_i$  for each ion.

$$q_{\text{Cl}} = \frac{(1.4 \text{ eq/L}) (1.0) (1 \text{ meq/L})}{20.41 \text{ meq/L}} = 0.069 \text{ eq/L}$$

$$q_{\text{SO}_4^{2-}} = \frac{(1.4 \text{ eq/L}) (9.1) (1.5 \text{ meq/L})}{20.41 \text{ meq/L}} = 0.936 \text{ eq/L}$$

$$q_{\text{NO}_3^-} = \frac{(1.4 \text{ eq/L}) (3.2) (1.8 \text{ meq/L})}{20.41 \text{ meq/L}} = 0.395 \text{ eq/L}$$

Check :  $0.069 + 0.936 + 0.395 = 1.4 \text{ eq/L}$  total capacity.

Note that because the sulfate concentration is more preferred over nitrate ( $9.1 \gg 3.2$ ), the equilibrium capacity of nitrate is low. In other words, nitrate will occupy only about 28 percent ( $0.395/1.4$ ) of the exchange sites on the resin.

3. Calculate the maximum quantity of water that can be treated per cycle before nitrate breakthrough occurs.

$$\text{Maximum volume treated} = \frac{(0.395 \text{ eq/L resin}) (10^3 \text{ meq/eq})}{1.8 \text{ meq/L water}} = 219 \text{ L water/L resin}$$

### Comment

When comparing the maximum bed volumes treated in Examples 16-3 and 16-4, with sulfate present, the capacity of nitrate is reduced by 60 percent. The impact of divalent anions on exchange capacity is significant. Note that this example applies to equilibrium applied in a batch reactor. In a column system, only the portion of the resin that is exhausted will be in equilibrium with the feed water. In the mass transfer zone, the resin will be in local equilibrium with the concentrations in the water in that region of the bed.

## 16-5 Ion Exchange Kinetics

The transport mechanisms for fixed-bed ion exchange processes are similar to those for fixed-bed adsorbers as discussed in Chap. 15 where the combined effects of liquid- and solid-phase transport is coupled with equilibrium thermodynamics. In the ion exchange process, these effects may include diffusion and convection coupled with the process exchange rate, electrochemical effects, and sometimes chemical reaction. Since ions diffuse at different rates, charge separation can arise inducing an electric field causing ionic migration to satisfy electroneutrality within the resin particle as discussed in Sec. 16-1. For example, as cation A diffuses into the resin particle, it is transferring charge to the resin, and this charge must be

offset by an equivalent charge by another ion (e.g., presaturant ion) or ions diffusing out of the resin particle into solution to satisfy the local electrical balance. As explained by Helfferich and Hwang (1991) if the ions diffusing out of the resin particle carried a weaker charge, a larger flux of the faster ion would result. For the charged ions, a net transfer of electric charge would result and violate the requirement of electrical neutrality. A small deviation from electrical neutrality causes an electric field that produces a force that enables all the charged ions in the electric field to move with a certain velocity (e.g., electrophoresis) called drift velocity. The direction of the drift of ions is that of diffusion of the slower ion. Consequently, drift velocity of the ion increases the flux of the slow diffusing ion and decreases the flux of the faster one, equalizing the net fluxes and so preventing any further buildup of the net charge.

For ion exchange processes, the ion flux ( $J_i$ ) contains both the diffusive and electrical flux terms as given by the Nernst–Plank (NP) equation and can be written for both the aqueous phase ( $J_{l,i}$ ) and resin phase ( $J_{s,i}$ ) as

$$J_{l,i} = -D_{l,i} \left[ \frac{\partial C_i(z, t)}{\partial r} + \frac{Z_i F C_i(z, t)}{RT} \frac{\partial \phi(z, t)}{\partial r} \right] \quad (16-30)$$

$$J_{s,i} = -D_{s,i} \left[ \frac{\partial C_{p,i}(r, z, t)}{\partial r} + \frac{Z_i F C_{p,i}(r, z, t)}{RT} \frac{\partial \phi(r, z, t)}{\partial r} \right] \quad (16-31)$$

where  $J_{l,i}$  = flux of ion  $i$  into the resin particles, eq/m<sup>2</sup> · s  
 $J_{s,i}$  = flux of ion  $i$  inside the resin particles, eq/m<sup>2</sup> · s  
 $D_{l,i}$  = aqueous-phase diffusion coefficient of ion  $i$ , m<sup>2</sup>/s  
 $D_{s,i}$  = solid- or resin-phase diffusion coefficient of ion  $i$ , m<sup>2</sup>/s  
 $C_i$  = aqueous-phase concentration of diffusing ion  $i$ , eq/L  
 $C_{p,i}$  = aqueous-phase concentration of diffusing ion  $i$  in the resin pores, eq/L  
 $\phi$  = electrical potential caused by migration of ion in solution, mV  
 $F$  = Faraday constant 96,484 C/mol  
 $R$  = universal gas constant, 0.08205 L · atm/mol · K  
 $T$  = temperature, K  
 $Z_i$  = charge of the diffusing ion, (–)  
 $r$  = dependant parameter in radial direction of the particle, m  
 $z$  = dependent parameter in axial direction of fixed bed, m  
 $t$  = dependent parameter of time of operation, d

For most ion exchange problems encountered in water treatment, the flux terms in Eqs. 16-30 and 16-31 can be simplified by assuming electroneutrality exists within aqueous film surrounding the resin phase and within the resin phase, and the flux of the nonexchanging coion across the resin–liquid

interface is negligible (Hokanson, 2004).

$$\sum C_i(z, t) = 0 \quad (\text{aqueous phase}) \quad (16-32)$$

$$\sum C_{p,i}(r, z, t) = 0 \quad (\text{resin phase}) \quad (16-33)$$

$$J_i = (\text{nonexchanging coion}) = 0 \quad (16-34)$$

Based on these assumptions the following condition of no net current flow can be derived:

$$\sum J_i = 0 \quad (\text{no net current flow}) \quad (16-35)$$

Equations 16-30 and 16-31 reduce to a form similar to Fick's law, and the flux is equal to the product of an "effective" diffusion coefficient and a concentration gradient. The effective diffusion coefficient includes electrical effects and is not constant and depends upon concentrations, diffusion coefficients, and charges of all the individual exchanging ions. Equation 16-30 and 16-31 can be rewritten in terms of an effective diffusion or mass transfer coefficient as

$$J_{l,i} = k_{f,i} [C_{b,i}(z, t) - C_{s,i}(z, t)] \quad (\text{aqueous phase}) \quad (16-36)$$

$$J_{s,i} = -\frac{D_{l,i}\varepsilon_p}{\tau_p} \frac{\partial C_{p,i}(r, z, t)}{\partial r} \quad (\text{resin phase}) \quad (16-37)$$

where  $k_{f,i}$  = film diffusion or mass transfer coefficient, m/s  
 $C_{b,i}$  = bulk aqueous-phase concentration of ion  $i$ , g/m<sup>3</sup>  
 $C_{s,i}$  = aqueous-phase concentration of ion  $i$  at the external surface of the resin particle, g/m<sup>3</sup>  
 $\varepsilon_p$  = void fraction of the resin particle, dimensionless  
 $\tau_p$  = resin particle tortuosity, dimensionless

Equations 16-36 and 16-37 are incorporated into fixed-bed and intraparticle mass balances, respectively; to provide a set of equations or model that can describe the fixed-bed ion exchange process (Hokanson, 2004; Wagner and Dranoff, 1967; Graham and Dranoff, 1972, Wildhagen et al., 1985; Haub and Foutch, 1986). The model mechanisms consist of advective transport of exchanging ions through the fixed-bed exchanger, diffusion of exchanging ions through the film surrounding the resin particles, and intraparticle diffusion of the exchanging ions within the resin particles. It is typically assumed that the rate of ion exchange on the resin is fast as compared to the mass transfer rates in the fluid and solid phases.

Most ion exchange applications in water treatment involve two rate controlling steps in-series, liquid-phase (film), and effective intraparticle mass transfer. Determination of the rate-controlling step must consider the mass flux. According to Eqs. 16-36 and 16-37, the flux terms contain the product of the mass transfer rate and the driving force for mass transfer. The slower

**Rate-Controlling  
Step in Fixed-Bed  
Ion Exchange  
Process**

flux will determine the rate-controlling step. Intuitively, one may think that since the stagnant film thickness surrounding the resin particles is small as compared to the diffusion path length (surface of the resin particle to the center of the resin particle) within the resin particle, that the intraparticle mass transfer rate controls the overall rate of mass transfer. Film transfer coefficients are typically on the order of  $10^{-5}$  to  $10^{-6}$  m/s versus intraparticle diffusion coefficients on the order of  $10^{-9}$  to  $10^{-10}$  m<sup>2</sup>/s. However, the driving force for each phase must also be considered. For Eq. 16-36 the driving force between the bulk solution and the surface of the resin particle cannot be greater than the bulk solution concentration. For Eq. 16-37, the driving force can be as high as the concentration of the fixed charges on the resin particle, which can be very large. As a result, the rate-controlling step can be difficult to determine.

As pointed out by Helfferich and Hwang (1991), liquid-phase mass transfer rate usually controls the ion exchange process when: (1) liquid-phase concentration is low, causing a small driving force in the liquid phase; (2) the resin exchange capacity is high, causing a large driving force in the resin phase; (3) the resin particle size is small, causing a small mass transfer length in the resin; (4) there is a low degree of crosslinking in the resin particle, causing an open resin matrix; and (5) the advective flow in the fixed bed is slow, causing the thickness of the stagnant film surrounding the resin particles to be large. In addition, the selectivity of the resin may also play a small role in impacting the driving force. The following expression was developed for predicting which phase would control the mass transfer rate (Helfferich, 1995):

$$\text{He} \equiv \frac{q_T D_p \delta}{C D_l r_0} \left( 5 + 2\alpha_j^i \right) \quad (16-38)$$

where He = Helfferich number, dimensionless

$\delta$  = stagnant film thickness between the bulk solution and the resin particle external surface, m

$r_0$  = resin particle radius, m

When  $\text{He} \ll 1$ , intraparticle diffusion will control the rate of mass transfer for the ion exchange process, and when  $\text{He} \gg 1$  liquid-phase diffusion will control the mass transfer rate in the ion exchange process. For He values near unity both rates will contribute in some degree to the control of the mass transfer rate.

A number of variables can influence the mass transfer rate and include particle size, flow rate, resin particle pore structure, and solution concentration. The resin particle size has a significant impact on process kinetics. As the resin particle size decreases, mass transfer rates increase in both the liquid and resin phases. The liquid-phase mass transfer rate is inversely proportional to resin particle size and as the particle size decreases the mass transfer rate increases. Similarly, the intraparticle mass transfer rate increases as the inverse of particle size raised to a higher power. There is a

trade-off between process kinetics and head loss in the bed. As the particle size decreases, the process kinetics increase, which will provide for a smaller mass transfer zone and higher capacity utilization in a given fixed bed, but at the expense of a higher head loss in the bed. The benefits of increased exchange rates with smaller resin particles must be weighed against the increased head loss within the fixed bed.

Flow rate can influence both the length of the mass transfer zone and fixed bed. If the film diffusion is controlling the rate of mass transfer, increasing the flow rate may decrease the film thickness for diffusion, decrease the length of the mass transfer zone and increase the capacity of the fixed bed. This will occur as long as the length of the mass transfer zone is shorter than the length of the fixed bed. If intraparticle diffusion is controlling the rate of mass transfer, and the flow rate is increased, the mass transfer zone will not be impacted, but the empty-bed contact time (EBCT) will be less and the bed usage rate will be lower. If the flow rate was decreased, the mass transfer zone length could increase; depending upon the magnitude of the He number, and the EBCT would increase causing the usage rate to increase as long as the mass transfer zone length is less than the bed length.

As discussed above, for gel-type resins with an open matrix (e.g., microreticular resin), film transfer is usually controlling the overall rate of mass transfer in the fixed bed. However, if the degree of resin crosslinking is high for a given resin (e.g., macroreticular resin), the resin matrix becomes very tortuous and intraparticle diffusion may control the rate of ion exchange in the fixed bed.

With respect to initial ion concentration, film diffusion is likely to be controlling for low initial concentrations. At high initial ion concentrations, intraparticle diffusion is more likely to control the rate of mass transfer. This usually occurs during regeneration when using high concentrations of regenerate solutions.

## 16-6 Ion Exchange Process Configurations

---

The ion exchange process is conducted in a fixed bed of resin with the water passing through the resin until a certain treatment objective is reached. The resin is then taken offline and regenerated, while another column is used to supply continuous treatment (if needed). A typical full-scale ion exchange plant operating in the down-flow mode is shown on Fig. 16-4.

The regeneration steps of an ion exchange resin are important to the overall efficiency of the process. There are two methods for regenerating an ion exchange resin: (1) co-current, where the regenerant is passed through the resin in the same flow direction as the solution being treated, and (2) countercurrent, where the regenerant is passed through the resin

### **Regeneration Methods**

**Figure 16-4**

Full-scale ion exchange plant operating in downward mode.

in the opposite direction as the solution being treated. Co-current and countercurrent regenerations are considered in the following discussion.

#### **CO-CURRENT OPERATION**

Co-current operation consists of the regeneration step being conducted in the same flow direction as the solution being treated. The direction of both flows is usually downward. When small concentrations of the unwanted ion(s) can be tolerated in the effluent (referred to as leakage) and the exchange in the regeneration step is favorable, co-current operation is chosen. However, in recent studies it has been found that co-current operation can reduce leakage of some unwanted ions more effectively than countercurrent systems (Clifford et al., 1987; Ghurye et al., 1999). For nitrate and arsenate ions it was found that the co-current process produced less leakage than the countercurrent process because the exchanged mass of these ions is located near the outlet of the resin bed. Consequently, flushing these ions back through the column with the countercurrent process produces more leakage. The location of these ions within the bed will depend upon the ions in the water matrix and their separation factors for a given resin. For example, for many SBA resins, sulfate has a higher affinity than either nitrate or arsenate. Consequently, the sulfate will push most of the exchanged arsenate and nitrate toward the end of the column. Upon regeneration, the preference for sulfate over chloride is reversed at high chloride concentrations and sulfate is easily removed from the resin.

**COUNTERCURRENT OPERATION**

In most cases, countercurrent operation will result in lower leakage levels and higher chemical efficiencies than co-current operation. In situations where (1) high-purity water is necessary, (2) chemical consumption must be reduced to a minimum, or (3) the least waste volume is produced, the countercurrent method of operation is used.

Countercurrent operation with the service flow operated in the upward direction will only be effective if the resin can be prevented from fluidizing. Any resin movement during the upflow cycle will destroy the ionic interface (exchange front) that ensures good exchange. A number of methods have been devised to prevent resin particle movement during upflow operation. Some of the more commonly used methods are presented in Table 16-8.

Advances in the use of fixed beds make certain processes more economical or provide better product purity. Two types of advances in fixed-bed design are the use of mixed beds of strong-acid and strong-base resins and the use of layered beds of a weakly ionized resin above a strong ionized resin, as discussed below.

**MIXED BEDS**

For the production of deionized water, a column containing intimately mixed strong-acid (in the  $H^+$  form) and strong-base resins (in the  $OH^-$  form) provides better water quality than the individual resins segregated in series. With mixed resins, the effluent from the contactor will be deionized water. The reactions from salt to base to water or from salt

**Table 16-8**

Methods for preventing particle movement during upflow operation

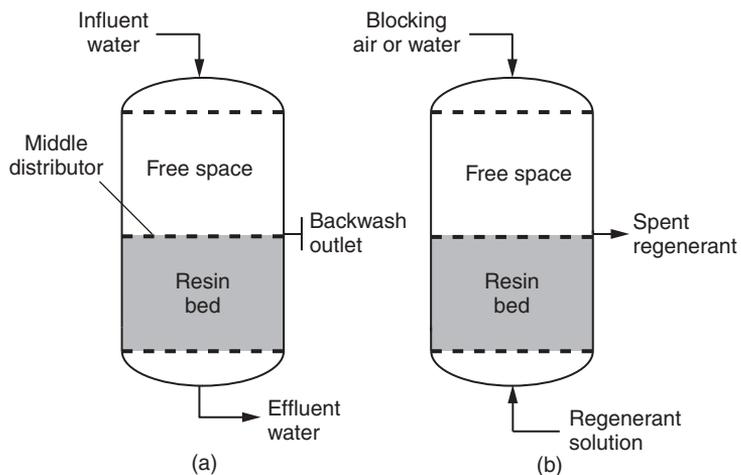

Type of Method	Description
Completely filled column	The ion exchange column is completely filled with resin and service and regeneration steps are run counterflow. A reservoir tank above the column provides space for occasional backwashing.
Use of inert granules to fill headspace	Compressible inert granules are used to fill the column's headspace during the service cycle, and they prevent the upward movement of the particles during upflow regeneration. A small reservoir is used periodically to withdraw the inert granules to backwash the resin.
Use of air or water blocking	Air or water can be introduced at the top of the column during upflow regeneration to block movement of particles. Blocking will result in increased waste volumes and has been virtually abandoned. However, only moderate air pressure is required and has been used successfully in some designs.

to acid to water will occur so rapidly that there are virtually no back reactions. Unfortunately, mixed beds cannot be regenerated in place and regeneration will require the separation of the two resin types into layers. Properly selecting the densities and particle sizes of the resins is the best method. Strong-base anion resins are normally lighter than SAC resins; hence backwashing prior to regeneration will place the SBA resin above the SAC resin. During regeneration, the regenerant solution is introduced at the top (e.g., NaOH) and bottom (e.g., HCl) of the respective beds and is simultaneously withdrawn at the interface. After regeneration, resins must be well mixed by an air-scouring operation. Probably the most important factor in achieving good product water is how well the resins are mixed, especially close to the exit of the bed.

#### FIXED-BED OPERATION

In the production of deionized water, the use of fixed beds has been the traditional approach to ion exchange. There are many important design features that must be addressed when considering ion exchange columns. Proper distribution and collection of flow is critical to good operation. For traditional downflow systems, the influent can be distributed with either a water hold-down system, where the entire vessel is kept completely filled with liquid at all times, or an air hold-down system, where the liquid level is kept several millimeters above the resin level when liquid is being introduced into the column. A water hold-down design is easier to install, operate, and control and is used most often in normal applications.

A schematic of an air or water hold-down system is provided on Fig. 16-5. In hold-down systems relatively large volumes of air or water are needed to maintain the packed resin bed in place during upflow regeneration. Although hold-down systems provide good water quality and regeneration

**Figure 16-5**  
Air and water ion exchange hold-down system: (a) loading cycle and (b) regeneration cycle.

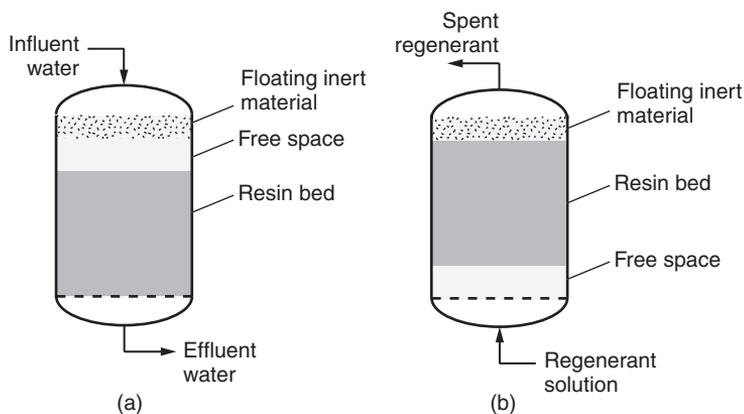

efficiency, they are equipment intensive. The issues associated with hold-down systems include the following: (1) the middle distributor can undergo mechanical damage due to resin swelling and shrinking, (2) there is high water and air consumption, (3) the regeneration process is time consuming, (4) the process is labor intensive, and (5) large vessels are required.

Recently, new design applications have made it possible to operate an ion exchange system continuously with ion removal and regeneration occurring simultaneously in different portions of a moving resin bed. Three ion exchange continuous operation systems that utilize the Dow UPCORE, the Bayer-Lewatit, and the Calgon ISEP systems discussed in this section. In addition, the MIEX process, which operates in a completely mixed reactor, was recently developed for removing dissolved organic carbon is also discussed.

### Types of Ion Exchange Processes

#### UPCORE SYSTEM

The UPCORE system, a countercurrent system in which the service flow is in the downward direction and the regeneration flow is in the upward direction, is illustrated on Fig. 16-6. If needed, the system can be converted to a co-current process. The top collector/distributor is surrounded by a small layer of floating inert material that enables the service water, spent regenerant, rinse water, and fine particles to pass while retaining the resin particles. The process is insensitive to fluctuations in service flow rates. During upflow regeneration, the resin bed is lifted in the compacted form moving up against the inert material at the top of the bed to maintain the packed state. During regeneration, fine particles (dirt, fine resin particles, etc.), which are trapped during the service cycle, are washed out with the regenerant and rinse waters. Usually such systems are used on groundwaters or similar supplies where backwashing is rarely required. To provide backwashing, a separate backwashing vessel is normally

**Figure 16-6**  
UPCORE countercurrent ion exchange systems: (a) loading cycle and (b) regeneration cycle.

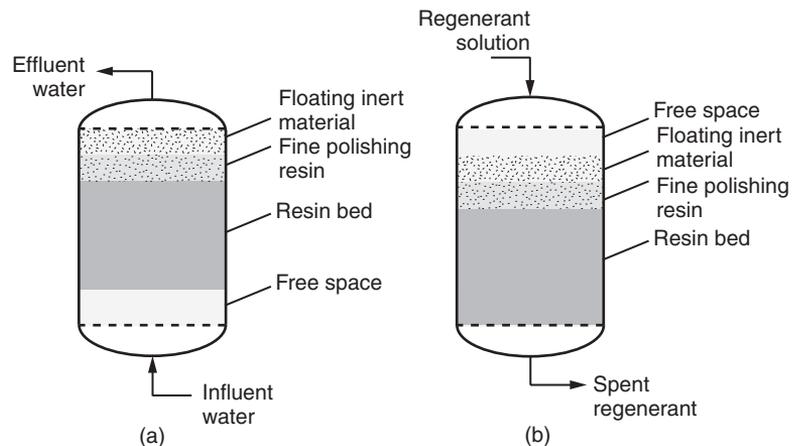

provided and the media is moved hydraulically from its normal vessel to the backwashing vessel, washed, and then moved back. Obviously, this arrangement is not attractive unless backwashing is rarely required.

#### BAYER-LEWATIT UPFLOW FLUIDIZED SYSTEM

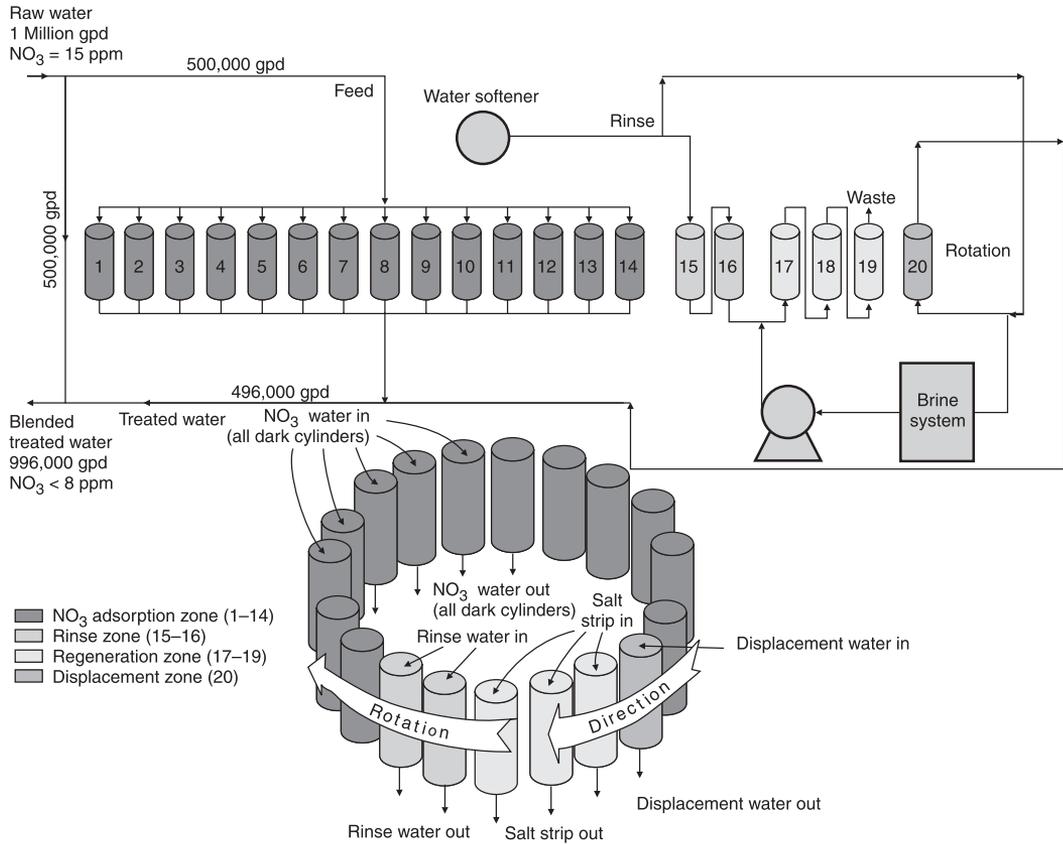

The Bayer-Lewatit upflow fluidized system, a countercurrent system in which the service flow is in the upward direction and the regeneration flow is in the downward direction, is shown on Fig. 16-7. Nozzle plate distributors are located at the top and bottom of the resin bed to ensure the resin is evenly distributed and held in place. A fine polishing resin layer is placed in the upper layer and is the first resin to be regenerated to reduce leakage. A small amount of inert floatable material is placed between the resin and the upper nozzle plate. The purpose of the floatable material is to prevent small beads or particles of resin from clogging the upper nozzle plate, and it also provides a more even flow distribution of the regenerant through the resin bed. Enough freeboard is provided to allow for expansion of the resin. The use of the upflow fluidized process is supposed to minimize the formation of clumps of resin and mechanical stress on the resins, causing swelling breakdown and attrition. The downflow rinse step minimizes the quantity of rinse water because the density of the rinse water is lower than the regenerant solution.

#### CALGON ISEP SYSTEM

The Calgon ISEP process, a countercurrent process, is illustrated schematically on Fig. 16-8 and photographically on Fig. 16-9. The process consists of about 20 to 30 small ion exchanger columns on a rotating platform. As the platform rotates at any given time, most of the columns are in the treatment mode while the others are in various phases of the regeneration cycle. The configuration provides for a flexible operation. A large valve is

**Figure 16-7**  
Bayer-Lewatit upflow fluidized ion exchange system: (a) loading cycle and (b) regeneration cycle.

**Figure 16-8**  
Schematic of Calgon ISEP ion exchange process.

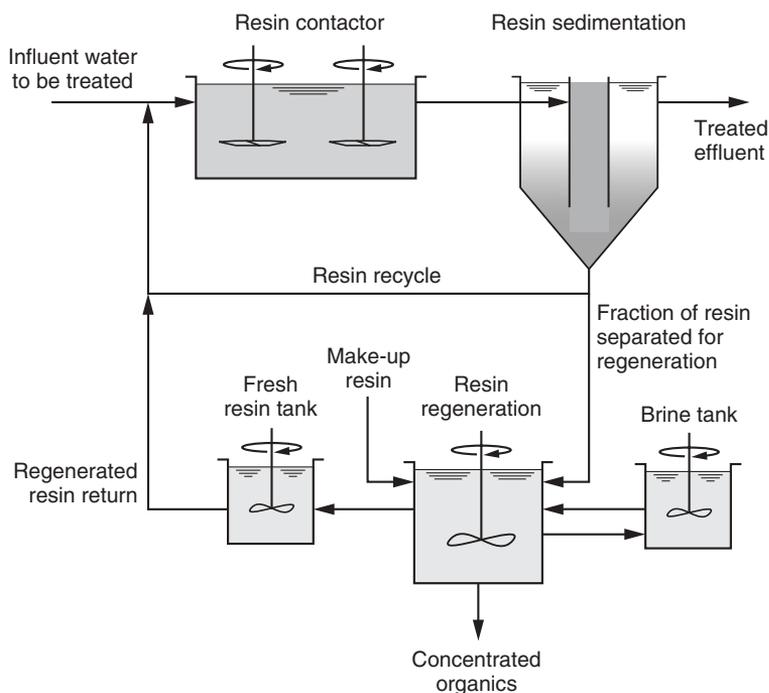

**Figure 16-9**  
Photograph of ion exchange canisters on rotating platform in Calgon ISEP ion exchange process (see Fig. 16-8).

used to control the various types of flows (service, regenerant, and rinse) to the columns. The process provides continuous treatment and is fully automated. The service cycles are short as compared to other conventional ion exchange processes, which enable ISEP to have a relatively low resin inventory. The ISEP process typically produces less brine waste as compared to a conventional system and produces low leakage by providing better control over the mass transfer zone.

#### MIEX MAGNETIC ION EXCHANGE RESIN

The Orica Limited Company of Australia developed the MIEX process for removal of dissolved organic carbon (DOC) from drinking water supplies. The process consists of a SBA exchange resin, usually in the chloride form, with a magnetic component built into it. The resin beads, which are smaller than the conventional resin beads (i.e., diameter  $\approx 180 \mu\text{m}$ ), are contacted with the water in a completely mixed reactor. A typical process flow diagram employing the MIEX resin is shown on Fig. 16-10. The negatively charged DOC molecules exchange with presaturant chloride ion on the resin and are removed from the water. The resin and water are then separated in an upflow settler as the resin beads will agglomerate due to their magnetic properties and rapidly settle out of the water. The settling rate can be as

**Figure 16-10**  
Schematic process flow diagram for use of MIEX ion exchange resin for pretreatment of surface water to reduce concentration of natural organic matter (NOM) before addition of coagulating chemical.

high as 15 m/h. The treated water goes on to further treatment. The settled resins are recovered and recycled to the front of the process. A portion of the recovered resin beads (5 to 10 percent) is removed for regeneration. The resin is regenerated with about 10 percent by weight NaCl for 30 min. The regenerated resin beads are stored and reintroduced into the process as needed. An important advantage of the MIEX DOC resin, compared to other ion exchange resins, is its apparent abrasion-resistant properties.

Because the DOC removal remains consistent in the contactor, the DOC leakage is controlled at a predetermined level. Also, because the resin has a high selectivity for DOC, the only inorganic anion that is exchanged is  $\text{SO}_4^{2-}$ .

Based on preliminary test results, it appears that the removal of DOC on the resin is a surface phenomenon. While other ion exchange resins may be suitable, the time it takes for the DOC to diffuse into the resin may limit their applicability. The performance of MIEX depends on the resin dose, the concentration and nature of the DOC, and the contact time. Reported DOC removal values have been as high as 80 percent, but site-specific testing is required. A pilot study for the City of West Palm Beach, Florida, achieved 67 percent TOC removal with MIEX, compared to 57 percent TOC removal with enhanced coagulation (MWH, 2010). Use of MIEX also reduced coagulant use and sludge production by about 80 percent compared to enhanced coagulation alone.

MIEX is a relatively new technology; as of the end of 2010, about 15 MIEX systems had been installed at treatment plants greater than 3785  $\text{m}^3/\text{d}$  (1 mgd) in North America.

## 16-7 Engineering Considerations in Ion Exchange Process Design

---

Important engineering considerations in developing an ion exchange treatment process include (1) problem definition, (2) establishment of treatment goals, (3) preliminary process analysis, (4) bench- and pilot-scale studies, and (5) development of process design criteria. These considerations are summarized in Table 16-9, discussed below briefly, and illustrated in a case study in the following section.

Initial consideration of an ion exchange process requires definition of the problem. Defining the problem will require characterization of the composition of the water to be treated (see Table 16-9). The presence of oxidants or reductants in the stream should also be evaluated. Depending upon the specific conditions, the most likely location to apply treatment should be determined so that possible design constraints such as process size, geography, and utility services (sewers, brine waste lines) can be considered in the initial phases of the design.

### **Problem Definition**

**Table 16-9**

Summary of engineering considerations for analysis of ion exchange process

Item	Key Elements/Objectives
Problem definition	<ol style="list-style-type: none"> <li>1. Characterize water to be treated, including (a) quantitative analysis of the ionic and nonionic constituents and their concentrations, (b) water temperature, (c) pH, (d) turbidity, and (d) density.</li> <li>2. Evaluate the presence of oxidants and/or reductants in the process stream.</li> <li>3. Determine the location of the treatment process that minimizes the impact of brine disposal and provides utility services (i.e., sewers, brine waste lines, roadways for salt transport).</li> </ol>
Define treatment goals/ design criteria and constraints	<ol style="list-style-type: none"> <li>1. Required purity of the water.</li> <li>2. Maximum allowable waste volume.</li> <li>3. Design constraints (availability of chemicals, space requirements, regulatory permitting, and cost considerations).</li> </ol>
Preliminary process analysis	<ol style="list-style-type: none"> <li>1. Literature survey of previous studies to determine process capabilities and limitations.</li> <li>2. Select several resins for preliminary assessment and followup bench and pilot plant studies.</li> <li>3. Using published and manufacturers' data for the resins selected, conduct equilibrium and/or mass transfer model calculations to evaluate process capabilities and limitations.</li> </ol>
Bench-scale studies	<ol style="list-style-type: none"> <li>1. Assess performance of ion exchange resin types.</li> <li>2. Develop preliminary operating parameters and characteristics. Operating parameters may include (a) saturation and elution curves to assess ion exchange performance, (b) hydraulic considerations (flow rate, head loss, backwashing rate), (c) regeneration requirements (i.e., salt requirements, backwash cycle time, rinse requirements, column requirements), and (d) scaleup requirements.</li> </ol>
Pilot plant studies	<ol style="list-style-type: none"> <li>1. Pilot-scale tests to validate bench-scale test results.</li> <li>2. Develop long-term operational information, including information on fouling.</li> </ol>
Develop design criteria for full-scale plant	<ol style="list-style-type: none"> <li>1. Based on the results of the bench-scale and pilot plant studies, develop design criteria for full-scale design, including (a) scaleup considerations; (b) column design details, including volume of resin, surface area of columns, number of columns, sidewall height, pressure drop, and inlet and outlet arrangements; (c) overall cycle time; and (d) regeneration requirements, including volume, salt quantity and concentration, rinse water, and regeneration cycle time.</li> </ol>

The next step is outlining the actual goals of the process such as required purity of the treated water and maximum waste volumes allowable (see Table 16-9). This step should include identifying possible design constraints such as the availability of chemicals, space requirements, regulatory permitting requirements and/or guidelines, and cost limitations.

### Treatment Goals and Objectives

Preliminary studies start with selection of promising ion exchange resins for bench-scale testing. Ions that can be removed by each type of ion exchange resin and the regenerant typically used for water treatment applications are summarized in Table 16-10. Preliminary calculations and a literature review combined with resin manufacturer's performance specifications can be used to assess and choose promising resins for bench-scale testing. When choosing a resin, the capacity, selectivity, and ease of regeneration need to be considered. Typical operating conditions for SBA and SAC resins in removing a number of common contaminants are summarized in Table 16-2. Ion exchange modeling software that includes column equilibrium and mass transfer models has been developed to describe the ion exchange process (Clifford and Majano, 1993; Guter, 1998; Hokanson et al., 1995; Liang et al., 1999; Snoeyink et al., 1987).

### Preliminary Process Analysis

Bench-scale studies are used to identify ion exchange resins and operating parameters that will provide the best possible performance and cost effectiveness over the design life period. For a specific application, the main criteria to be developed in a bench-scale study are length of removal run, service flow rate, regenerant dose, backwash flow rate, and regenerant concentration. Other variables such as resin stability under cyclic operation must be monitored over long periods of time and will require pilot-scale

### Bench- and Pilot-Scale Studies

**Table 16-10**

Types and characteristics of ion exchange resins

Resin Type	Functional Group	Ions Removed	Regenerant	Operating pH Range
Strong-acid cationic (SAC) resin	Sulfonate, $\text{SO}_3^-$	$\text{Ca}^{2+}$ , $\text{Mg}^{2+}$ , $\text{Ra}^{2+}$ , $\text{Ba}^{2+}$ , $\text{Pb}^{2+}$	HCl or NaCl	1–14
Weak-acid cationic (WAC) resin	Carboxylate, $\text{RCOO}^-$	$\text{Ca}^{2+}$ , $\text{Mg}^{2+}$ , $\text{Ra}^{2+}$ , $\text{Ba}^{2+}$ , $\text{Pb}^{2+}$	HCl	>7
Strong-base anionic (SBA) resin	Quaternary amine, $\text{RN}(\text{CH}_3)_3^+$	$\text{NO}_3^-$ , $\text{SO}_4^{2-}$ , $\text{ClO}_4^-$ , $\text{HAsO}_3^{2-}$ , $\text{SeO}_3^{2-}$	NaOH or NaCl	1–13
Weak-base anionic (WBA) resin	Tertiary amine, $\text{RN}(\text{CH}_3)_2\text{H}^+$	$\text{NO}_3^-$ , $\text{SO}_4^{2-}$ , $\text{ClO}_4^-$ , $\text{HAsO}_3^{2-}$ , $\text{SeO}_3^{2-}$	NaOH or $\text{Ca}(\text{OH})_2$	<6

testing. Before considering these variables, it will be useful to discuss the use of small laboratory columns.

#### USE OF SMALL-DIAMETER COLUMNS

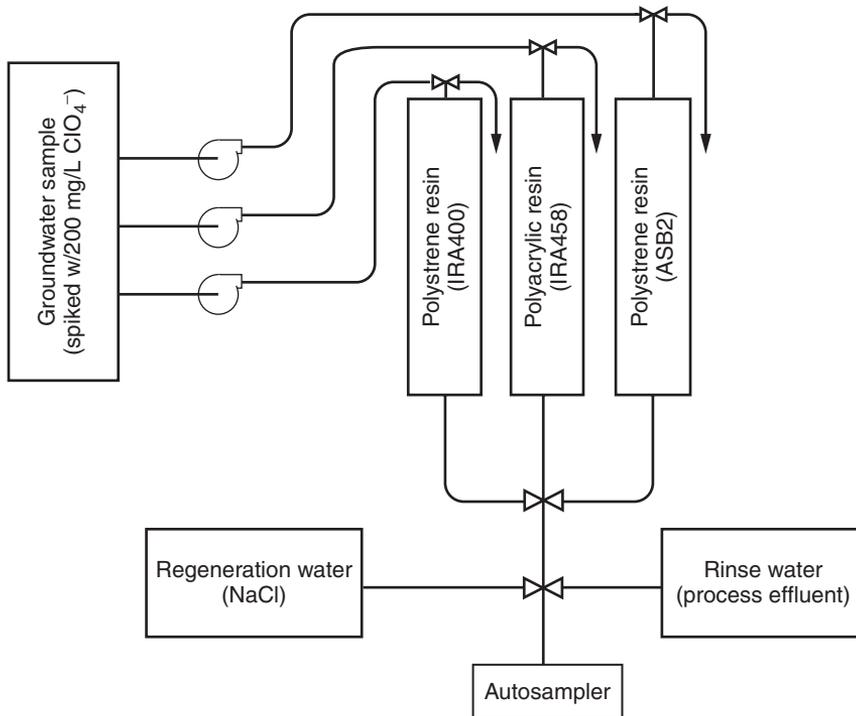

Small-diameter columns can be used to develop meaningful process data if operated properly. Column studies are used primarily to evaluate and compare resin performance in terms of capacity and ease of regeneration. For example, an automated small-column system used to perform laboratory studies for the removal of perchlorate from a groundwater is shown on Fig. 16-11 and schematically on Fig. 16-12. Operational parameters that correspond to full-scale values are summarized in Table 16-2 for SBA resins. Because the main issues of concern are mass transfer and operating exchange capacity, small (1.0- to 5.0-cm-inside-diameter) columns can be scaled directly to full-scale design if the loading rate and empty-bed contact time are the same. Because resin particles are small and the ratio of column diameter to particle diameter is large ( $>25$ ), the error due to channeling of the water down the walls of the column is minimized.

The hydraulics of full-scale operation cannot be modeled completely by small-scale columns because deviations in flow patterns can exist and should be evaluated at the pilot scale (see Fig. 16-13). However, if full-scale depth is not possible to match in the preliminary studies, a minimum packed-bed depth of 0.6 to 0.9 m (2 to 3 ft) should be adequate to properly design a

**Figure 16-12**  
Schematic of small-scale laboratory ion exchange system shown in Fig. 16-11.

**Figure 16-13**  
Pilot-scale ion exchange column used to verify bench-scale column tests and obtain data on fouling.

**Figure 16-14**

Pressure drop curves at various water temperature as function of filtration flow rate for strong-base type I acrylic anion exchange resin (A-850, Purolite).

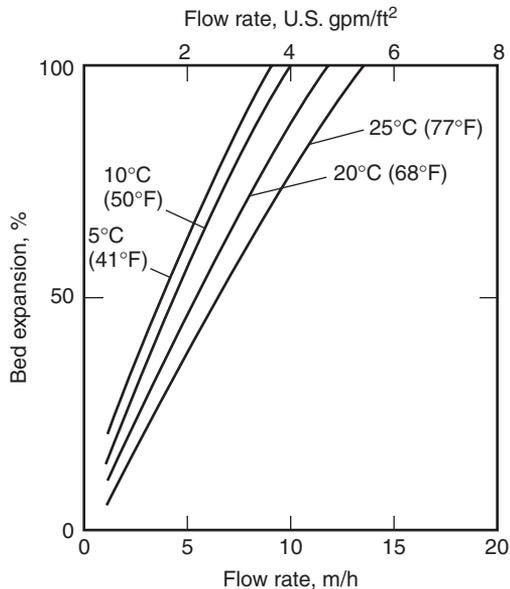

laboratory or pilot exchange column. For most commercially available resins pressure drop curves versus flow rate and temperature and bed expansion (for backwash) versus flow rate and temperature can be obtained from the manufacturer. For example, performance curves for both the pressure drop and bed expansion as a function of flow rate are given on Figs. 16-14 and 16-15, respectively. During operation, the maximum pressure drop in an ion exchange column should not exceed 172 kPa (25 psi).

#### SATURATION LOADING AND ELUTION CURVES

The two main types of data collected from small-scale column testing are saturation loading curves and elution curves. Data developed from these curves form the basis for the pilot plant studies and for the development of full-scale designs.

##### *Saturation loading curves*

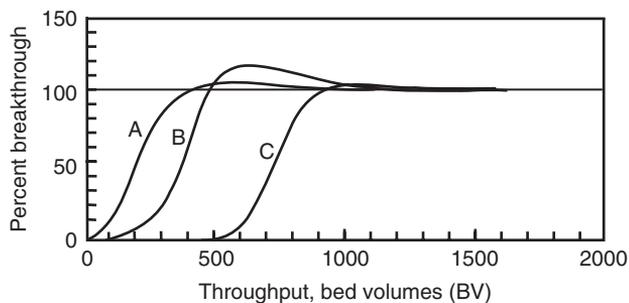

The saturation loading curve is obtained by passing the process stream or a simulated stream of the same chemical composition through a fully regenerated column of resin. A sample of the actual process stream should be fed through the column for a couple of runs. During the runs, samples of the effluent are collected and analyzed until the effluent concentration of the contaminant of interest equals the influent concentration. The effluent concentration is plotted in terms of percent breakthrough, equivalents per liter, or normality as a function of the number of bed volumes of process

**Figure 16-15**  
Filter bed expansion as function of backwash flow rate at various water temperatures for strong-base type I acrylic anion exchange resin (A-850, Purolite).

stream treated to develop a saturation loading curve. Bed volumes are defined as the average flow rate through the ion exchange column divided by the volume of the resin in the column, including the void fraction.

Generalized saturation loading curves for water containing three ions (A, B, and C) that were treated through an exchange column are presented on Fig. 16-16. As shown on Fig. 16-16, each anion has an effluent profile with the less preferred ions (i.e., A and B) appearing first in the effluent followed by the preferred anion (i.e., C). The observed chromatographic effect shown on Fig. 16-16 depends upon the equilibrium and mass transfer conditions within the column. Percentage concentrations greater than 100 are possible because of the competitive effects among the competing ions, which force previously exchanged ions off the resin. For example, the highest observed effluent concentration for ion B is about 120 percent, or

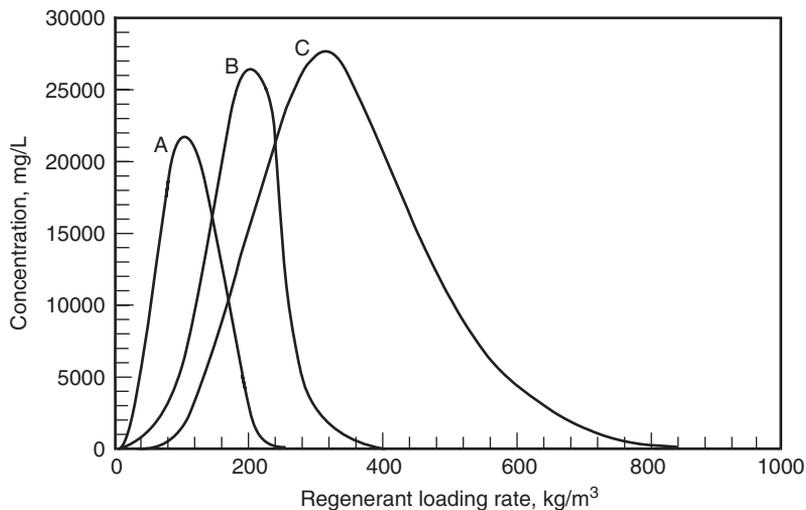

**Figure 16-16**  
Generalized saturation loading curves for compounds A, B, and C.

1.2 times its average influent concentration. In the previous sections, both binary and multicomponent equilibria were discussed and mathematical descriptions were developed. The chromatographic effect within a column can be described when these equilibrium descriptions are incorporated into mass balance expressions. Saturation loading curves similar to the ones shown on Fig. 16-16 but over several loading and regeneration cycles provide the performance data necessary for design engineers to size the columns and determine the operational aspects of the column design.

#### *Regeneration curves*

After completing each saturation loading curve, the resin must be eluted with an excess of regenerant to fully convert it back to its presaturant form. A regeneration curve is obtained, similar to a breakthrough curve, by collecting sample volumes of regenerant after it has passed through the bed and determining the concentrations of the ions of interest in each sample volume. The bed volumes of regenerant used can be converted in terms of a salt loading rate by multiplying it by the salt concentration used and dividing by the volume of the resin bed. These data can be used to choose a regeneration level that will be optimum with respect to operating capacity (resin conversion) and regenerant efficiency.

Generalized regeneration curves for ions A, B, and C for the regeneration of a resin are presented on Fig. 16-17. Notice that with a salt loading of about  $240 \text{ kg/m}^3$  all of ion A elutes rapidly and is replaced by chloride ions if the resin is an SBA form and sodium if the resin is an SAC form. Ion B requires a little longer to be removed and requires about  $350 \text{ kg/m}^3$ . Ion C requires about  $850 \text{ kg/m}^3$  to ensure that a significant fraction is removed. From equilibrium theory it is known that divalent ions (i.e., ion

**Figure 16-17**  
Generalized regeneration curves for regeneration of a resin loaded with compounds A, B, and C.

A on Fig. 16-17) will not be preferred in concentrated solutions and hence are easily replaced by sodium or chloride ions.

#### SERVICE FLOW RATE (SFR) ASSESSMENT

There are two types of flow rates of interest in ion exchange applications: (1) the volumetric flow rate and (2) the surface area loading rate. The volumetric flow rate, usually expressed in L/L · h (gpm/ft<sup>3</sup>) or bed volumes per hour (BV/h), is inversely related to the contact time between the solution and the resin and thus the kinetics of exchange. The surface area loading rate, expressed in m/h (gpm/ft<sup>2</sup>), is a measure of the superficial flow velocity through the resin bed. The superficial flow velocity must be considered in the scaleup to ensure that excessive flow rates that could damage the resin do not occur.

To determine the optimum SFR, the rate must be varied during the saturation loading tests over a range of choices to see if any noticeable maximum in breakthrough capacity is achieved at a specific flow rate. Typically, the volumetric flow rate is the criterion used because it is directly related to the film mass transfer rate. The main goal in determining the optimum SFR is to reduce the capital cost of equipment. The optimum SFR will minimize the impact of the film mass transfer resistance and consequently shorten the length of the mass transfer zone. The higher the acceptable flow rate, the smaller the contactor can be for a given treatment flow because the mass transfer zone length can be contained in a smaller column. Typical service flow rates range from 8 to 40 BV/h (1 to 5 gpm/ft<sup>3</sup>).

### Example 16-5 Calculation of BV/h

An ion exchange column has a column loading time of 56 h at a service flow of 6.0 ML/d. The column has a diameter of 3.66 m and a resin depth of 1.1 m. Calculate the service flow in BV/h.

#### Solution

1. Calculate the volume of the bed occupied by the resin:

$$BV = \text{area} \times \text{depth} = \frac{1}{4}\pi(3.66 \text{ m})^2 \times 1.1 \text{ m} = 11.67 \text{ m}^3$$

2. Calculate the service flow rate in BV/h:

$$\begin{aligned} BV/h &= Q \times (1 \text{ BV}/11.67 \text{ m}^3) \\ &= (6.0 \times 10^6 \text{ L/d})(d/24 \text{ h})(\text{m}^3/1000 \text{ L})(1 \text{ BV}/11.67 \text{ m}^3) \\ &= 21.6 \text{ BV/h} \end{aligned}$$

**REGENERATION REQUIREMENTS**

The three variables of concern during regeneration are (1) concentration of the regenerant, (2) regenerant flow rate, and (3) regenerant dosage.

*Concentration and flow rate*

A typical scheme to determine optimum conditions would be to choose a fairly slow (2 to 5 BV/h or less) rate and an excess of regenerant, then vary the concentration of regenerant and develop elution curves for each concentration. An optimum concentration would be one that elutes the resin as rapidly as possible. Next, the optimum rate can be determined by keeping the optimum concentration and excess regenerant dose constant while varying the flow rate. Normally, a slower flow rate will allow for a more complete attainment of equilibria conditions but may not be as important a factor when the separation factor favors the ion already on the resin. In many ion exchange applications the only way to fully convert a resin is to use an excess of regenerant.

*Regenerant dose*

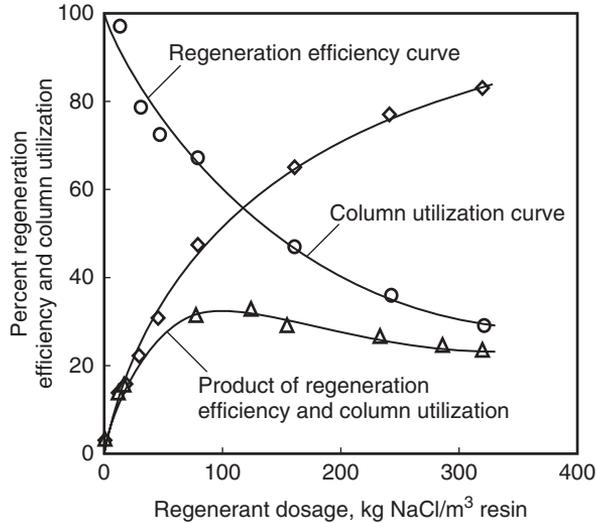

Using the experimentally determined values of concentration and flow rate, the optimum dose of regenerant can be determined. The dose is usually expressed in grams of regenerant per liter of resin (pounds of regenerant per cubic foot of resin). An elution curve should be developed for the optimum set of conditions. Using this curve, it is possible to determine regeneration efficiency and column utilization curves as a function of regenerant dosage.

During regeneration, if  $\alpha < 1$ , an excess of regenerant must be used to convert the resin to 100 percent regenerant form. Instead of converting the resin completely to this form, the amount of regenerant is chosen so that the column will be converted to a degree that will give the required quality of effluent for a reasonable run length. A plot of regeneration efficiency and column utilization versus regeneration level for a strong-acid exchanger being used for softening is given on Fig. 16-18.

Regeneration efficiency is the actual hardness (or other species of interest) removed by the given amount of salt (or other regenerant) divided by the theoretical hardness that could be removed by that amount of salt assuming 100 percent conversion. Column utilization represents the actual hardness removed by the regenerant divided by the total available exchange capacity of the resin in the column. The product of the two percentages for a given dosage is plotted on Fig. 16-18. The curve peaks roughly where the two curves intersect, and this peak usually indicates the optimum conditions.

**OPERATION TO BREAKTHROUGH**

Once the above parameters have been established, it is necessary to operate the column to an allowable breakthrough point and leakage level for

**Figure 16-18**

Efficiency and column utilization as function of regeneration level for strong-acid resin used for softening. Conditions: influent hardness, 500 mg/L as  $\text{CaCO}_3$ ; service flow rate,  $267 \text{ L/min} \cdot \text{m}^3$ ; regeneration rate,  $67 \text{ L/min} \cdot \text{m}^3$ ; 10% NaCl.

a number of cycles (3 to 5) to stabilize the system. The break point is defined as the point where the target ions first appear in the column effluent. Leakage is defined as the appearance of a low concentration of undesired influent ions in the column effluent during the initial part of the exhaustion. Leakage is caused by residual ions in the resin at the bottom of the column due to incomplete regeneration that are displaced by other ionic species coming down the column. A cycle can then be run to get a good indication of what can be expected in the full-scale column.

Once the results of the bench-scale studies are available, the findings are used to develop design criteria for the full-scale installation. Scale-up considerations, the selection of service flow rates, regeneration requirements, and inlet and outlet considerations are considered below.

### Development of Column Design Criteria

#### SCALEUP CONSIDERATIONS

Data derived from small-column experiments can be scaled up directly to any diameter column should the height of the bed remain constant. If the small-column experiments were done at a reasonable height (0.6 to 1 m), then increasing the height in a full-scale design usually will not change the shape of the breakthrough curve when plotted as concentration versus time, but will extend service time. In exchanges where the separation factor is greater than 1 for the ion to be removed, the mass transfer zone length or exchange zone will be relatively small with respect to the column height. Increasing the column depth for the same flow rate will not increase the breakthrough capacity with respect to bed volumes.

**COLUMN DESIGN DETAILS**

Maintaining the same volumetric flow rate as determined in the small-scale experiments will produce similar cycle times and effluent concentration profiles. If the height of the column is kept constant, then the superficial velocity will also remain equal. If the column is deepened and the volumetric flow rate is kept the same, the superficial velocity will be increased by the proportion that the height has increased. The increased flow should not be a problem, unless a critical range of flow velocities is reached. Typical superficial velocities are in the range of 10 to 36 m/h (4 to 15 gpm/ft<sup>2</sup>). Excessive velocities will increase the pressure drop through the column and could adversely affect the stability of the resin beads. Once the optimum service flow rate is known, the design details of the full-scale columns, including volume of resin, surface area of columns, number of columns, side wall height, and pressure drop, can be determined. For example, the amount of resin volume needed to treat a given flow of water will be

$$\text{Required resin volume, m}^3 = \frac{\text{treated-water flow rate (L/min)}}{\text{service flow rate (L/min} \cdot \text{m}^3)} = \frac{Q}{\text{SFR}} \quad (16-39)$$

Based on this volume and the desired depth of the resin, the diameter of a single column can be determined. Should the required diameter be much larger than 4 m (12 ft), two or more columns should be used. Typical bed depths used in the industry range from 0.75 to 3 m (2.5 to 10 ft). Determination of the column design details is illustrated in the following section.

One of the major reasons for poor ion exchange performance is the poor design of the feed distribution and outlet effluent collection facilities in contactors. The feed must be distributed uniformly over the resin surface and collected uniformly from the bottom of the column to prevent channeling, maldistribution of flow, and density currents. If the ion exchange columns are not properly designed, premature breakthrough and excessive leakage can result.

**REGENERATION REQUIREMENTS**

Unless the treated-water flow demand is intermittent, to prevent interruption of the service cycle for regeneration, two or more columns or a treated-water storage reservoir are required. If the exhaustion cycle is long (16 to 24 h), a reservoir can provide sufficient water during regeneration time, normally 1 to 2 h. Based on manufacturer's design data or laboratory studies, the regeneration requirements can be calculated. For most ion exchange applications, a typical regeneration cycle is as follows:

1. End of service run
2. Backwash
3. Regeneration

4. Slow displacement rinse
5. Fast rinse
6. Stand-by [optional if extra column(s) in service and the regeneration time is breakthrough volume/(number of columns -1)]
7. Beginning of service cycle

#### *Backwashing*

Backwashing is typically done to reclassify the resin so that there will be a gradual increase in particle size from top to bottom and to help prevent channeling. Ion exchange media will act as good filter media; hence backwashing will remove trapped particulate matter from the resin. Fifty to 75 percent bed expansion is normal, and proper freeboard should be allowed for in-column design. Backwashing will typically last 5 to 15 min. Every ion exchange system should be designed so it can be backwashed, but backwashing is often only necessary at infrequent intervals. This is particularly true when treating groundwater, which is relatively free of particles.

Backwashing can have important impacts on leakage. When regeneration is in the co-current mode and leakage is an issue, backwashing after each regeneration cycle is performed to thoroughly mix the resin and dramatically reduce leakage. When regeneration is in the countercurrent mode, backwashing is best avoided altogether, but if required, it should be done before regeneration so leakage is minimized.

#### *Regenerant consumption*

Regenerant consumption per cycle based on design criteria must be determined. The rinses following regeneration are normally operated in the co-current mode: the slow rinse for one to two bed volumes at the regeneration flow rate to displace most of the regenerant from the bed and the fast rinse at the rate of service flow rate for 10 to 30 min. The rinse can be monitored using an online conductivity meter at the effluent of the column to determine when the cycle is complete. An inventory of used brine and rinse volumes must be calculated to adequately prepare for disposal. The disposal of brine is typically a costly part of operation and maintenance cost along with regenerant chemical costs. The disposal of concentration brines may be the critical factor in many potential applications.

## 16-8 Ion Exchange Process Design Case Study

---

The purpose of the case study presented in this section is to illustrate the steps required in developing design criteria for an ion exchange plant. Although the approach is developed for the removal of perchlorate ions from a groundwater, the same steps would be required for other ionic

constituents. The laboratory and pilot plant information for this design approach case study was taken from Najm et al. (1999).

### Problem Definition

A groundwater that is being considered for use as a municipal drinking water source was found to have a perchlorate concentration of 90  $\mu\text{g/L}$ . At the time of this discovery, the regulatory agency was considering a maximum contaminant level of 4  $\mu\text{g/L}$ . The municipality is proposing to pump and treat about 0.16  $\text{m}^3/\text{s}$  (2500 gpm) using an ion exchange process. Water quality parameters for the groundwater are presented in Table 16-11.

### Treatment Goals/Design Criteria and Constraints

A full-scale ion exchange system including a regeneration facility to treat the groundwater to the above regulatory requirement is to be designed so that an assessment of the cost of treatment can be made. The design criteria that need to be determined are

1. Column requirements (number of columns, column dimensions)
2. Maximum SFR and head loss requirements
3. Cycle times (regeneration time, rinse time)
4. Regeneration and rinse requirements (quantities)
5. Type of resin

### Preliminary Process Analysis

To determine the important design and operational parameters required for effective treatment of perchlorate from this groundwater, laboratory and pilot plant studies are needed. Based on a review of the literature and past experience, three SBA ion exchange resins (two polystyrene and one polyacrylic resin) were selected for bench and pilot plant studies.

### Laboratory and Pilot Plant Studies

The design sequence begins with performing laboratory and pilot plant studies to determine the most efficient resin in terms of operational or

**Table 16-11**

Water quality parameters for groundwater for ion exchange process design case study

Parameter	Unit	Value
Alkalinity	mg/L as $\text{CaCO}_3$	122
Hardness	mg/L	163
pH	Unitless	7.8
Nitrate	mg/L as N	6.6
Sulfate	mg/L	53
Perchlorate	$\mu\text{g/L}$	90
TOC	mg/L	0.9
Temperature	$^\circ\text{C}$	15

working capacity, regeneration requirements including regenerant salt concentration and loading, rate and regeneration, and rinse volume requirements. Once these parameters are established, pilot plant testing is performed to evaluate long-term performance of the most promising resin(s). The results of the pilot plant studies are used to establish the full-scale design criteria listed above.

#### LABORATORY STUDIES

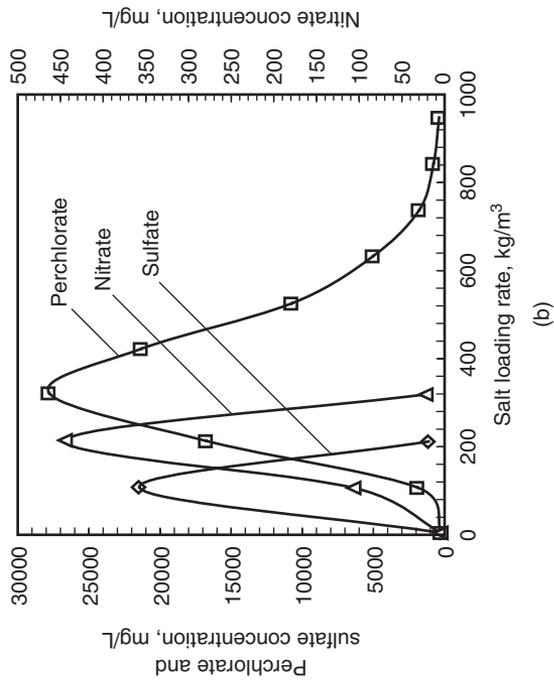

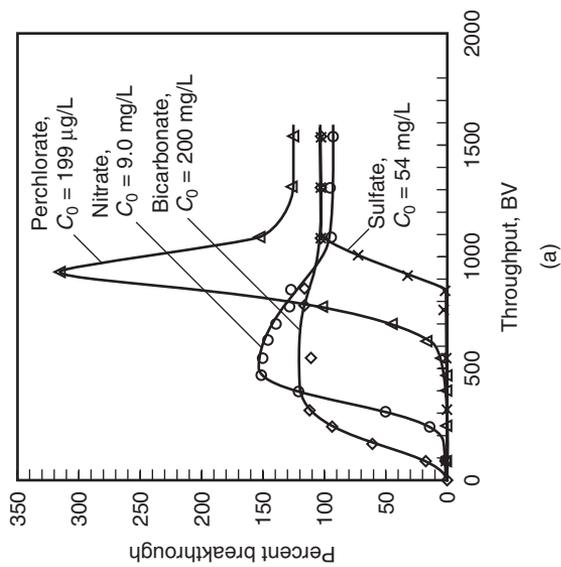

It should be noted that all of the laboratory and pilot plant data developed in this case study are not presented. Only the information pertinent to determining the most efficient and least cost design is presented (see Najm et al., 1999). Laboratory studies were performed on the groundwater to evaluate the three ion exchange resins selected for study, characterize the perchlorate breakthrough, evaluate the regeneration efficiency, and identify the conditions for pilot testing. Column breakthrough was defined as exceeding the perchlorate minimum reporting limit of  $4 \mu\text{g/L}$  so as to minimize perchlorate leakage. Typical saturation and elution curves for an SBA resin are shown on Fig. 16-19.

Countercurrent regeneration was employed using salt loading rates of 240, 480, and  $720 \text{ kg NaCl/m}^3$  (15, 30, and  $45 \text{ lb NaCl/ft}^3$ ). Rinse volumes were determined when the conductivity of the effluent rinse decreased to less than 700 S/cm. From the results of the laboratory study it was found that SBA resins are effective for the removal of perchlorate from groundwater, but the process requires optimization. Polystyrene resins had a higher affinity for perchlorate but are difficult to regenerate, whereas the polyacrylic resins have a moderate affinity for perchlorate and can be regenerated effectively. Perchlorate leakage occurred at a salt loading of  $240 \text{ kg NaCl/m}^3$  ( $15 \text{ lb NaCl/ft}^3$ ), and further testing is necessary to identify long-term working capacity and a salt loading of  $480 \text{ kg NaCl/m}^3$  ( $30 \text{ lb NaCl/ft}^3$ ) or greater for effective regeneration to eliminate perchlorate leakage.

#### PILOT PLANT STUDIES

Based on laboratory studies, pilot plant studies were conducted to demonstrate the performance of the three resins operated under full-scale operating conditions for several regeneration cycles and to validate the laboratory results. The pilot plant design and operational parameters presented in Table 16-12 were based on the typical design values summarized in Table 16-2 for SBA resins. The important parameters of the pilot plant study are displayed below.

Based on the results of the pilot study, the polyacrylic resin was found to provide the best working capacity while minimizing the salt quantity requirements. A pilot plant result for the most promising SBA resin operated for 31 loading cycles is displayed on Fig. 16-20. The resin was regenerated using 16 BV of  $480 \text{ kg/m}^3$  ( $30 \text{ lb/ft}^3$ ) salt regeneration, salt strength of

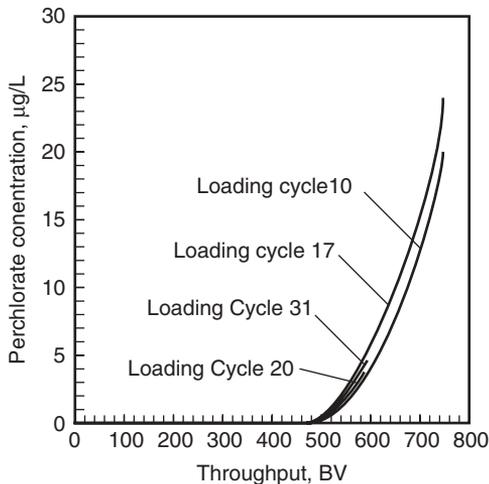

**Figure 16-19** Typical saturation and regeneration curves: (a) saturation loading curves for perchlorate contaminated groundwater on SBA resin and (b) regeneration curves for regeneration of strong-base resin loaded with perchlorate, sulfate, and nitrate (Adapted from Najm and Trussell, 2001).

**Table 16-12**

Operational parameters utilized for pilot plant studies to assess resin performance

Parameter	SI Units	Value	U.S. Customary	
			Units	Value
Operational mode	—	Countercurrent	—	Countercurrent
EBCT	min	1.5	min	1.5
Column diameter	m	0.0509	ft	0.167
Resin depth	m	0.862	ft	2.83
Service flow rate	BV/h	40	gpm/ft <sup>3</sup>	5.0
Flow rate per column	m <sup>3</sup> /h	0.0681	gpm	0.3

<sup>a</sup>Column rinsed until effluent conductivity decreased to less than 700 S/cm.

**Figure 16-20**

Pilot plant effluent profiles for perchlorate on SBA resin operated for total of 31 cycles at 480 kg/m<sup>3</sup> (30 lb/ft<sup>3</sup>) salt regeneration rate (Adapted from Najm and Trussell, 2001).

10 percent (specific gravity 1.07), and between 2 and 6 BV of rinse water. The initial breakthrough occurred at 560 BV and consistently produced regenerated column runs with a design leakage of less than 4 µg/L. Consequently, the columns could be loaded up to 560 BV prior to regeneration without exceeding the allowable design leakage point. Because perchlorate

breakthrough (at 4  $\mu\text{g/L}$ ) consistently occurred at 560 BV for 31 cycles, full regeneration of the resin was accomplished.

### Development of Full-Scale Design Criteria

Design criteria for a full-scale ion exchange treatment plant were developed based on the results of the bench-scale and pilot plant study. The plant is sized for a maximum finished water capacity of 0.160  $\text{m}^3/\text{s}$  (2500 gpm). The plant is sized such that one column is in the regeneration mode on standby while the others are in the operational mode. The service flow rate used in the pilot plant study was 40 BV/h, which is on the high end of service flow rates. The high rate was used to decrease the time required to perform the pilot studies. Consequently, a lower SFR of 28 BV/h (3.5 gpm/ $\text{ft}^3$ ) was used for the full-scale design (see summary design criteria in Table 16-13).

#### ION EXCHANGE COLUMN DESIGN

Design of the ion exchange columns involves the determination of the volume of resin, the surface area of resin required, the number of columns, the sidewall height, and the pressure drop.

##### *Volume of resin*

The number of columns can be found by first calculating the total volume of resin required assuming a typical SFR of 28 BV/h (3.5 gpm/ $\text{ft}^3$ ):

$$\begin{aligned}\text{Total required resin volume} &= \frac{Q}{\text{SFR}} = \frac{0.160 \text{ m}^3/\text{s}}{(28 \text{ BV/h})(1 \text{ h}/3600 \text{ s})} \\ &= 20.6 \text{ m}^3 (727 \text{ ft}^3)\end{aligned}$$

##### *Surface area of resin required*

As discussed above, the EBCT of the pilot plant should be about the same as the EBCT used in the full-scale design. Because a resin depth of 0.863 m (2.83 ft) was used in the pilot plant study, a similar full-scale design with a depth of 1.0 m (3 ft) will be used. Consequently, the total ion exchange surface area required is determined to be

$$\text{Total required surface area} = \frac{\text{resin volume}}{\text{resin depth}} = \frac{20.6 \text{ m}^3}{1.0 \text{ m}} = 20.6 \text{ m}^2 (223 \text{ ft}^2)$$

Ion exchange columns come in standard sizes from the manufacturer. Typically, they may have column diameters of 1.0 m (4 ft), 2.0 m (6 ft), 3.0 m (10 ft), 4.0 m (13 ft), and 5.0 m (16 ft). If a 3-m column diameter is chosen for the design, the column would provide 7.1  $\text{m}^2$  (76.4  $\text{ft}^2$ ) of service area and the volume occupied by the resin would be 7.1  $\text{m}^3$ .

**Table 16-13**

Summary of design criteria for perchlorate removal case study

Parameter	SI Units	Value	U.S. Customary	
			Units	Value
Design product water capacity	m <sup>3</sup> /s	0.160	gpm	2,536
Minimum water temperature	°C	15	°F	59
Resin type	—	SBA, polyacrylic, type I	—	SBA, polyacrylic, type I
Effective resin size	mm	0.6	in.	0.024
SFR	BV/h	28	gpm/ft <sup>3</sup>	3.6
EBCT	min	2.14	min	2.14
Resin depth	m	1.0	ft	3.0
Total minimum sidewall depth	m	3.15	ft	10.3
Required resin volume	m <sup>3</sup>	20.6	ft <sup>3</sup>	728
Column diameter	m	3.0	ft	10
Number of columns	—	4	—	4
BVs to perchlorate breakthrough (single column)	BV	560	BV	560
Salt loading rate (NaCl)	kg/m <sup>3</sup>	480	lb/ft <sup>3</sup>	30
Salt strength	%	10	%	10
Rinse volume	BV	6	BV	6
Clean-water head loss rate	kPa/m	60.8	psi/ft	2.7
Clean-water head loss	kPa	60.8	psi	8.8
Regeneration volume per column	BV	4.5	BV	4.5
Number of regenerations for each column per year	—	438	—	438
Spent regeneration solution volume per column	m <sup>3</sup>	32	gal	8,454
Annual regeneration solution volume per column	m <sup>3</sup> /yr	14,016	Mgal/yr	3.7
Salt quantity required per column	kg	3,408	lb	7,513
Annual salt quantity required per column	kg/yr	1.5 × 10 <sup>6</sup>	lb/yr	3.3 × 10 <sup>6</sup>
Rinse volume required per column	m <sup>3</sup>	43	gal	11,360
Annual rinse volume per column	m <sup>3</sup> /yr	18,834	Mgal/yr	5.0
Total annual salt requirements	kg/yr	4.50 × 10 <sup>6</sup>	lb/yr	9.9 × 10 <sup>6</sup>
Total annual regeneration solution volume	m <sup>3</sup> /yr	42,048	Mgal/yr	11.1
Total annual rinse requirements	m <sup>3</sup> /yr	56,502	Mgal/yr	15.0
Total regeneration cycle time	min	32.4	min	32.4

*Number of columns*

If the total column area is divided by the area of one column, the number of columns required can be calculated as

$$\text{Required number of columns} = \frac{\text{total column area}}{\text{area of one column}} = \frac{20.6 \text{ m}^2}{7.1 \text{ m}^2} = 2.9 \approx 3$$

With one column in the regeneration or standby mode a total of four 3.0-m- (10-ft) diameter columns are required.

*Sidewall height*

The total sidewall height of the column must include the depth of the resin, height for inlet distributor, height for resin support, and height for backwashing. As discussed above, the depth of the resin was chosen as 1.0 m. The heights for the inlet distributor and resin support underdrain can be obtained from the manufacturer, which in this case were 1.0 and 0.5 m, respectively. The sidewall height of the ion exchange columns must include room for bed expansion due to backwashing. Bed expansion can be calculated using manufacturer's performance curves such as those shown on Fig. 16-15.

If the backwash superficial velocity from the pilot study is 6.0 m/h (2.43 gpm/ft<sup>2</sup>) and the water temperature is 15°C, the percent bed expansion required during backwashing and extra height required for backwashing can be determined. From Fig. 16-14, the percent expansion required is about 65 percent. The expanded height required for backwash is

$$\text{Expanded bed height} = 0.65 \times 1.0 \text{ m} = 0.65 \text{ m}$$

The total sidewall height should be a minimum of 3.15 m (1.0 + 0.65 + 1.0 + 0.5) (10.33 ft).

*Pressure drop*

Before continuing the design calculations, the column pressure drop needs to be checked. As noted previously, the maximum pressure drop for the ion exchange resin bed should not exceed 172 kPa (25 psi). Manufacturers provide pressure drop curves for commercially available resins such as shown previously on Fig. 16-14. The superficial velocity for this system is 28 m/h, the initial pressure drop through the resin is 0.62 kg/cm<sup>2</sup>/m of bed depth, as shown on Fig. 16-14. For 1.0 m of resin depth, the clean-water pressure drop is 0.62 kg/cm<sup>2</sup>, or 60.8 kPa (8.8 lb/in.<sup>2</sup>). In this case, the clean-water pressure drop column design is well below the maximum allowable pressure drop (60.8 kPa ≪ 172 kPa). If these curves are not available, the column head loss can be calculated (see Chap. 11, Eq. 11-13). Typically, the pressure drop can be determined in the pilot plant studies if the loading rate and EBCT used in the pilot columns are the same as those in the full-scale design.

**OVERALL CYCLE TIME**

As discussed above, perchlorate breakthrough in the pilot plant study consistently occurred at 560 BV for 31 cycles, at which time full regeneration of the resin was accomplished. The time for each column loading cycle can be calculated by dividing 560 BV by the SFR as shown:

$$\frac{\text{Time}}{\text{Loading cycle}} = \frac{\text{bed volumes/loading cycle}}{\text{SFR}} = \frac{560 \text{ BV}}{28 \text{ BV/h}} = 20 \text{ h}$$

If the columns are staggered or started at different times, then each column will be regenerated every 20 h and the blended effluent will not exceed 4 µg/L perchlorate concentration.

**REGENERATION REQUIREMENTS**

Based on the results of the pilot plant studies, it was found that the perchlorate-loaded columns could be regenerated fully using 480 kg NaCl/m<sup>3</sup> (30 lb NaCl/ft<sup>3</sup>) of resin with a salt strength of 10 percent. For the full-scale design, 480 kg NaCl/m<sup>3</sup> (30 lb/ft<sup>3</sup>) salt loading rate with a 10 percent salt strength (specific gravity 1.07) will be used. The salt solution can be calculated from the specific gravity of the salt and the salt strength as

$$\begin{aligned} 10\% \text{ salt solution} &= (0.1 \text{ kg NaCl/kg soln}) (1070 \text{ kg soln/m}^3 \text{ soln}) \\ &= 107 \text{ kg NaCl/m}^3 \text{ soln} \end{aligned}$$

*Regeneration volume*

The regeneration volume can be calculated by dividing the salt requirements per volume of resin by the salt solution concentration:

$$\begin{aligned} \text{Required regeneration volume per bed volume} &= \frac{480 \text{ kg NaCl/m}^3 \text{ resin}}{107 \text{ kg NaCl/m}^3 \text{ soln}} \\ &= 4.5 \text{ L m}^3 \text{ soln/m}^3 \text{ resin} \end{aligned}$$

*Salt quantity*

The total quantity of salt required on an annual basis can be calculated by multiplying the number of regenerations in a year by the quantity of salt required per regeneration. The number of regenerations can be calculated by dividing the number of hours in a year by the loading cycle time per column:

$$\begin{aligned} \text{Number of regenerations for each column per year} &= \frac{(365 \text{ d/yr}) (24 \text{ h/d})}{20 \text{ h/regen}} \\ &= 438/\text{yr} \end{aligned}$$

The quantity of salt per regeneration per column is calculated as

$$\begin{aligned} \text{Salt quantity per column regeneration} \\ &= (7.1 \text{ m}^3 \text{ resin/regen}) (480 \text{ kg NaCl/m}^3 \text{ resin}) \\ &= 3408 \text{ kg NaCl (7531 lb)} \end{aligned}$$

The annual salt consumption requirement per column is given as

$$\begin{aligned} \text{Annual salt quantity required per column} \\ &= (438 \text{ regen/yr}) (3408 \text{ kg NaCl/regen}) \\ &= (1.5 \times 10^6 \text{ kg NaCl/yr}) (3.3 \times 10^6 \text{ lb/yr}) \end{aligned}$$

The volume of spent regeneration solution per column regeneration is given as

$$\begin{aligned} \text{Spent regeneration solution per column} \\ &= (7.1 \text{ m}^3 \text{ resin/BV}) \times 4.5 \text{ BV} \\ &= 32 \text{ m}^3/\text{column} \quad \text{or} \quad 1130 \text{ gal/column} \end{aligned}$$

The total annual volume of spent regeneration solution per column is calculated as

$$\begin{aligned}\text{Total annual spent regeneration solution per column} \\ &= (32 \text{ m}^3/\text{column}) (438 \text{ columns/yr}) \\ &= 14,016 \text{ m}^3/\text{yr} \quad \text{or} \quad 3.7 \text{ Mgal/yr}\end{aligned}$$

The total annual quantity of salt required and regeneration solution generated for the whole plant will be three times the above quantities because within every 20-h period each of the three columns in service will be regenerated. The total plant quantity values are shown in Table 16-11.

#### *Rinse water requirement*

The quantity of rinse water can be determined based on the rinse quantity used in the pilot plant study. In the pilot plant study, 2 to 6 BV were used to reduce the conductivity of the rinse water below 700 S/cm. To be conservative, 6 BV will be used for the full-scale design. The quantity of rinse volume per regeneration is calculated as

$$\begin{aligned}\text{Rinse volume per column} &= (7.1 \text{ m}^3 \text{ resin/BV}) (6 \text{ BV}) \\ &= 43 \text{ m}^3/\text{column} \quad \text{or} \quad 11,360 \text{ gal/column}\end{aligned}$$

The total annual rinse volume is given as

$$\begin{aligned}\text{Annual rinse volume per column} &= (43 \text{ m}^3/\text{column}) (438 \text{ columns/yr}) \\ &= 18,834 \text{ m}^3/\text{yr} \quad \text{or} \quad 5.0 \text{ Mgal/yr}\end{aligned}$$

#### *Regeneration cycle time*

The cycle time for the salt regeneration is calculated by multiplying the EBCT by the number of bed volumes of regeneration solution per column. The EBCT is first calculated by dividing the resin depth in the column by the superficial velocity as shown:

$$\begin{aligned}\text{EBCT} &= \frac{1 \text{ m}}{28 \text{ m/h}} (60 \text{ min/h}) = 2.14 \text{ min} \\ \text{Regeneration time per column} &= \text{EBCT} \left( \frac{\text{BV}}{\text{regen}} \right) \\ &= (2.14 \text{ min/BV}) (4.5 \text{ BV}) = 9.6 \text{ min}\end{aligned}$$

Similarly, the cycle time for the rinse step is calculated as

$$\begin{aligned}\text{Rinse time per column} &= \text{EBCT} \left( \frac{\text{BV}}{\text{regen}} \right) = (2.14 \text{ min/BV}) (6 \text{ BV}) \\ &= 12.8 \text{ min}\end{aligned}$$

Typical backwash times range from 5 to 20 min, so choosing a backwash time of 10 min, the total time a column will be out of service for the

regeneration cycle, can be estimated to be

$$\begin{aligned}
 &\text{Total regeneration cycle time per column} \\
 &= \text{regeneration time per column} + \text{rinse time per column} \\
 &\quad + \text{backwash time per column} \qquad (16-40) \\
 &= 9.6 \text{ min} + 12.8 \text{ min} + 10 \text{ min} \\
 &= 32.4 \text{ min}
 \end{aligned}$$

The design parameters developed for the full-scale process design for perchlorate removal are summarized in Table 16-13.

### Case Study Design Summary

## Problems and Discussion Topics

---

- 16-1 A SAC exchanger is employed to remove calcium hardness from water. The capacity of the resin is 2.0 meq/mL in the sodium form. If calcium concentrations in the influent and effluent are 44 and 0.44 mg/L, determine the maximum volume of water that can be treated per cycle given the following:

Cations	meq/L	Anions	meq/L
Ca <sup>2+</sup>	2.2	HCO <sub>3</sub> <sup>-</sup>	2.9
Mg <sup>2+</sup>	1.0	Cl <sup>-</sup>	3.1
Na <sup>+</sup>	3.0	SO <sub>4</sub> <sup>2-</sup>	0.2
Total	6.2	Total	6.2

- 16-2 Consider the removal of perchlorate from well water using an SBA exchange resin. The following table lists the major anions contained in the well water. Assuming perchlorate is completely removed from solution, calculate the maximum volume of water that can be treated per liter of resin assuming equilibrium conditions. Assume total resin capacity of the SBA is 1.4 eq/L.

Parameter	Unit	Value
Alkalinity	mg/L as CaCO <sub>3</sub>	200
Perchlorate	mg/L	200
Nitrate	mg/L	9.0
Sulfate	mg/L	55
pH	Unitless	8.0

- 16-3 A small public water system is considering removing calcium from its water using ion exchange. The average daily flow rate is about 2 ML/d and the influent calcium concentration is 200 mg/L as CaCO<sub>3</sub>. If a SAC exchange resin in the sodium form is to be used, estimate the minimum daily volume of resin that would be required assuming that calcium is completely removed and is the only cation

exchanging on the resin. Assume the total resin capacity of the SAC resin is 2.0 eq/L in the chloride form.

- 16-4 Describe the differences between SAC exchanger resins and SBA exchanger resins.
- 16-5 Explain the differences between type I and type II exchanger resins.
- 16-6 Describe and explain the operational advantages of using co-current regeneration versus countercurrent regeneration.
- 16-7 A small public water system is considering removing barium from its well water using ion exchange. The average daily flow rate is about 1.5 ML/d (400,000 gpd) and the influent barium concentration is 11.3 mg/L. If an SBC exchange resin is to be used, estimate the minimum daily volume of resin that would be required assuming that barium is completely removed and is the only cation exchanging on the resin.
- 16-8 An SBA exchanger resin is used to remove nitrate ions from well water that contains high chloride concentration. Usually bicarbonate and sulfate are present in the water (assume they are negligible). The total resin capacity is 1.5 eq/L. Calculate the maximum volume of water that can be treated per liter of resin. The water has the following composition:

Cations	meq/L	Anions	meq/L
Ca <sup>2+</sup>	1.4	SO <sub>4</sub> <sup>2-</sup>	0.0
Mg <sup>2+</sup>	0.8	Cl <sup>-</sup>	3.0
Na <sup>+</sup>	2.6	NO <sub>3</sub> <sup>-</sup>	1.8
Total	4.8	Total	4.8

- 16-9 A small municipal water supply treats a maximum daily flow of 5.0 ML/d, maximum weekly flow of 25 ML/wk, and a maximum nitrate concentration of 18 mg/L. The plant treats 5 ML of water and operates only 7 h per day and 5 days per week, and there is sufficient storage capacity for the weekend demand. The treatment objective for the ion exchange process is 0.6 mg/L NO<sub>3</sub>-N and will be blended with untreated water at 18 mg/L NO<sub>3</sub>-N to produce a final product water of 8 mg/L or less NO<sub>3</sub>-N. With a standard of 10 mg/L as NO<sub>3</sub>-N, determine the flow rate of the ion exchanger and blending rate.
- 16-10 A groundwater contains the following anion concentration exchanger (NO<sub>3</sub>-N = 18 mg/L, SO<sub>4</sub><sup>2-</sup> = 50 mg/L, Cl<sup>-</sup> = 35 mg/L, and HCO<sub>3</sub><sup>-</sup> = 85 mg/L). Assuming nitrate is removed completely from solution, calculate the equilibrium exchange capacity for each ion, and the maximum volume of water that can be treated per liter of resin, assuming equilibrium conditions. Assume total resin capacity of the SBA is equal to 1.4 eq/L.

- 16-11 Given the information in Problems 16-8 and 16-9, design a 5-ML/d ion exchanger for nitrate removal. Determine the number of columns required assuming 4-m diameter columns and a minimum bed depth of 0.762 m and the regenerant requirements including salt used, brine production, total volume of brine storage tank, and regeneration cycle time for the ion exchanger. Based on pilot studies, it was found that adequate regeneration can be obtained with a salt dose of  $320 \text{ kg/m}^3$  resin, a salt concentration of 14 percent, and the specific weight of the salt is 2.165. The capacity of the brine storage tank must be sufficient to handle 10 resin regenerations. The water temperature is  $10^\circ\text{C}$ . Assume the working capacity for the SBA resin is the same as the maximum volume treated determined in Problem 16-8.
- 16-12 Perchlorate at a concentration of  $100 \text{ }\mu\text{g/L}$  was discovered recently in a groundwater that is being considered for use as a drinking water source. Because the action level for perchlorate is  $4 \text{ }\mu\text{g/L}$ , the regulatory agency is requiring remediation of the groundwater. The municipality is proposing to pump and treat about  $0.158 \text{ m}^3/\text{s}$  (2500 gpm) using ion exchange process. To obtain information on the treatment of the water that can be used for the design of a full-scale treatment plant, pilot plant ion exchange studies have been performed. Using the information given below on the water quality and the pilot plant study parameters, design an ion exchange system including a regeneration facility to treat the groundwater to the above regulatory requirement. Determine the following full-scale design criteria: plant size (number of columns, column dimensions) maximum service loading rate, single-column service time, single-column regeneration and rinse volume requirements and regeneration time, head loss requirements, and spent-brine disposal. Assume the inlet distributor and resin support underdrain require 1.0 and 0.5 m of column height, respectively.

### Water quality parameters

Parameter	Unit	Value
Alkalinity	mg/L as $\text{CaCO}_3$	150
Hardness	mg/L	140
PH	Unitless	7.8
Nitrate	mg/L as N	4.0
Sulfate	mg/L	50
Perchlorate	$\mu\text{g/L}$	85
TOC	mg/L	1.5
Temperature	$^\circ\text{C}$	10

### Summary of the pilot plant operational parameters

Parameter	SI Units	Value
Operational mode	—	Countercurrent
EBCT	min	1.5
Column diameter	m	0.0509
Resin depth	m	0.862
Service flow rate	BV/h	30
Flow rate per column	m <sup>3</sup> /h	0.0681
Backwash rate	m/h	6.0
Column resin volume	m <sup>3</sup>	0.00176
Regenerant type	—	NaCl
Regenerant strength	%	10
	mg/L	100,000
Salt loading rate	kg/m <sup>3</sup>	480
Regeneration and rinse flow rate	m <sup>3</sup> /h	0.0363
Regeneration volume	BV	10
Rinse volume	BV	6
Initial BV to breakthrough <sup>a</sup>	BV	550

<sup>a</sup>Full regeneration and no leakage occurred for 31 cycles.

## Terminology for Reverse Osmosis

<b>Term</b>	<b>Definition</b>
Active layer	Layer of membrane that provides the separation capabilities.
Asymmetric structure	Membrane formed of a single material but with multiple layers that are structurally different and have different functions.
Array	Full unit of water production in a reverse osmosis system, which may include multiple stages.
Concentrate	Portion of feed water that has not passed through the membrane. Constituents removed from the permeate are concentrated in the concentrate. Also known as brine.
Concentration polarization	Accumulation of solutes near a membrane surface due to boundary layer effects and the rejection of solutes by the membrane as water passes through the membrane.
Dense membrane	Material that is permeable to certain constituents, such as water, even though it does not have pores.
Limiting salt	Salt that reaches its saturation concentration first as water is concentrated in a reverse osmosis system.
Membrane element	Smallest distinct unit of production capacity in a reverse osmosis system; several membrane elements are arranged in series in a pressure vessel.
Nanofiltration membrane	Reverse osmosis membrane product engineered for selective removal of divalent ions or natural organic matter while allowing passage of smaller monovalent ions.
Osmosis	Flow of solvent through a semipermeable membrane from a dilute solution into a concentrated one.

Term	Definition
Osmotic pressure	Pressure required to balance the difference in chemical potential between two solutions separated by a semipermeable membrane.
Permeate	Portion of feed water that has passed through the membrane. Solutes have been largely removed from this stream so that it is usable for potable purposes. Also known as product water.
Reverse osmosis	Physicochemical separation process in which water flows through a semipermeable membrane due to the application of an external pressure in excess of the osmotic pressure.
Semipermeable membrane	Material that is permeable to some components in a solution but not others; e.g., a material permeable to water but not permeable to salts.
Spiral wound element	Most common type of reverse osmosis membrane element, in which envelopes of membrane material are wrapped around a permeate tube and treated water flows spirally through the envelope to the tube.
Stage	Group of pressure vessels operated in parallel as a single component of water production.
Thin-film composite	Reverse osmosis membranes composed of two or more materials cast on top of one another, where one material is the active layer and other materials form the support layers.

Reverse osmosis (RO) is a membrane treatment process used to separate dissolved solutes from water. It includes any pressure-driven membrane that uses preferential diffusion for separation. A typical RO membrane is made of synthetic *semipermeable* material, which is defined as a material that is permeable, to some components in the feed stream and impermeable to other components and has an overall thickness of less than 1 mm. Water is pumped at high pressure across the surface of the membrane, causing a portion of the water to pass through the membrane, as shown schematically on Fig. 17-1. Water passing through the membrane, called *permeate*, is relatively free of targeted dissolved solutes, while the remaining water, called *concentrate* (also commonly called retentate, reject water, or brine), exits at the far end of the pressure vessel. The delineation of membrane processes, applications for RO, a historical perspective, a process description, process fundamentals, and process design are presented in this chapter.

**Figure 17-1**  
Schematic of separation process through reverse osmosis membrane.

## 17-1 Classification of Membrane Processes

Membrane processes were introduced in Chap. 12, where it was noted that the membranes used in municipal water treatment include microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO) membranes. From a physicochemical perspective, these four types of membranes are used in two distinct processes in water treatment (1) membrane filtration and (2) reverse osmosis. They are differentiated by the types of materials rejected, characteristic pore dimensions, and operating pressures. Membrane filtration is used primarily for the removal of particulate matter, whereas RO accomplishes a variety of treatment objectives involving the separation of dissolved solutes from water.

Membrane filtration is covered in Chap. 12, in which a hierarchy of membranes used in water treatment is described (Fig. 12-2), and additional details are provided on the delineation between membrane filtration and RO (Sec. 12-1) including a table of significant differences between these processes (Table 12-1). Common membrane nomenclature is included in Chap. 12 as well as here.

Nanofiltration membranes were designed by FilmTec Corporation around 1983 to remove divalent anions from seawater for applications in the oil industry. The word *nanofiltration* was coined because the separation cutoff size was about 1 nm, and the membranes were designed for removal of specific ionic species, whereas other RO membranes of that era were indiscriminate with respect to the ionic species removed. The ability of NF membranes to simultaneously remove divalent cations (hardness) and natural organic matter while achieving only low monovalent ion removal made them ideal for certain water treatment applications. While NF membranes were a unique product in the 1980s, membrane manufacturers have since engineered a variety of RO membranes with different formulations, permeation capabilities, and rejection characteristics. These products provide a full range of different capabilities, and some new RO

membranes have characteristics similar to the original NF membranes. A variety of names have been applied to these new products, including “loose” RO membranes, softening membranes, and low-pressure RO membranes. Manufacturers will continue to develop new RO membranes to achieve specific goals, and NF membranes are just one in a succession of many innovative developments in the field of RO.

## 17-2 Applications for Reverse Osmosis

Uses for RO in water treatment as well as alternative processes are listed in Table 17-1. These objectives encompass the desalination of ocean or brackish water, advanced treatment for water reuse, softening, natural organic matter (NOM) removal for controlling disinfection by-product (DBP) formation, and specific contaminant removal.

The scarcity of freshwater sources may mean a strong future for the use of RO for desalination of ocean water or seawater. About 97.5 percent of the earth’s water is in the oceans, and about 75 percent of the world’s population live in coastal areas (Bindra and Abosh, 2001). The salinity of the ocean ranges from about 34,000 to 38,000 mg/L as total dissolved solids (TDS) (Stumm and Morgan 1996), nearly two orders of magnitude higher than that of potable water [the World Health Organization’s (WHO’s

### Desalination of Ocean Water or Seawater

**Table 17-1**

Reverse osmosis objectives and alternative processes

Process Objective	Membrane Process Name	Alternative Processes
Ocean or seawater desalination	High-pressure RO, seawater RO	Multistage flash (MSF) distillation, multieffect distillation (MED), vapor compression distillation (VCD)
Brackish water desalination	RO, low-pressure RO, NF	Multistage flash distillation, <sup>a</sup> multieffect distillation, <sup>a</sup> vapor compression, <sup>a</sup> electrodialysis, electrodialysis reversal
Softening	Membrane softening, NF	Lime softening, ion exchange
NOM removal for DBP control	NF	Enhanced coagulation/softening, GAC
Specific contaminant removal <sup>b</sup>	RO	Ion exchange, activated alumina, coagulation, lime softening, electrodialysis, electrodialysis reversal
Water reuse	RO	Advanced oxidation
High-purity process water	RO	Ion exchange, distillation

<sup>a</sup>MSF, MED, and VCD are rarely competitive economically for brackish water desalination.

<sup>b</sup>Applicability of alternative processes depends on the specific contaminants to be removed and their concentration.

**Table 17-2**

Typical concentration of important solutes in seawater

Salt	Concentration, mg/L
Cations	
Sodium, Na <sup>+</sup>	10,800
Magnesium, Mg <sup>2+</sup>	1,290
Calcium, Ca <sup>2+</sup>	412
Potassium, K <sup>+</sup>	399
Strontium, Sr <sup>2+</sup>	7.9
Barium, Ba <sup>2+</sup>	0.02
Anions	
Chloride, Cl <sup>-</sup>	19,400
Sulfate, SO <sub>4</sub> <sup>2-</sup>	2,700
Total carbonate, CO <sub>3</sub> <sup>2-</sup>	142

guidance level for TDS is 1000 mg/L and the United States has a secondary standard of 500 mg/L)]. The concentration of important ions in seawater is shown in Table 17-2. Seawater also contains several important neutral species, including 3 mg/L of silicon (present as H<sub>4</sub>SiO<sub>4</sub>) and 4.6 mg/L of boron (present as H<sub>3</sub>BO<sub>3</sub>). Boron is a concern because neutral species are poorly removed by conventional RO membranes, as will be presented later, and California has a notification limit of 1 mg/L for boron in drinking water.

Desalination costs are dropping, and the process is becoming more competitive with other treatment options in areas where freshwater is scarce, although desalination of ocean water is an energy-intensive process.

The Middle East is currently the most prominent market for desalination of ocean water. Virtually 100 percent of the drinking water in Kuwait and Qatar and 40 to 60 percent of the drinking water in Bahrain, Saudi Arabia, and Malta is produced by desalination (Bremere et al., 2001). Thermal processes such as multistage flash (MSF) distillation and multieffect distillation (MED) are common in the Middle East, which has vast energy resources but little freshwater. Worldwide, 43 percent of desalination is done with thermal processes and 56 percent is done with membrane processes (NRC, 2008).

Interest in the oceans as a source water is growing in other areas, including coastal areas of the United States. Tampa, Florida, commissioned

a 95,000-m<sup>3</sup>/d (25-mgd) RO plant in 2003, and a number of communities in California are considering the Pacific Ocean as a source of municipal water.

Interest in desalination of brackish groundwater has increased in areas short on freshwater, such as the southwest region of the United States. Communities in that area are rapidly growing beyond the availability of local freshwater supplies. Brackish groundwater with low to moderate salinity (1000 to 5000 mg/L TDS) are relatively common, and use of these resources has become reasonable as desalination costs have dropped and costs to obtain additional freshwater resources has increased. The difference in feed water quality between brackish water and seawater can lead to differences in design and operation, including differences in pretreatment, feed pressure, configuration of stages, water recovery, fouling prevention, and waste disposal (Greenlee et al., 2009). Since energy consumption is directly related to feed water TDS, brackish water desalination is not nearly as energy intensive as seawater desalination. However, disposal of the concentrate is a significant challenge.

### **Desalination of Brackish Groundwater**

Along with brackish groundwater as an alternative source of water, many communities in water-scarce areas are considering the increased use of recycled treated wastewater. Water reuse for nonpotable uses such as irrigation of municipal greenspaces (parks, golf courses, road medians, etc.) and industrial process water is practiced in some areas, but treating wastewater to sufficient quality for potable reuse would increase flexibility for using the resource and eliminate the need for community dual-pipe systems. A concern in potable reuse applications, however, is the presence of pharmaceuticals, personal care products, endocrine disrupting compounds, unregulated contaminants, and other contaminants of emerging concern. RO's ability to remove virtually all contaminants in water, including many synthetic organic chemicals, has increased the interest in incorporating RO into wastewater treatment process trains as an advanced treatment process.

### **Water Reuse**

Nanofiltration or softening membranes are capable of removing 80 to 95 percent of divalent ions such as calcium and magnesium with low removal of low-molecular-weight (MW) monovalent ions such as sodium and chloride. By allowing passage of sodium and chloride, the osmotic pressure differential is minimized. Nanofiltration membranes can soften water without the voluminous sludge production of lime softening, although concentrate disposal can be a significant regulatory obstacle. Nanofiltration membranes that effectively remove hardness are also effective at removing NOM, making them an excellent treatment option for color removal and DBP formation control because removing NOM and color from water before disinfection with free chlorine typically reduces the formation of DBPs. Nanofiltration membranes have widespread use in Florida,

### **Softening and NOM Removal**

where the groundwater is either brackish or very hard, highly colored freshwater.

### Specific Contaminant Removal

An additional use for RO is specific contaminant removal. The EPA has designated RO as a best available technology (BAT) for removal of numerous inorganic contaminants, including antimony, arsenic, barium, fluoride, nitrate, nitrite, and selenium, and radionuclides, including beta-particle and photon emitters, alpha emitters, and radium-226. Reverse osmosis has also been demonstrated to be effective for removing larger MW synthetic organics such as pesticides (Baier et al., 1987). Use of RO for specific contaminants, however, is less common because alternative technologies are frequently more cost effective and the disposal of the concentrate stream may present challenges.

## 17-3 History of Reverse Osmosis in Water Treatment

---

The process of osmosis through semipermeable membranes was first observed in 1748 by Jean Antoine Nollet (Laidler and Meiser, 1999). The feasibility of desalinating seawater with semipermeable membranes was first seriously investigated in 1949 at the University of California at Los Angeles (UCLA) and in about 1955 at the University of Florida, with funding provided by the newly formed U.S. Department of Interior Office of Saline Water (Glater, 1998). Researchers at both UCLA and the University of Florida successfully produced freshwater from seawater in the mid-1950s, but the flux was too low to be commercially viable. Research focused on reducing the membrane thickness, and in 1959, Loeb and Sourirajan of UCLA succeeded in producing the first asymmetric RO membrane (Lonsdale, 1982). *Asymmetric* membranes are formed from a single material that develops into active and support layers during the casting process (in other words, the membranes are chemically homogeneous but physically heterogeneous). Due to the thinness of the *active layer*, which provides separation capabilities, the asymmetric membrane was a major breakthrough. That advancement, along with the development of the spiral wound element to increase packing density and thin-film composite membranes, led to the commercial viability of membrane desalination.

In June of 1965, the first commercial membrane desalination plant began providing potable water to the City of Coalinga, California. The plant, with combined experimental and production capabilities, produced  $19 \text{ m}^3/\text{d}$  (0.005 mgd) of potable water from 2500 mg/L TDS feed water by operating at 41 bar (600 psi) pressure,  $34 \text{ L}/\text{m}^2 \cdot \text{h}$  ( $20 \text{ gal}/\text{ft}^2 \cdot \text{d}$ ) flux, and 50 percent recovery (Stevens and Loeb, 1967). Other plants soon followed. The construction of Water Factory 21 in California helped the industry standardize on specific configurations, such as the 8-in. spiral-wound element. In the mid-1970s, RO applications were extended from

desalting to the softening applications mentioned earlier. The first membrane softening plant was built in Pelican Bay, Florida, in 1977 (AWWA, 2007). The use of membranes to remove NOM paralleled the development of membrane softening (Taylor et al., 1987) because many groundwater supplies in Florida are both hard and colored, and NOM and hardness can be removed simultaneously by membranes.

By the end of 2008, the total installed capacity of desalination plants was  $42 \times 10^6 \text{ m}^3/\text{d}$  (11 billion gallons per day) worldwide. Over 1100 RO plants are operating in the United States with a total capacity of around  $5.7 \times 10^6 \text{ m}^3/\text{day}$  (1500 mgd) (NRC, 2008), which represents about 3 percent of water withdrawn by public water systems. Reverse osmosis plants have been built in every state in the United States.

The future of RO is promising. Growth in the world population, the urbanization of coastal and arid areas, the scarcity of freshwater supplies, the increasing contamination of freshwater supplies, greater reliance on oceans and poorer quality supplies (brackish groundwater, treated wastewater), and improvements in membrane technology suggest continued rapid growth of reverse osmosis installations. The installation of desalination facilities is expected to double between 2005 and 2015 (Wang et al., 2010).

## 17-4 Reverse Osmosis Process Description

---

Reverse osmosis relies on differences between the physical and chemical properties of the solutes and water to achieve separation. A high-pressure feed stream is directed across the surface of a semipermeable material, and due to a pressure differential between the feed and permeate sides of the membrane, a portion of the feed stream passes through the membrane. As water passes through the membrane, solutes are rejected and the feed stream becomes more concentrated. The permeate stream exits at nearly atmospheric pressure, while the concentrate remains at nearly the feed pressure. Reverse osmosis is a continuous separation process; that is, there is no periodic backwash cycle.

A typical RO facility is shown on Fig. 17-2. The smallest unit of production capacity in a membrane plant is called a *membrane element*. The membrane elements are enclosed in pressure vessels mounted on skids, which have piping connections for feed, permeate, and concentrate streams. A group of pressure vessels operated in parallel is called a *stage*. The concentrate from one stage can be fed to a subsequent stage to increase water recovery (a multistage system, sometimes called a brine-staged system) or the permeate from one stage can be fed to a second stage to increase solute removal (a two-pass system, also sometimes called a permeate-staged system). In multistaged systems, the number of pressure vessels decreases in each succeeding stage to maintain sufficient velocity in the feed channel

**Figure 17-2**  
Typical reverse osmosis facility.

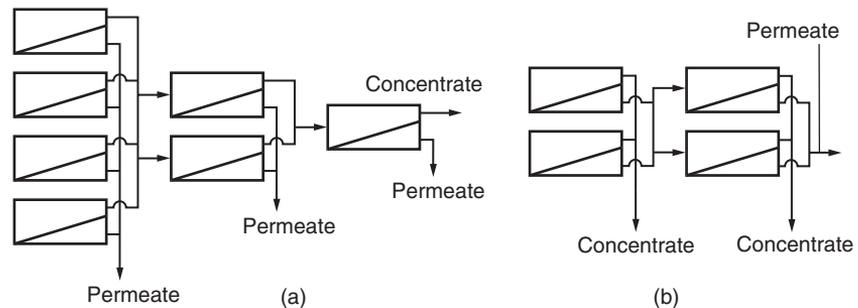

as permeate is extracted from the feed water stream. A unit of production capacity, which may contain one or more stages, is called an *array*. Schematics of various arrays are shown on Fig. 17-3. The ratio of permeate to feed water flow (recovery) ranges from about 50 percent for seawater RO systems to about 90 percent for low-pressure RO systems. Several factors limit recovery, most notably osmotic pressure, concentration polarization, and the solubility of sparingly soluble salts.

### Pretreatment and Posttreatment

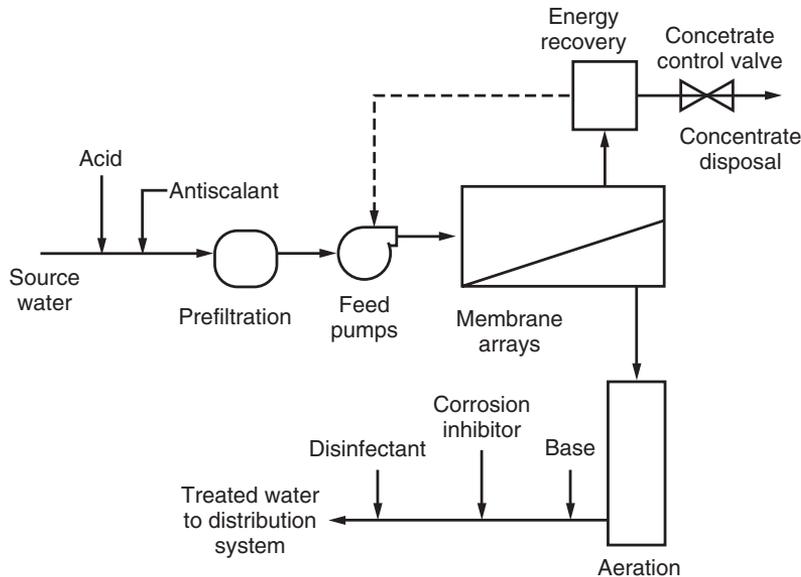

A schematic of an RO system with typical pretreatment and posttreatment processes is shown on Fig. 17-4 and described below.

#### PRETREATMENT

Feed water pretreatment is required in virtually all RO systems. When sparingly soluble salts are present, one purpose of pretreatment is to

**Figure 17-3**  
Array configurations of reverse osmosis facilities:  
(a)  $4 \times 2 \times 1$  concentrate-staged array,  
(b) two-pass system.

**Figure 17-4**  
Schematic of typical reverse osmosis facility.

prevent scaling. Solutes are concentrated as water is removed from the feed stream, and the resulting concentration can be higher than the solubility product of various salts. Without pretreatment, these salts can precipitate onto the membrane surface and irreversibly damage the membrane. Scale control consists of pH adjustment and/or antiscalant addition. Adjusting the pH changes the solubility of precipitates and antiscalants interfere with crystal formation or slow the rate of precipitate formation.

The second pretreatment process is filtration to remove particles. Without a backwash cycle, particles can clog the feed channels or accumulate on the membrane surface unless the concentration is low. As a minimum, cartridge filtration with a 5- $\mu\text{m}$  strainer opening is used, although granular filtration or membrane filtration pretreatment is often necessary for surface water sources. Disinfection is another typical pretreatment step and is used to prevent biofouling. Some membrane materials are incompatible with disinfectants, so the disinfectant can only be applied in specific situations and must be matched to the specific membrane type.

After pretreatment, the feed water is pressurized with feed pumps. The feed water pressure ranges from 5 to 10 bar (73 to 145 psi) for NF membranes, from 10 to 30 bar (145 to 430 psi) for low-pressure and brackish water RO, and from 55 to 85 bar (800 to 1200 psi) for seawater RO.

#### POSTTREATMENT

Permeate typically requires posttreatment, which consists of removal of dissolved gases and alkalinity and pH adjustment. Membranes do not efficiently remove small, uncharged molecules, in particular dissolved gases.

If hydrogen sulfide is present in the source groundwater, it must be stripped prior to distribution to consumers. If sulfides are removed in the stripping process, provisions must be made to scrub the sulfides from the stripping tower off-gas to prevent odor and corrosion problems. The stripping of carbon dioxide raises pH and reduces the amount of base needed to stabilize the water. Permeate is typically low in hardness and alkalinity and frequently has been adjusted to an acidic pH value to control scaling. Consequently, the permeate is corrosive to downstream equipment and piping. Alkalinity and pH adjustments are accomplished with various bases, and corrosion inhibitors are used to control corrosion.

### **Concentrate Stream**

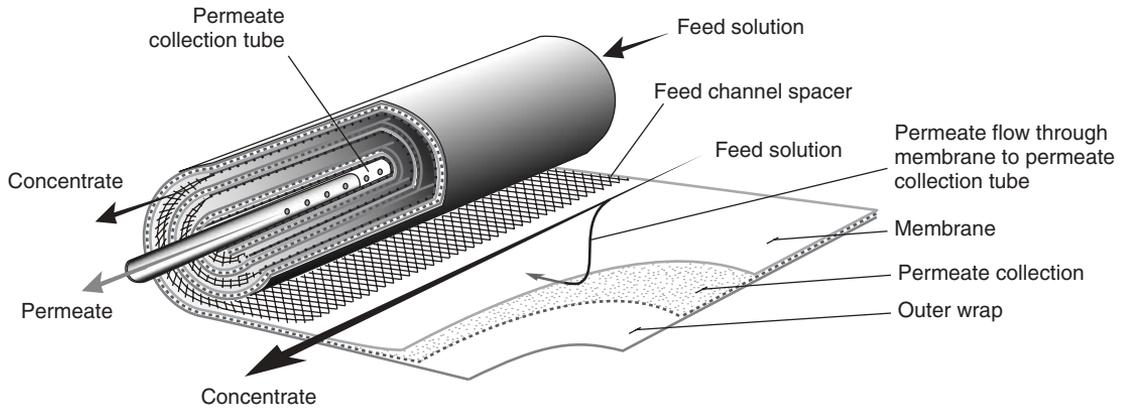

The concentrate stream is under high pressure when it exits the final membrane element. This pressure is dissipated through the concentrate control valve, which can be a significant waste of energy. Seawater RO systems utilize energy recovery equipment on the concentrate line, and some brackish water RO systems are starting to use energy recovery as well. Unlike cross-flow membrane filtration, the concentrate stream is not recycled to the head of the plant but is a waste stream that must be discarded. Concentrate disposal can be a significant issue in the design of RO facilities and the concentrate may require treatment before disposal. Methods for concentrate disposal are discussed in Chap. 21 and include ocean, brackish river, or estuary discharge; discharge to a municipal sewer; and deep-well injection. Other concentrate disposal options, including evaporation ponds, infiltration basins, and irrigation, are used by a small number of facilities.

### **Membrane Element Configuration**

Reverse osmosis membrane elements are fabricated in either a spiral-wound configuration or a hollow-fine-fiber (HFF) configuration.

#### **SPIRAL-WOUND MODULES**

Spiral-wound modules are constructed of several elements in series. The basic construction of a spiral-wound element is shown on Fig. 17-5, and a photograph of typical elements is shown on Fig. 17-6. An envelope is formed by sealing two sheets of flat-sheet membrane material along three sides, with the active membrane layer facing out. A permeate carrier spacer material inside the envelope prevents the inside surfaces from touching each other and provides a flow path for the permeate inside the envelope. The open ends of several envelopes are attached to a perforated central tube known as a permeate collection tube. Feed-side mesh spacers are placed between the envelopes to provide a flow path and create turbulence in the feed water. By rolling the membrane envelopes around the permeate collection tube, the exterior spacer forms a spirally shaped feed channel. This channel, exposed to element feed water at one end and concentrate at the other end, is known as the feed-concentrate channel. Membrane feed water passes through this channel and is exposed to the membrane surface.

**Figure 17-5**  
Construction of spiral-wound membrane element.

**Figure 17-6**  
Photograph of spiral-wound membrane elements. (Courtesy GE Infrastructure Water Technologies.)

Spiral-wound elements are typically 1 m (40 in.) to 1.5 m (60 in.) long and 0.1 m (4 in.) to 0.46 m (18 in.) in diameter, although 0.2 m (8 in.) diameter elements are most common. Four to seven elements are arranged in series in a pressure vessel, with the permeate collection tubes of the spiral-wound elements coupled together.

During operation, pressurized feed water enters one side of the pressure vessel and encounters the first membrane element. As the water flows tangentially across the membrane surface, a portion of the water passes through the membrane surface and into the membrane envelope and flows spirally toward the permeate collection tube. The remaining feed water, now concentrated, flows to the next element in series, and the process is repeated until the concentrate exits the pressure vessel. Individual spiral-wound membrane elements have a permeate recovery of 5 to 15 percent per element. Head loss develops as feed water flows through the feed channels and spacers, which reduces the driving force for flow through the membrane surface. This feed-side head loss across a membrane element is low, typically less than 0.5 bar (7 psi) per element.

#### **HOLLOW-FINE-FIBER MODULES**

The HFF configuration is similar to the hollow fibers used in membrane filtration. Feed water passes over the outside of the fiber and is forced through the wall of the fiber, and the permeate is collected in the lumen (or inner annulus) of the fiber. The original manufacturer of HFF membranes was DuPont, which manufactured fiber with an outside diameter (OD) of 0.085 mm (about the thickness of human hair) and inside diameter of 0.042 mm, considerably thinner than the hollow fibers used in membrane filtration, which have an OD of 1 to 2 mm (about the thickness of pencil lead) (Lonsdale, 1982). The active surface of the membrane is on the outside surface of the fiber and is 0.1 to 1  $\mu\text{m}$  thick. DuPont HFFs are still in widespread use but are no longer commercially available. The only current manufacturer of hollow-fiber RO membranes is Toyobo in Japan. In a typical HFF module, the feed enters one end of the module and the concentrated brine exits from the opposite end. The fibers are folded and suspended lengthwise in the module, with the open ends of a set of fibers exposed at each end of the module. The fiber bundles are wound helically around a center tube. A single module can contain several hundred thousand fibers and have surface area up to 10 times that of spiral wound elements. Product water recovery per element is 30 percent.

## 17-5 Reverse Osmosis Fundamentals

---

The fundamentals of RO include the membrane material properties, the phenomenon of osmotic pressure, the mechanisms for water and solute permeation, the equations used to predict water and solute flux, and the phenomenon of concentration polarization. These topics are addressed in this section.

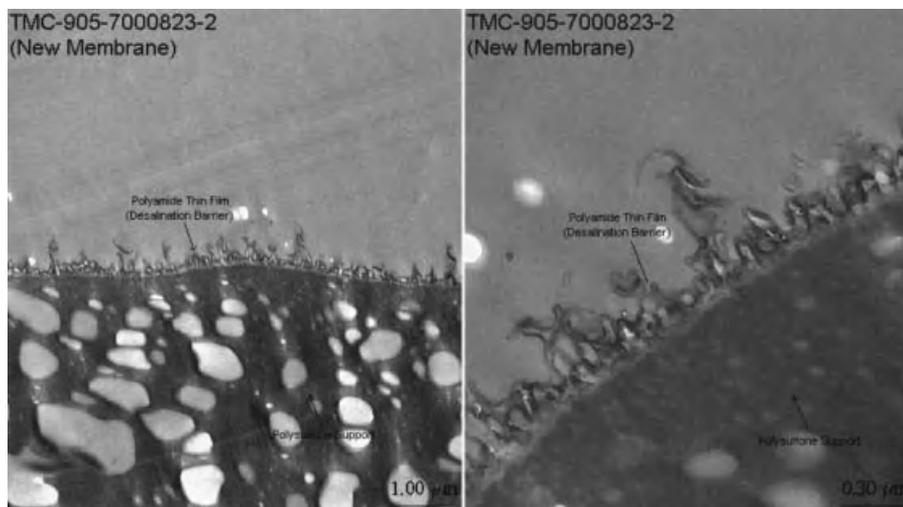

An understanding of the mechanisms that control RO begins with an understanding of the membrane. Important properties include the physical structure, chemistry, and rejection capabilities of the membranes.

**Membrane  
Structure,  
Material  
Chemistry, and  
Rejection  
Capabilities**

**MEMBRANE STRUCTURE**

The resistance to flow through a membrane is inversely proportional to thickness. To achieve any appreciable water flux, the active membrane layer must be extremely thin, which in RO and NF membranes ranges from about 0.1 to 2  $\mu\text{m}$ . Material this thin lacks structural integrity, so these membranes are comprised of several layers, with a thin active layer providing separation capabilities and thicker, more porous layers providing structural integrity. Multilayer membranes are fabricated in two ways. As previously mentioned, asymmetric membranes are formed from a single material that develops into active and support layers during the casting process (in other words, the membranes are chemically homogeneous but physically heterogeneous). *Thin-film composite* membranes are composed of two or more materials cast on top of one another. An advantage of thin-film membranes is that separation and structural properties can be optimized independently using appropriate materials for each function. A cross section of an RO membrane is shown on Fig. 17-7.

The active layer of RO membranes must selectively allow water to pass through the material while rejecting dissolved solutes that may have

**Figure 17-7**  
Microphotographs of asymmetric reverse osmosis membrane. (TEM images courtesy Bob Riley.)

dimensions similar to water molecules. Separation of small ions cannot be accomplished if they are convectively carried with liquid water. Thus, RO membranes are fabricated of a *dense* material, meaning a permeable but not porous material with no void spaces through which liquid water travels. Water and solutes dissolve into the solid membrane material, diffuse through the solid, and reappear on the permeate side of the membrane. The mechanics of permeation through a dense material will be discussed in detail later in this chapter. Low-pressure RO or NF membranes may have void spaces large enough for the convective flow of liquid water through the membrane.

#### **MEMBRANE MATERIAL**

Membrane performance is strongly affected by the physical and chemical properties of the material. The ideal membrane material is one that can produce a high flux without clogging or fouling and is physically durable, chemically stable, nonbiodegradable, chemically resistant, and inexpensive. Important characteristics of membrane materials, methods of determination, and effects on membrane performance were discussed in Chap. 12 and shown in Table 12-7. The materials most widely used in RO are cellulosic derivatives and polyamide derivatives.

#### *Cellulose acetate membranes*

The original RO membrane developed by Loeb and Sourirajan in 1960 was fabricated of cellulose acetate (CA), and RO membranes using this material are still commercially available. Membranes composed of CA are typically of asymmetric construction. Cellulose acetate is hydrophilic, which helps to maintain high flux values and to minimize fouling. The structural properties of CA are not ideal, however, and the material is not tolerant of temperatures above 30°C, tends to hydrolyze when the pH value is below 3 or above 8, is susceptible to biological degradation, and degrades with free-chlorine concentrations above 1 mg/L, depending on the concentration and duration of contact. In addition, membrane compaction due to the high operating pressure and asymmetric construction causes a reduction of flux over time.

#### *Polyamide membranes*

Polyamide (PA) membranes are chemically and physically more stable than CA membranes, generally immune to bacterial degradation, stable over a pH range of 3 to 11, and do not hydrolyze in water. Under similar pressure and temperature conditions, PA membranes can produce higher water flux and higher salt rejection than CA membranes. However, PA membranes are more hydrophobic and susceptible to fouling than CA membranes and are not tolerant of free chlorine in any concentration. Any residual oxidant such as chlorine in the feed will cause rapid deterioration of the

membrane. For most applications, dechlorination is required if the feed water is chlorinated and can be done with sodium bisulfite, sulfur dioxide, or activated carbon. Sensors and instrumentation must be provided to monitor the feed water for oxidants that may damage the material and shut down the system if any are detected. Some PA membranes have a rougher surface than CA membranes, which can increase susceptibility to biological and particulate fouling. Polyamide membranes are typically of thin-film construction. The PAs are used for the active layer, and durable materials such as polyethersulfone are used for the support material. The support layer is essentially a standard UF membrane and provides little resistance to flow.

#### REJECTION CAPABILITIES

The rejection capabilities of RO and NF membranes are designated with either a percent salt rejection or a molecular weight cutoff (MWCO) value. Salt rejection is typically used for RO membranes:

$$\text{Rej} = 1 - \frac{C_P}{C_F} \quad (17-1)$$

where       $\text{Rej}$  = rejection, dimensionless (expressed as a fraction)

$C_P$  = concentration in permeate, mol/L

$C_F$  = concentration in feed water, mol/L

Rejection can be calculated for bulk parameters such as TDS or conductivity. For membrane rating, however, rejection of specific salts is specified. Sodium chloride rejection is normally specified for high-pressure RO membranes, whereas  $\text{MgSO}_4$  rejection is often specified for NF or low-pressure RO membranes.

Nanofiltration membranes can also be characterized by MWCO. The MWCO of NF membranes is typically determined by passage of solutes such as sodium chloride and magnesium sulfate. The MWCO of NF membranes is typically 1000 Daltons (Da), also known as atomic mass units (amu), or less.

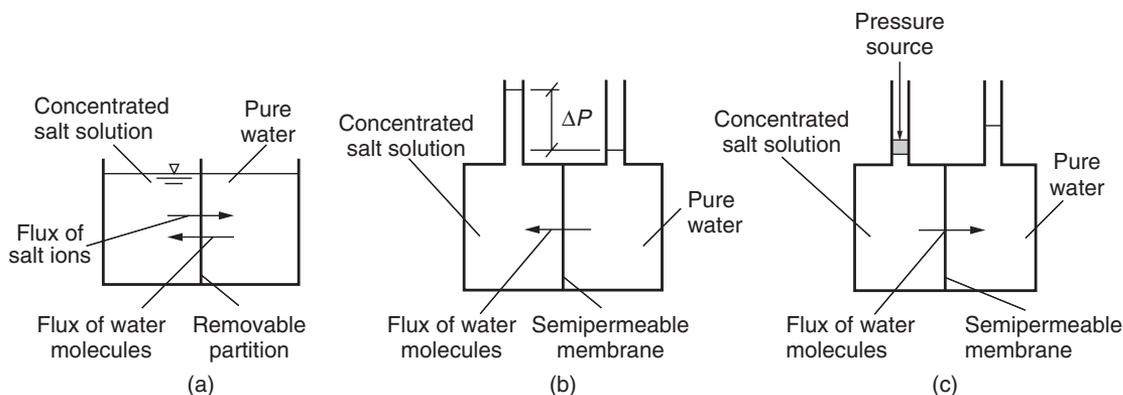

Osmosis is the flow of solvent through a semipermeable membrane, from a dilute solution into a concentrated one. Osmosis reduces the flux through an RO membrane by inducing a driving force for flow in the opposite direction.

The physicochemical foundation for osmosis is rooted in the thermodynamics of diffusion, as described in this section.

#### DIFFUSION AND OSMOSIS

Consider a vessel with a removable partition that is filled with two solutions to exactly the same level, as shown on Fig. 17-8a. The left side is filled with

## Osmotic Pressure

**Figure 17-8**

Diffusion sketch for reverse osmosis: (a) diffusion, (b) osmosis, and (c) reverse osmosis.

a concentrated salt solution, the right with pure water, and the partition is gently removed without disturbing the solutions. Initially, the contents are in a nonequilibrium state and the salt will eventually diffuse through the water until the concentration is the same throughout the vessel. With salt ions diffusing from left to right across the plane originally occupied by the partition, conservation of mass requires a flux of water molecules in the opposite direction. Without a flux of water molecules from right to left, mass accumulates on the right side of the container, which is unthinkable with a continuous water surface. Equilibrium requires mass transport in both directions.

On Fig. 17-8b, the top of the vessel has been closed and fitted with manometer tubes and the removable partition has been replaced with a semipermeable membrane. The semipermeable membrane allows the flow of water but prevents the flow of salt. Filling the chambers with salt solution and pure water again creates a thermodynamically unstable system, which must be equilibrated by diffusion. Because the membrane prevents the flux of salt, however, mass accumulates in the left chamber, causing the water level in the left manometer to rise and in the right manometer to drop. This flow of water from the pure side to the salt solution is osmosis. Water flux occurs despite the difference in hydrostatic pressure that develops due to the difference in manometer levels.

#### OSMOTIC PRESSURE

The driving force for diffusion is typically described as a concentration gradient, although a more rigorous thermodynamic explanation is a gradient in Gibbs energy (Laidler and Meiser, 1999). The concept of Gibbs energy ( $G$ ) and its relationship to concentration were introduced in Chap. 5. When the vessels on Fig. 17-8 were filled with water and salt solutions, the two

sides had different values of Gibbs energy due to differences in salt concentration. Equilibrium is defined thermodynamically when  $\Delta G = 0$ , so the gradient in Gibbs energy across the first vessel caused the simultaneous diffusion of salt ions and water molecules, and the system was driven toward an equilibrium condition in which the Gibbs energy (and concentration and water level) was equal throughout the system. In the second vessel, water stops flowing from right to left when the vessel reaches thermodynamic equilibrium but both pressure and concentration are unequal between the chambers. Although Gibbs energy is constant throughout the second vessel at equilibrium, the Gibbs energy includes components to account for both the pressure and concentration differences.

The discussion of Gibbs energy in Chap. 5 was done under conditions of constant temperature and pressure. To describe osmosis, a more general description of Gibbs energy is needed. The general form of the Gibbs function is

$$\partial G = V \partial P - S \partial T + \sum_i \mu_i^\circ \partial n_i \quad (17-2)$$

where

- $G$  = Gibbs energy, J
- $V$  = volume, m<sup>3</sup>
- $P$  = pressure, Pa
- $S$  = entropy, J/K
- $T$  = absolute temperature, K (273 + °C)
- $\mu_i^\circ$  = chemical potential of solute  $i$ , J/mol
- $n_i$  = amount of solute  $i$  in solution, mol

Chemical potential is defined as the change in Gibbs energy resulting from a change in the amount of component  $i$  when temperature and pressure are held constant:

$$\mu_i^\circ = \left. \frac{\partial G}{\partial n_i} \right|_{P,T} \quad (17-3)$$

Therefore, the last term in Eq. 17-2 ( $\mu_i^\circ \partial n_i$ ) describes the difference in Gibbs energy resulting from the difference in the amount of solute between the chambers (when volume is constant, the difference in amount equals the difference in concentration). Under constant-temperature conditions (i.e.,  $\partial T = 0$ ), Eq. 17-2 says equilibrium ( $\partial G = 0$ ) will be achieved when the sum of the Gibbs energy gradient due to chemical potential is offset by the pressure gradient between the two chambers:

$$\partial G = 0 \quad \text{when} \quad V \partial P = - \sum_i \mu_i^\circ \partial n_i \quad (17-4)$$

The pressure required to balance the difference in chemical potential of a solute is called the *osmotic pressure* and is given the symbol  $\pi$ . When the

vessel in the second experiment reaches equilibrium, the difference in hydrostatic pressure between the manometers is equal and opposite to the difference in osmotic pressure between the two chambers. An equation for osmotic pressure can be derived thermodynamically using assumptions of incompressible and ideal solution behavior:

$$\pi = \frac{-RT}{V_b} \ln x_W \quad (17-5)$$

where  $\pi$  = osmotic pressure, bar  
 $V_b$  = molar volume of pure water, L/mol  
 $x_W$  = mole fraction of water, mol/mol  
 $R$  = universal gas constant, 0.083145 L·bar/mol · K

In dilute solution (i.e.,  $x_W \cong 1$ ), Eq. 17-5 can be approximated by the van't Hoff equation for osmotic pressure (Eq. 17-6), which is identical in form to the ideal gas law ( $PV = nRT$ ):

$$\pi = \frac{n_S}{V} RT \quad \text{or} \quad \pi = CRT \quad (17-6)$$

where  $n_S$  = total amount of all solutes in solution, mol  
 $C$  = concentration of all solutes, mol/L  
 $V$  = volume of solution, L

Equation 17-6 was derived assuming infinitely dilute solutions, which is often not the case in RO systems. To account for the assumption of diluteness, the nonideal behavior of concentrated solutions, and the compressibility of liquid at high pressure, a nonideality coefficient (osmotic coefficient  $\phi$ ) must be incorporated into the equation:

$$\pi = \phi CRT \quad (17-7)$$

where  $\phi$  = osmotic coefficient, unitless

It should be noted that the thermodynamic equation for osmotic pressure (Eq. 17-5) contains no terms identifying the solute. Osmotic pressure is strictly a function of the concentration, or mole fraction, of water in the system. Solutes reduce the mole fraction of water, and the effect of multiple solutes is additive because they cumulatively reduce the mole fraction of water. Solutes that dissociate also have an additive effect on the mole fraction of water (e.g., addition of 1 mol of NaCl produces 2 mol of ions in solution, doubling the osmotic pressure compared to a solute that does not dissociate). If multiple solutes are added on an equal-mass basis, the solute with the lowest molecular weight produces the greatest osmotic pressure. The use of Eq. 17-7 is demonstrated in Example 17-1.

### Example 17-1 Osmotic pressure calculations

Calculate the osmotic pressure of 1000-mg/L solutions of the following solutes at a temperature of 20°C assuming an osmotic coefficient of 0.95: (1) NaCl, (2) SrSO<sub>4</sub>, and (3) glucose (C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>). Note that NaCl and SrSO<sub>4</sub> both dissociate into 2 ions when dissolved into water.

#### Solution

1. Determine the osmotic pressure for NaCl, first by calculating the molar concentration of ions and then using Eq. 17-7:

$$C = \frac{(2 \text{ mol ion/mol NaCl})(1000 \text{ mg/L})}{(10^3 \text{ mg/g})(58.4 \text{ g/mol})} = 0.0342 \text{ mol/L}$$

$$\begin{aligned} \pi &= \phi CRT = (0.95)(0.0342 \text{ mol/L})(0.083145 \text{ L} \cdot \text{bar/K} \cdot \text{mol})(293 \text{ K}) \\ &= 0.79 \text{ bar} \end{aligned}$$

2. Determine the osmotic pressure for SrSO<sub>4</sub>:

$$C = \frac{(2 \text{ mol ion/mol SrSO}_4)(1000 \text{ mg/L})}{(10^3 \text{ mg/g})(183.6 \text{ g/mol})} = 0.0109 \text{ mol/L}$$

$$\begin{aligned} \pi &= (0.95)(0.0109 \text{ mol/L})(0.083145 \text{ L} \cdot \text{bar/K} \cdot \text{mol})(293 \text{ K}) \\ &= 0.25 \text{ bar} \end{aligned}$$

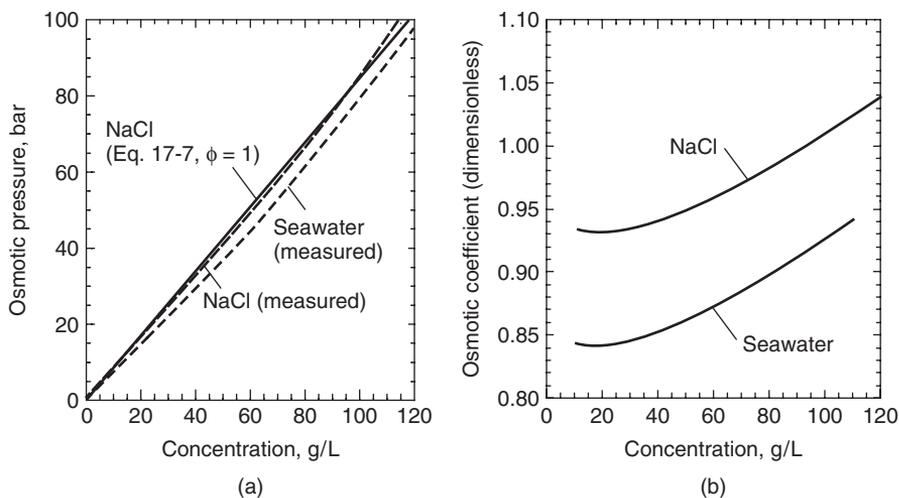

3. Determine the osmotic pressure for glucose (no dissociation):

$$C = \frac{1000 \text{ mg/L}}{(10^3 \text{ mg/g})(180 \text{ g/mol})} = 0.0056 \text{ mol/L}$$

$$\begin{aligned} \pi &= (0.95)(0.00556 \text{ mol/L})(0.083145 \text{ L} \cdot \text{bar/K} \cdot \text{mol})(293 \text{ K}) \\ &= 0.13 \text{ bar} \end{aligned}$$

#### Comment

Each solution contains the same mass of solute. Because NaCl and SrSO<sub>4</sub> dissociate into two ions, the molar ion concentration is double the molar concentration of added salt. The NaCl has a higher osmotic pressure because it has a lower molecular weight. Even though SrSO<sub>4</sub> and glucose have nearly the same molecular weight, the osmotic pressure of SrSO<sub>4</sub> is nearly double that of glucose because it dissociates.

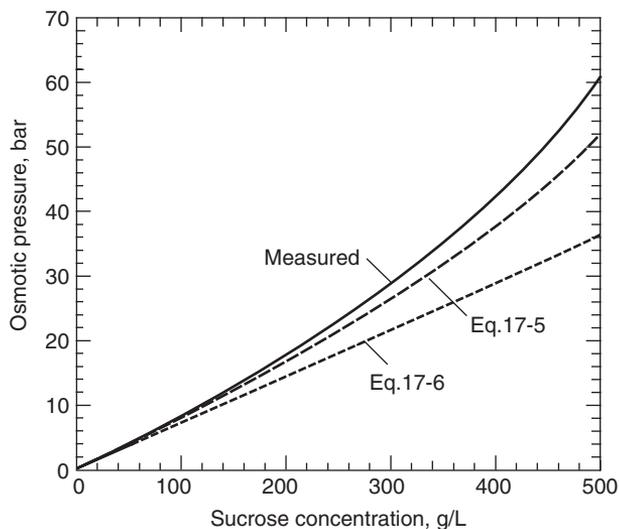

**Figure 17-9**

(a) Osmotic pressure of aqueous solutions of sodium chloride. (b) Osmotic coefficients for sodium chloride and seawater (osmotic coefficient for seawater with the van't Hoff equation is based on a concentration of NaCl equal to the TDS of the seawater).

The osmotic pressure of a solution of sodium chloride, calculated with Eq. 17-7 and  $\phi = 1$ , is shown on Fig. 17-9a along with experimentally determined values. Over the range of salt concentrations of interest in seawater desalination, the osmotic coefficient for sodium chloride ranges from 0.93 to 1.03 and is shown as a function of solution concentration on Fig. 17-9b. Osmotic coefficients for other electrolytes are available in Robinson and Stokes (1959). The deviation between measured and calculated values of osmotic pressure can be significantly greater for other solutes and higher concentrations, as shown for sucrose solutions on Fig. 17-10.

Reported values for the osmotic pressure of seawater (Sourirajan, 1970) are about 10 percent below measured values for sodium chloride, as shown on Fig. 17-9a, due to the presence of compounds with a higher molecular weight than sodium chloride. The osmotic pressure for seawater can be calculated with Eq. 17-7 and an equivalent concentration of sodium chloride by using the osmotic coefficient for seawater shown on Fig. 17-9b.

Two opposing forces contribute to the rate of water flow through the semipermeable membrane on Fig. 17-8b: (1) the concentration gradient and (2) the pressure gradient. These opposing forces are exploited in RO. Consider a new experiment using the apparatus on Fig. 17-8, modified so that it is possible to exert an external force on the left side, as shown on Fig. 17-8c. Applying a force equivalent to the osmotic pressure places the system in thermodynamic equilibrium, and no water flows. Applying a force in excess of the osmotic pressure places the system in nonequilibrium,

**Figure 17-10**

Osmotic pressure of aqueous solutions of sucrose.

with a pressure gradient exceeding the chemical potential gradient. Liquid would flow from left to right, that is, from the concentrated solution to the dilute solution. The process of causing water to flow from a concentrated solution to a dilute solution across a semipermeable membrane by the application of an external pressure in excess of the osmotic pressure is called reverse osmosis.

Models have been developed to describe the flux of water and solutes through RO membranes using two basic approaches. The first approach relies on fundamental thermodynamics and does not depend on a physical description of the membrane. The other approach uses physical and chemical descriptions of the membrane and feed solution, such as membrane thickness and porosity. Mathematical development of the models that include descriptions of the membrane and feed solution is beyond the scope of this text but can be found in the published literature (Cheryan and Nichols, 1992; Lonsdale, 1972; Lonsdale et al., 1965; Merten, 1966; Noordman and Wesselingh, 2002; Reid, 1972; Spiegler and Kedem, 1966; Wiesner and Aptel, 1996). For a student learning about RO, the important issue is to develop a conceptual understanding of how water and solutes pass through RO membranes. To promote this understanding, a basic qualitative description of the solution–diffusion, pore flow, and preferential sorption–capillary flow models are presented in the following sections.

#### SOLUTION–DIFFUSION MODEL

The solution–diffusion model (Lonsdale et al., 1965) describes permeation through a dense membrane where the active layer is permeable but does not

#### Models for Water and Solute Transport through RO Membranes

have pores. Water and solutes dissolve into the solid membrane material, diffuse through the solid, and reliquefy on the permeate side of the membrane. Dissolution of water and solutes into a solid material occurs if the solid is loose enough to allow individual water and solute molecules to travel along the interstices between polymer molecules of the membrane. Liquids behave as liquids because of attractive interactions with surrounding liquid molecules. Thus, even if water molecules travel along a defined path (which hypothetically could be called a pore), they are surrounded by polymer molecules and not other water molecules and therefore are dissolved in the solid, not present as a liquid phase. Diffusion occurs by movement of the water and solute molecules in the direction of the Gibbs energy gradient. Separation occurs when the flux of the water is different from the flux of the solutes.

Equation 17-7 describes a proportionality between osmotic pressure and concentration. Therefore, the driving force (Gibbs energy gradient) for any component can be written equivalently in terms of either pressure or concentration provided the mass transfer coefficient has the proper units. For water, the driving force is expressed in terms of the net pressure gradient, that is, the applied pressure in excess of the osmotic pressure. Solute transport is expressed in terms of the concentration gradient, and most models neglect the effect of applied pressure on solute transport. Flux through the membrane is determined by both solubility and diffusivity. Components of low solubility have a low driving force, and components of low diffusivity have a low diffusion coefficient. The solution–diffusion model predicts that separation occurs because the solubility, diffusivity, or both of the solutes are much lower than those of water, resulting in a lower solute concentration in the permeate than in the feed.

#### **PORE FLOW MODELS**

The solution–diffusion model does not consider convective flow through the membrane. Other models consider RO membranes to have void spaces (pores) through which liquid water travels. The pore flow models consider water and solute fluxes to be coupled, meaning the solutes are convected through the membrane with the water. Thus, rejection occurs through mechanisms similar to those described in Chap. 12 for membrane filtration, meaning the solute molecules are “strained” at the entrance to the pores. Because solute and water molecules are similar in size, the rejection mechanism is not a physical sieving and must consider chemical effects such as electrostatic repulsion between the ions and membrane material.

#### **PREFERENTIAL SORPTION–CAPILLARY FLOW MODEL**

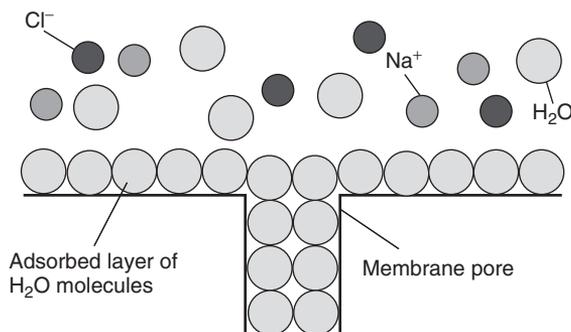

A third description of water and salt permeation through membranes is provided by the preferential sorption–capillary flow model, which assumes that the membrane has pores. Separation occurs when one component of the feed solution (either the solute or the water) is preferentially

adsorbed to the pore walls and is transported through the membrane by surface diffusion. Membrane materials with a low dielectric constant, such as cellulose acetate, repel ions and preferentially adsorb water, forming a sorbed layer with a reduced concentration of salts. The sorbed layer moves through the membrane by surface diffusion, leaving behind solution components that are repelled from the membrane surface. Separation is a function of the surface chemistry of the membrane and solutes, rather than pore dimensions, although the maximum pore dimension to effect good removal of solutes is two times the thickness of the adsorbed layer, as shown on Fig. 17-11.

### COUPLING

Other models consider a combination of permeation mechanisms. The solution–diffusion–imperfection model (Sherwood et al., 1967) assumes that water and solute permeate the membrane by both solution–diffusion and pore flow. The permeation by solution–diffusion is uncoupled but the pore flow is completely coupled. The flux of water by solution–diffusion is proportional to the net applied pressure ( $\Delta P - \Delta\pi$ ), the diffusion of solutes is proportional to the concentration gradient ( $\Delta C$ ), and pore flow is proportional to the applied pressure gradient ( $\Delta P$ ). To achieve high rejection, the pore flow must be a small fraction of the total flow.

In addition to coupling between water and solutes, coupling between solutes must be considered. Electroneutrality must be maintained in both the permeate and the concentrate streams. Thus, preferential transport of ions of one charge can influence the transport of ions of the opposite charge. For instance, negative rejection of hydrogen ions (the concentration of hydrogen ions in the permeate is higher than in the feed solution, manifested as a lower pH in the permeate) is typically observed in RO operations. This occurs because of higher flux of negatively charged ions, such as chloride, than the salt's coion, sodium. Because hydrogen ions are more mobile than sodium ions, the flux of hydrogen ions increases to maintain electroneutrality in the permeate.

**Figure 17-11** Preferential-sorption capillary flow model. Ions are repelled from the membrane surface, resulting in an adsorbed layer of water. The adsorbed water flows through capillary pores in the membrane surface, and the repelled species are left in the feed solution. Good separation can be obtained if the pore diameter is less than 2 times the adsorbed layer thickness.

## Mechanisms of Solute Rejection

The membrane permeation models suggest various mechanisms for rejection. The basic mechanisms of rejection are electrostatic repulsion at the membrane surface, solubility and diffusivity through the membrane material due to chemical effects, or straining due to the size and other chemical properties of molecules.

Reverse osmosis and NF membranes are often negatively charged in operation because of the presence of ionized functional groups, such as carboxylates, in the membrane material. Negatively charged ions may be rejected at the membrane surface due to electrostatic repulsion, and positively charged ions may be rejected to maintain electroneutrality in the feed and permeate solutions. The presence of polar and hydrogen-bondable functional groups in the membrane increases the solubility of polar compounds such as water over nonpolar compounds, providing a mechanism for greater flux of water through the membrane. Large molecules would be expected to have lower diffusivity through the membrane material or be unable to pass through the membrane at all.

Experimental observations are consistent with these rejection mechanisms. Small polar molecules such as water generally have the highest flux. Dissolved gases such as  $\text{H}_2\text{S}$  and  $\text{CO}_2$ , which are small, uncharged, and polar, also permeate RO membranes well. Monovalent ions such as  $\text{Na}^+$  and  $\text{Cl}^-$  permeate better than divalent ions ( $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ) because the divalent ions have greater electrostatic repulsion. Acids and bases ( $\text{HCl}$ ,  $\text{NaOH}$ ) permeate better than their salts ( $\text{Na}^+$ ,  $\text{Cl}^-$ ) because of decreased electrostatic repulsion.

Silica is present in water as uncharged silicic acid ( $\text{H}_4\text{SiO}_4$ ) below the  $\text{p}K_a$  of 9.84 and is poorly rejected by RO membranes. Similarly, boron is present in water as uncharged boric acid ( $\text{H}_3\text{BO}_3$ ) below the  $\text{p}K_a$  of 9.24 and also permeates well. The poor removal of boron, coupled with a 1 mg/L notification level in California, often requires specific design considerations for seawater RO systems in that state, such as design of two-pass systems. Increasing the pH to above the  $\text{p}K_a$  values results in good removal for both silica and boron.

Within a homologous series, permeation increases with decreasing molecular weight. High-molecular-weight organic materials do not permeate RO membranes at all. Reverse osmosis membranes are capable of rejecting up to 99 percent of monovalent ions. Nanofiltration membranes reject between 80 and 99 percent of divalent ions while achieving low rejection of monovalent ions.

## Equations for Water and Solute Flux

Based on the models presented above, a variety of equations have been developed for the rate of water and solute mass transfer through an RO membrane. Ultimately, these models express flux as the product of a mass transfer coefficient and a driving force. The driving force for water flux

through RO membranes is the net pressure differential, or the difference between the applied and osmotic pressure differentials:

$$\Delta P_{\text{NET}} = \Delta P - \Delta \pi = (P_F - P_P) - (\pi_F - \pi_P) \quad (17-8)$$

where  $\Delta P_{\text{NET}}$  = net transmembrane pressure, bar

Subscripts  $F$  and  $P$  refer to the feed and permeate, respectively.

The water flux through RO membranes is described by the expression

$$J_W = k_W(\Delta P - \Delta \pi) \quad (17-9)$$

where  $J_W$  = volumetric flux of water,  $\text{L}/\text{m}^2 \cdot \text{h}$

$k_W$  = mass transfer coefficient for water flux,  $\text{L}/\text{m}^2 \cdot \text{h} \cdot \text{bar}$

Water flux is normally reported as a volumetric flux ( $\text{L}/\text{m}^2 \cdot \text{h}$  or  $\text{gal}/\text{ft}^2 \cdot \text{d}$ ) and the mass transfer coefficient is typically reported with units of  $\text{L}/\text{m}^2 \cdot \text{h} \cdot \text{bar}$  or  $\text{gal}/\text{ft}^2 \cdot \text{d} \cdot \text{atm}$ . Equation 17-9 is valid at any point on the membrane surface between the feed water entrance and concentrate discharge in a membrane element, but it should be noted that both applied and osmotic pressures change continuously along the length of a spiral-wound element due to head loss and the changing solute concentration. As a result, overall flux must be determined by integrating Eq. 17-9 across the length of the membrane element, as will be demonstrated in the design section of this chapter.

The driving force for solute flux is the concentration gradient, and the flux of solutes through RO membranes is expressed as

$$J_S = k_S(\Delta C) \quad (17-10)$$

where  $J_S$  = mass flux of solute,  $\text{mg}/\text{m}^2 \cdot \text{h}$

$k_S$  = mass transfer coefficient for solute flux,  $\text{L}/\text{m}^2 \cdot \text{h}$  or  $\text{m}/\text{h}$

$\Delta C$  = concentration gradient across membrane,  $\text{mg}/\text{L}$

Solute flux is normally reported as a mass flux with units of  $\text{mg}/\text{m}^2 \cdot \text{h}$  or  $\text{lb}/\text{ft}^2 \cdot \text{d}$ . Values of  $k_W$  and  $k_S$  are determined experimentally by membrane manufacturers. The solute concentration in the permeate is the ratio of the fluxes of solutes and water, as shown by

$$C_P = \frac{J_S}{J_W} \quad (17-11)$$

Thus, the lower the flux of solutes or the higher the flux of water, the better removal of solutes is achieved and the permeate will have a lower solute concentration. The ratio of permeate flow to feed water flow, or recovery, is calculated as

$$r = \frac{Q_P}{Q_F} \quad (17-12)$$

where  $Q = \text{flow, m}^3/\text{s}$   
 $r = \text{recovery, dimensionless}$

Using flow and mass balance principles, the solute concentration in the concentrate stream can be calculated from the recovery and solute rejection. The pertinent flow and mass balances using flow and concentration terminology as shown on Fig. 17-1 are

$$\text{Flow balance: } Q_F = Q_P + Q_C \quad (17-13)$$

$$\text{Mass balance: } C_F Q_F = C_P Q_P + C_C Q_C \quad (17-14)$$

where  $C = \text{concentration, mol/L or mg/L}$

Combining the mass and flow balances with Eq. 17-1 (rejection) and Eq. 17-12 (recovery) yields the following expression for the solute concentration in the concentrate stream:

$$C_C = C_F \left[ \frac{1 - (1 - \text{Rej})r}{1 - r} \right] \quad (17-15)$$

where  $\text{Rej} = \text{rejection (dimensionless, expressed as a fraction)}$

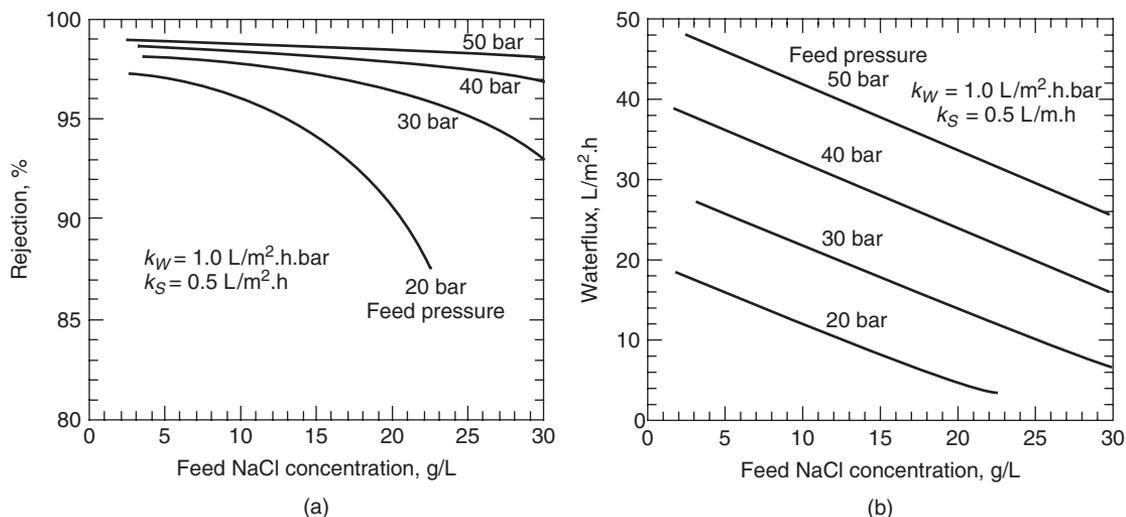

Rejection is frequently close to 100 percent, in which case Eq. 17-15 can be simplified as follows:

$$C_C = C_F \left( \frac{1}{1 - r} \right) \quad (17-16)$$

As shown in Eqs. 17-9 and 17-10, water flux depends on the pressure gradient and solute flux depends on the concentration gradient. As feed water solute concentration increases at constant pressure, the water flux decreases (because of higher  $\Delta\pi$ ) and the solute flux increases (because of higher  $\Delta C$ ), which reduces rejection and causes a deterioration of permeate quality. As the feed water pressure increases, water flux increases but the solute flux is essentially constant. Therefore, as the water flux increases, the permeate solute concentration decreases, and the rejection increases. These relationships are illustrated on Fig. 17-12.

### Temperature and Pressure Dependence

Membrane performance declines (water flux decreases, solute flux increases) due to fouling and membrane aging. However, fluxes of water and solute also vary because of changes in feed water temperature, pressure, velocity, and concentration. To evaluate the true decline in system performance due to fouling and aging, permeate flow rate and salt passage must be compared at standard conditions. Reverse osmosis design manuals present equations for normalizing RO membrane performance in slightly different ways; the equations presented here are adapted from ASTM (2001e) and AWWA (2007). These procedures incorporate the

**Figure 17-12**

Effect of feed water concentration and pressure on (a) percent solute rejection and (b) water flux.

use of temperature and pressure correction factors, evaluated at standard (subscript  $S$ ) and measured (subscript  $M$ ) conditions:

$$J_{W,S} = J_{W,M} (\text{TCF}) \frac{\text{NDP}_S}{\text{NDP}_M} \quad (17-17)$$

or

$$Q_{P,S} = Q_{P,M} (\text{TCF}) \frac{\text{NDP}_S}{\text{NDP}_M} \quad (17-18)$$

where TCF = temperature correction factor (defined below),  
dimensionless

NDP = net driving pressure (defined below), bar

Temperature affects the fluid viscosity and the membrane material. The relationship between membrane material, temperature, and flux is specific to individual products, so TCF values should normally be obtained from membrane manufacturers, who determine values experimentally. If manufacturer TCF values are unavailable, the relationship between flux and fluid viscosity can be approximated by the following expression, which may be appropriate for membranes containing pores:

$$\text{TCF} = (1.03)^{T_S - T_M} \quad (17-19)$$

where  $T$  = temperature,  $^{\circ}\text{C}$

The standard temperature is typically taken to be 25°C for reverse osmosis operation.

The net driving pressure accounts for changes in feed and permeate pressures, feed channel head loss, and osmotic pressure. In spiral-wound elements, the applied pressure decreases and osmotic pressure increases continuously along the length of the feed–concentrate channel as permeate flows through the membrane. Thus, the net driving pressure must take average conditions into account, as shown in

$$\text{NDP} = \Delta P - \Delta \pi = (P_{\text{FC,ave}} - P_P) - (\pi_{\text{FC,ave}} - \pi_P) \quad (17-20)$$

where  $P_{\text{FC,ave}}$  = average pressure in the feed–concentrate channel, bar  
 $= \frac{1}{2} (P_F + P_C)$   
 $P_P$  = permeate pressure, bar  
 $\pi_{\text{FC,ave}}$  = average feed–concentrate osmotic pressure (see below), bar  
 $\pi_P$  = permeate osmotic pressure, bar

Feed, concentrate, and permeate pressures are easily measured using system instrumentation. Osmotic pressure must be calculated from solute concentration using Eq. 17-7. Although osmotic pressure increases continuously along the length of a spiral-wound element, solute concentration normally can only be measured in the feed and concentrate streams. Manufacturers use various procedures for determining the average concentration in the feed–concentrate channel and must be contacted for procedures for calculating the average concentration in the feed–concentrate channel. The two most common approaches for determining the average concentration in the feed channel are (1) an arithmetic average (Eq. 17-21) and (2) the log mean average (Eq. 17-22):

$$C_{\text{FC,ave}} = \frac{1}{2} (C_F + C_C) \quad (17-21)$$

$$C_{\text{FC,ave}} = \frac{C_F}{r} \ln \left( \frac{1}{1-r} \right) \quad (17-22)$$

Because head loss is a function of feed flow and osmotic pressure is a function of solute concentration, the system design must establish standard conditions for these parameters in addition to applied pressure.

Solute flux across the membrane is affected by temperature and solute concentration, so it is standardized by multiplying the measured flux by the TCF and ratio of concentration at standard and measured conditions, as follows:

$$J_{S,S} = J_{S,M} (\text{TCF}) \frac{C_{\text{FC,S}}}{C_{\text{FC,M}}} \quad (17-23)$$

Membrane performance, however, is usually evaluated in terms of salt passage rather than solute flux. Salt passage is defined as the ratio of permeate concentration to feed concentration:

$$SP = \frac{C_P}{C_F} = 1 - Re_j \quad (17-24)$$

where  $SP$  = salt passage

By rearranging and substituting Eqs. 17-11, 17-17, and 17-24 into Eq. 17-23, standard membrane performance in terms of salt passage is obtained (ASTM, 2001e) as follows:

$$SP_S = SP_M \left( \frac{NDP_M}{NDP_S} \right) \left( \frac{C_{FC,S}}{C_{FC,M}} \right) \left( \frac{C_{F,M}}{C_{F,S}} \right) \quad (17-25)$$

Rearranging Eq. 17-25 in terms of rejection yields the expression

$$Re_{j_S} = 1 - (1 - Re_{j_M}) \left( \frac{NDP_M}{NDP_S} \right) \left( \frac{C_{F,M}}{C_{F,S}} \right) \left( \frac{C_{FC,S}}{C_{FC,M}} \right) \quad (17-26)$$

In multistage systems, it is necessary to standardize the water flux and recovery for each stage independently. The procedures for standardizing RO performance data are shown in Example 17-2.

### Example 17-2 Standardization of RO operating data

An RO system uses a shallow brackish groundwater that averages around 4500 mg/L TDS composed primarily of sodium chloride. Permeate flow is maintained constant, but temperature, pressure, and feed concentration change over time as shown in the table below. The operators need to determine whether fouling has occurred between January and May.

Parameter	Unit	January 1	May 31
Permeate flow	m <sup>3</sup> /d	7500	7500
Feed pressure	bar	34.5	32.1
Concentrate pressure	bar	31.4	29.1
Permeate pressure	bar	0.25	0.25
Feed TDS concentration	mg/L	4612	4735
Permeate TDS concentration	mg/L	212	230
Recovery	%	0.69	0.72
Water temperature	°C	11	18

The pressure vessels contain seven membrane elements. The manufacturer has stated that performance data for this membrane element were developed using the following standard conditions:

Parameter	Unit	Standard
Temperature	°C	25
Feed pressure	bar	30
Permeate pressure	bar	0
Head loss per element	bar	0.4
Feed TDS concentration	mg/L	2000
Permeate TDS concentration	mg/L	100
Recovery	%	80

Determine the change in system performance (permeate flow and salt passage) that has occurred between January 1 and May 31. Assume  $\phi = 1.0$ .

### Solution

1. Calculate the TCF for the January operating condition:

$$TCF_{Jan} = (1.03)^{T_s - T_M} = (1.03)^{25 - 11} = 1.512$$

2. Calculate the NDP for the January operating condition.
  - a. Calculate the average molar solute concentration in the feed-concentrate channel using Eq. 17-22:

$$C_{CF,Jan} = \frac{C_F}{r} \ln \left( \frac{1}{1-r} \right) = \frac{4612 \text{ mg/L}}{0.69} \ln \left( \frac{1}{1-0.69} \right)$$

$$= 7828 \text{ mg/L}$$

$$C_{CF,Jan} = \frac{(7828 \text{ mg/L})(2 \text{ mol ions/mol NaCl})}{(10^3 \text{ mg/g})(58.4 \text{ g/mol})}$$

$$= 0.268 \text{ mol/L}$$

- b. Calculate the osmotic pressure in the feed-concentrate channel using Eq. 17-7:

$$\pi_{CF,Jan} = \phi CRT$$

$$= (0.268 \text{ mol/L})(0.083145 \text{ L} \cdot \text{bar/K} \cdot \text{mol})(284 \text{ K})$$

$$= 6.33 \text{ bar}$$

- c. Calculate the molar concentration and osmotic pressure in the permeate:

$$C_{P,Jan} = \frac{(212 \text{ mg/L})(2 \text{ mol ions/mol NaCl})}{(10^3 \text{ mg/g})(58.4 \text{ g/mol})} = 0.0073 \text{ mol/L}$$

$$\pi_{P,Jan} = (0.0073 \text{ mol/L})(0.083145 \text{ L} \cdot \text{bar/K} \cdot \text{mol})(284 \text{ K})$$

$$= 0.17 \text{ bar}$$

- d. Calculate the NDP for the January operating condition using Eq. 17-20:

$$P_{FC,ave} = \frac{1}{2} (P_F + P_C) = \frac{1}{2} (34.5 + 31.4) = 32.95 \text{ bar}$$

$$\begin{aligned} \text{NDP} &= (32.95 \text{ bar} - 0.25 \text{ bar}) - (6.33 \text{ bar} - 0.17 \text{ bar}) \\ &= 26.5 \text{ bar} \end{aligned}$$

3. Repeat the calculations in steps 1 and 2 for the standard condition and the May operating condition. The concentrate pressure is not given for the standard operating condition, but can be calculated from the given head loss information:

$$h_L = (0.4 \text{ bar/element})(7 \text{ elements}) = 2.8 \text{ bar}$$

$$P_C = 30 \text{ bar} - 2.8 \text{ bar} = 27.2 \text{ bar}$$

The remaining calculations are summarized in the table below:

Parameter	Unit	Standard Conditions	January 4 Conditions	May 23 Conditions
TCF		1.0	1.51	1.23
$C_{CF,ave}$	mg/L	4024	7828	8372
$\pi_{CF}$	bar	3.36	6.33	6.94
$\pi_P$	bar	0.08	0.17	0.19
$P_{CF,ave}$	bar	28.6	32.95	30.6
NDP	bar	25.3	26.5	23.6

4. Calculate the standard permeate flow for each date using Eq. 17-17:

$$\begin{aligned} Q_{W,S(\text{Jan})} &= 7500 \text{ m}^3/\text{d} (1.51) \left( \frac{25.3 \text{ bar}}{26.5 \text{ bar}} \right) \\ &= 10,800 \text{ m}^3/\text{d} \end{aligned}$$

$$\begin{aligned} Q_{W,S(\text{May})} &= 7500 \text{ m}^3/\text{d} (1.23) \left( \frac{25.3 \text{ bar}}{23.6 \text{ bar}} \right) \\ &= 9900 \text{ m}^3/\text{d} \end{aligned}$$

5. Calculate the actual salt passage for each date using Eq. 17-24:

$$SP_{M,\text{Jan}} = \frac{212 \text{ mg/L}}{4612 \text{ mg/L}} = 0.046$$

$$SP_{M,\text{May}} = \frac{230 \text{ mg/L}}{4735 \text{ mg/L}} = 0.049$$

6. Calculate the standard salt passage for each date using Eq. 17-25:

$$\begin{aligned} SP_{S(\text{Jan})} &= (0.046) \left( \frac{26.5 \text{ bar}}{25.3 \text{ bar}} \right) \left( \frac{4612 \text{ mg/L}}{2000 \text{ mg/L}} \right) \left( \frac{4024 \text{ mg/L}}{7828 \text{ mg/L}} \right) \\ &= 0.057 \end{aligned}$$

$$\begin{aligned} SP_{S(\text{May})} &= (0.049) \left( \frac{23.6 \text{ bar}}{25.3 \text{ bar}} \right) \left( \frac{4735 \text{ mg/L}}{2000 \text{ mg/L}} \right) \left( \frac{4024 \text{ mg/L}}{8372 \text{ mg/L}} \right) \\ &= 0.052 \end{aligned}$$

### Comment

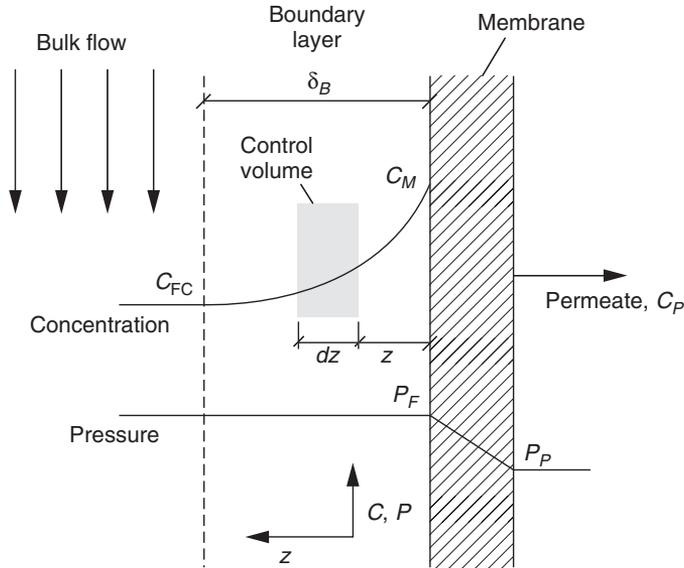

Even though the membrane system is producing the same permeate flow with less pressure in May than in January, there has been a 8 percent loss of system performance because the standard permeate flow has declined from 10800 to 9900 m<sup>3</sup>/d. The standard salt passage also decreased between January and May, even though a higher permeate concentration was observed.

## Concentration Polarization

Concentration polarization (CP) is the accumulation of solutes near the membrane surface and has adverse effects on membrane performance. The flux of water through the membrane brings feed water (containing water and solute) to the membrane surface, and as clean water flows through the membrane, the solutes accumulate near the membrane surface. In membrane filtration, particles contact the membrane and form a cake layer. Because the rejection mechanisms for reverse osmosis are different, solutes stay in solution and form a boundary layer of higher concentration at the membrane surface. Thus, the concentration in the feed solution becomes polarized, with the concentration at the membrane surface higher than the concentration in the bulk feed water in the feed channel.

Concentration polarization has several negative impacts on RO performance:

1. Water flux is lower because the osmotic pressure gradient is higher due to the higher concentration of solutes at the membrane surface.
2. Rejection is lower due to an increase in solute transport across the membrane from an increase in the concentration gradient and a decrease in the water flux.
3. Solubility limits of solutes may be exceeded, leading to precipitation and scaling.

**Figure 17-13**  
Schematic of concentration polarization.

Equations for concentration polarization can be derived from film theory (see Chap. 7) and mass balances. In the membrane schematic shown on Fig. 17-13, feed water is traveling vertically on the left side of the membrane and water is passing through the membrane to the right. According to film theory, a boundary layer forms at the surface of the membrane. Water and solutes move through the boundary layer toward the membrane surface. As water passes through the membrane, the solute concentration at the membrane surface increases. The concentration gradient in the boundary layer leads to diffusion of solutes back toward the bulk feed water. During continuous operation, a steady-state condition is reached in which the solute concentration at the membrane surface is constant with respect to time because the convective flow of solutes toward the membrane is balanced by the diffusive flow of solutes away from the surface. The solute flux toward the membrane surface due to the convective flow of water is described by the expression

$$J_s = J_w C \quad (17-27)$$

A mass balance can be developed at the membrane surface as follows:

$$\text{Mass accumulation} = \text{mass in} - \text{mass out} \quad (17-28)$$

With no accumulation of mass at steady state, the solute flux toward the membrane surface must be balanced by fluxes of solute flowing away from

the membrane (due to diffusion) and through the membrane (into the permeate) as follows:

$$\frac{dM}{dt} = 0 = J_W Ca - D_L \frac{dC}{dz} a - J_W C_P a \quad (17-29)$$

where  $M$  = mass of solute, g  
 $t$  = time, s  
 $D_L$  = diffusion coefficient for solute in water, m<sup>2</sup>/s  
 $z$  = distance perpendicular to membrane surface, m  
 $a$  = surface area of membrane, m<sup>2</sup>

Equation 17-29 applies not only at the membrane surface but also at any plane in the boundary layer because the net solute flux must be constant throughout the boundary layer to prevent the accumulation of solute anywhere within that layer (the last term in Eq. 17-29 represents the solute that must pass through the boundary layer and the membrane to end up in the permeate). Rearranging and integrating Eq. 17-29 across the thickness of the boundary layer with the boundary conditions  $C(0) = C_M$  and  $C(\delta_B) = C_{FC}$ , where  $C_{FC}$  is the concentration in the feed-concentrate channel and  $C_M$  is the concentration at the membrane surface, are done in the following equations:

$$D_L \int_{C_M}^{C_{FC}} \frac{dC}{C - C_P} = -J_W \int_0^{\delta_B} dz \quad (17-30)$$

Integrating yields

$$\ln \left( \frac{C_M - C_P}{C_{FC} - C_P} \right) = \frac{J_W \delta_B}{D_L} \quad (17-31)$$

$$\frac{C_M - C_P}{C_{FC} - C_P} = e^{(J_W \delta_B)/D_L} = e^{J_W/k_{CP}} \quad (17-32)$$

where  $k_{CP} = D_L/\delta_B$  concentration polarization mass transfer coefficient, m/s

The concentration polarization mass transfer coefficient describes the diffusion of solutes away from the membrane surface. Concentration polarization is expressed as the ratio of the membrane and feed-concentrate channel solute concentrations as follows:

$$\beta = \frac{C_M}{C_{FC}} \quad (17-33)$$

where  $\beta$  = concentration polarization factor, dimensionless

Combining Eq. 17-33 with Eqs. 17-1 and 17-32 results in the following expression:

$$\beta = (1 - \text{Rej}) + \text{Rej} (e^{J_W/k_{CP}}) \quad (17-34)$$

If rejection is high (greater than 99 percent), Eq. 17-34 can be reasonably simplified as follows:

$$\beta = e^{J_W/k_{CP}} \quad (17-35)$$

To predict the extent of concentration polarization, the value of the concentration polarization mass transfer coefficient is needed. As demonstrated in Chap. 7, mass transfer coefficients are often calculated using a correlation between Sherwood (Sh), Reynolds (Re), and Schmidt (Sc) numbers. Correlations for mass transfer coefficients depend on physical characteristics of the system and the flow conditions (e.g., laminar or turbulent). To promote turbulent conditions and minimize concentration polarization in RO membrane elements, spiral-wound elements contain mesh feed channel spacers and maintain a high velocity flow parallel to the membrane surface. The feed channel spacer complicates the flow patterns and promotes turbulence. The superficial velocity (assuming an empty channel) in a spiral-wound element typically ranges from 0.02 to 0.2 m/s, but the actual velocity is higher because of the space taken up by the spacer.

In the spacer-filled feed channel of a spiral-wound element, Schock and Miquel (1987) found that the concentration polarization mass transfer coefficient could be predicted by the following equation, when calculations for the velocity in the channel and the hydraulic diameter took the presence of the spacer into account:

$$k_{CP} = 0.023 \frac{D_L}{d_H} (\text{Re})^{0.875} (\text{Sc})^{0.25} \quad (17-36)$$

$$\text{Re} = \frac{\rho v d_H}{\mu} \quad (17-37)$$

$$\text{Sc} = \frac{\mu}{\rho D_L} \quad (17-38)$$

where

- Re = Reynolds number, dimensionless
- Sc = Schmidt number, dimensionless
- $v$  = velocity in feed channel, m/s
- $\rho$  = feed water density, kg/m<sup>3</sup>
- $\mu$  = feed water dynamic viscosity, kg/m · s
- $d_H$  = hydraulic diameter, m

The hydraulic diameter is defined as

$$d_H = \frac{4 (\text{volume of flow channel})}{\text{wetted surface}} \quad (17-39)$$

For hollow-fiber membranes (circular cross section), the hydraulic diameter is equal to the inside fiber diameter. Spiral-wound membranes can be approximated by flow through a slit, where the width is much larger than the feed channel height ( $w \gg h$ ). In an empty channel (i.e., the spacer is neglected), the hydraulic diameter is twice the feed channel height, as shown in the equation

$$d_H = \frac{4wh}{2w + 2h} \approx 2h \quad (17-40)$$

where  $h$  = feed channel height, m  
 $w$  = channel width, m

The feed channel height in typical spiral-wound elements ranges from about 0.4 to 1.2 mm and is governed by the thickness of the spacer.

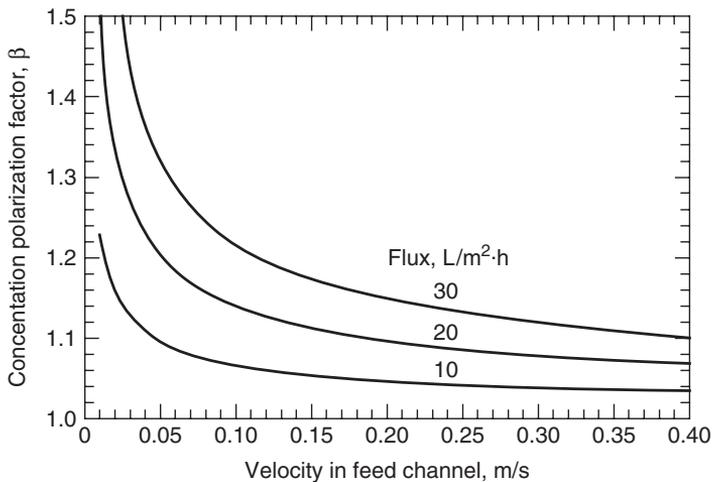

Because the mesh spacer affects mass transfer in the feed channel and many feed spacer configurations have been developed, numerous other correlations have been developed for the mass transfer coefficient. Mariñas and Urama (1996) developed a correlation using the channel height and the superficial velocity, which eliminates the task of determining the parameters of the spacer. Their correlation is

$$k_{CP} = \lambda \frac{D_L}{d_H} (\text{Re})^{0.50} (\text{Sc})^{1/3} \quad (17-41)$$

where  $\lambda$  ranged from 0.40 to 0.54 for different elements. Many spacer configurations have been evaluated in small flat-sheet membrane cells instead of spiral-wound elements, and in those cases, the mass transfer correlation often has an additional term for the ratio of the channel height ( $d_H$ ) to channel length ( $L$ ). For instance, the correlation presented by Shakaib et al. (2009) for spacers with axial and transverse filaments is

$$k_{CP} = 0.664 \frac{D_L}{d_H} (\text{Re})^{0.5} (\text{Sc})^{0.33} \left( \frac{d_H}{L} \right)^{0.5} \quad (17-42)$$

Concentration polarization varies along the length of a membrane element; the parameters that change most significantly are the velocity in the feed channel ( $v$ ) and the permeate flux ( $J_W$ ). Variation in the concentration polarization factor as a function of these parameters is shown on Fig. 17-14. As might be expected, concentration polarization increases as the permeate flux increases and as the velocity in the feed channel decreases.

**Figure 17-14**  
 Concentration polarization factors as function of feed channel velocity and permeate flux.

The maximum concentration polarization allowed for membrane elements is specified by manufacturers;  $\beta = 1.2$  is a typical value. The importance of maintaining a high velocity in the feed–concentrate channel, particularly for membranes that achieve higher permeate flux, is clearly demonstrated on Fig. 17-14. Calculation of the concentration polarization factor is illustrated in Example 17-3.

### Example 17-3 Concentration polarization

For a spiral-wound element, calculate the concentration polarization factor and the concentration of sodium at the membrane surface given the following information: water temperature 20°C, feed channel velocity 0.15 m/s, feed channel height 0.86 mm, permeate flux 25 L/m<sup>2</sup> · h, sodium concentration 6000 mg/L, and diffusivity of sodium in water 1.35 × 10<sup>-9</sup> m<sup>2</sup>/s. Use the correlation in Eq. 17-41 and a value of 0.47 for the coefficient. Assume that the rejection is high enough that the impact of sodium flux through the membrane can be ignored. Water density and viscosity at 20°C can be found in Table C-1 in App. C.

#### Solution

1. Calculate the Reynolds and Schmidt numbers using Eqs. 17-37 and 17-38. Because the feed channel height is 0.86 mm, the hydraulic diameter is 1.72 mm:

$$\text{Re} = \frac{\rho v d_H}{\mu} = \frac{(998 \text{ kg/m}^3)(0.15 \text{ m/s})(1.72 \text{ mm})}{(1.0 \times 10^{-3} \text{ kg/m} \cdot \text{s})(10^3 \text{ mm/m})} = 257$$

$$\text{Sc} = \frac{\mu}{\rho D_L} = \frac{1.0 \times 10^{-3} \text{ kg/m} \cdot \text{s}}{(998 \text{ kg/m}^3)(1.35 \times 10^{-9} \text{ m}^2/\text{s})} = 742$$

2. Calculate  $k_{CP}$  using Eq. 17-41:

$$k_{CP} = \frac{(0.47)(1.35 \times 10^{-9} \text{ m}^2/\text{s})(257)^{0.5}(742)^{1/3}}{(1.72 \text{ mm})(10^{-3} \text{ m/mm})} = 5.36 \times 10^{-5} \text{ m/s}$$

3. Because the rejection is high,  $\beta$  can be calculated using Eq. 17-35 (otherwise, Eq. 17-34 must be used):

$$\beta = \exp\left(\frac{J_W}{k_{CP}}\right) = \exp\left[\frac{(25 \text{ L/m}^2 \cdot \text{h})(10^{-3} \text{ m}^3/\text{L})}{(5.36 \times 10^{-5} \text{ m/s})(3600 \text{ s/h})}\right] = 1.14$$

4. Calculate the sodium concentration at the membrane surface using Eq. 17-33:

$$C_M = (1.14)(6000 \text{ mg/L}) = 6840 \text{ mg/L}$$

## 17-6 Fouling and Scaling

---

Nanofiltration and RO membranes are susceptible to fouling via a variety of mechanisms. The primary sources of fouling and scaling are particulate matter, precipitation of insoluble inorganic salts, oxidation of soluble metals, and biological matter.

### **Particulate Fouling**

Particulate fouling is a concern in RO because the operational cycle does not include a backwashing step to remove accumulated solids (in fact, backwashing might cause the active layer of thin-film membranes to separate from the support layers). Virtually all RO systems require pretreatment to minimize particulate fouling. Fouling by residual particulate matter affects the cleaning frequency.

#### **PLUGGING AND CAKE FORMATION**

Both inorganic and organic materials, including microbial constituents and biological debris, can cause particulate fouling, which includes plugging and cake formation. Plugging is the entrapment of large particles in the feed channels and piping. Hollow-fine-fiber membranes are reported to have more significant plugging problems because the high packing density of the fibers inside the pressure vessel results in very small spaces between the fibers. The mesh spacers in spiral-wound elements are sized to minimize plugging, but an excessive load of particulate matter may cause plugging anyway. Plugging is minimized by prefiltration of the feed water, and RO membrane manufacturers recommend prefiltration through 5- $\mu\text{m}$  cartridge filters as a minimum prefiltration step for protection of the membrane elements.

Particulate matter forming a cake on the membrane surface adds resistance to flow and affects system performance. Source waters with excessive potential for particulate fouling require advanced pretreatment to lower the particulate concentration to an acceptable level. Coagulation and filtration (using sand, carbon, or other filter media) are sometimes used for pretreatment as well as MF and UF.

#### **ASSESSMENT OF PARTICLE FOULING**

It is important to assess the fouling tendency prior to design and construction of an RO facility and to monitor the fouling tendency during operation. Empirical tests have been developed to assess particulate fouling, including the silt density index (SDI) and the modified fouling index (MFI). The SDI (ASTM, 2001b) is a timed filtration test using three time intervals through a gridded membrane filter with a mean pore size of  $0.45 \pm 0.02 \mu\text{m}$  and a diameter of 47 mm at a constant applied pressure of 2.07 bar (30 psi). The first interval is the duration necessary to collect 500 mL of permeate. Filtration continues through the second interval without recording volume until 15 min has elapsed (including the first time interval). Occasionally,

a duration shorter than 15 min is used for waters with high fouling tendency. At the end of 15 min, the third interval is started, during which an additional 500-mL aliquot of water is filtered through the now-dirty membrane, and the time is recorded. The SDI is calculated from these time intervals:

$$\text{SDI} = \frac{100(1 - t_I/t_F)}{t_T} \quad (17-43)$$

where SDI = silt density index,  $\text{min}^{-1}$

$t_I$  = time to collect first 500-mL sample, min

$t_F$  = time to collect final 500-mL sample, min

$t_T$  = duration of first two test intervals (15 min)

The MFI (Schippers and Verdouw, 1980) uses identical test equipment but different procedures from the SDI. The volume filtered is recorded at 30-s intervals during the MFI test. The flow rate is determined from volume and time data, and the inverse of the flow rate is plotted as a function of volume filtered. An example of the plotted data is shown on Fig. 17-15. A portion of the graph is generally linear, and the MFI is the slope of the graph in this region, that is,

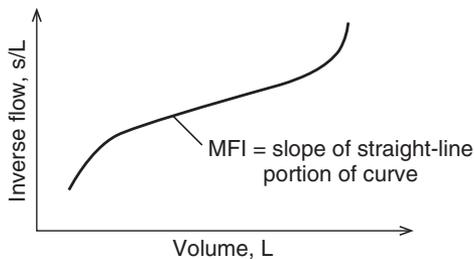

$$\frac{\Delta t}{\Delta V} = \frac{1}{Q} = (\text{MFI})V + b \quad (17-44)$$

where MFI = modified fouling index,  $\text{s/L}^2$

$V$  = volume of permeate, L

$b$  = intercept of linear portion of graph

The SDI and MFI have been criticized as being too simplistic to accurately predict RO membrane fouling. They operate in a dead-end, constant-pressure filtration mode, whereas full-scale RO systems operate with a significant cross flow and constant flux. They use a  $0.45\text{-}\mu\text{m}$  filter so they only nominally measure fouling by material larger than that size. Research suggests that colloidal matter smaller than  $0.45\ \mu\text{m}$  may cause significant fouling of RO membranes. As a result, a revised MFI test that uses a 13-kDa UF membrane has also been developed (Boerlage et al., 2002, 2003).

**Figure 17-15**  
Determination of modified fouling index (MFI).

The SDI and MFI might best be considered as screening tests that can indicate unacceptable feed water quality. A high value is a good indicator of fouling problems in RO systems, but a low value does not necessarily mean the source water has a low fouling tendency. RO manufacturers typically specify a maximum SDI value of 4 to 5  $\text{min}^{-1}$ . High SDI or MFI values indicate pretreatment is required to remove particulate matter. When lower SDI or MFI values are measured, pilot tests are often necessary to determine the appropriate level of pretreatment to minimize fouling.

### Precipitation of Inorganic Salts and Scaling

Inorganic scaling occurs when salts in solution are concentrated beyond their solubility limits and form precipitates. Common sparingly soluble salts are listed in Table 17-3. If the ions that comprise these salts are concentrated past the solubility product, precipitation occurs. Precipitation reactions and solubility calculations were introduced in Chap. 5. The precipitation reaction for a typical salt is as follows:

The solubility product is written as

$$K_{\text{SP}} = \{\text{Ca}^{2+}\}\{\text{SO}_4^{2-}\} = \gamma_{\text{Ca}}[\text{Ca}^{2+}]\gamma_{\text{SO}_4}[\text{SO}_4^{2-}] \quad (17-46)$$

where

$$\begin{aligned} K_{\text{SP}} &= \text{solubility product} \\ \{\text{Ca}^{2+}\} &= \text{calcium activity} \\ \{\text{SO}_4^{2-}\} &= \text{sulfate activity} \\ \gamma_{\text{Ca}} &= \text{activity coefficient for calcium} \\ \gamma_{\text{SO}_4} &= \text{activity coefficient for sulfate} \end{aligned}$$

**Table 17-3**

Typical limiting salts and their solubility products

Salt	Equation	Solubility Product ( $\text{p}K_{\text{sp}}$ at 25°C)
Calcium carbonate (aragonite)	$\text{CaCO}_3(\text{s}) \rightleftharpoons \text{Ca}^{2+} + \text{CO}_3^{2-}$	8.2
Calcium fluoride	$\text{CaF}_2(\text{s}) \rightleftharpoons \text{Ca}^{2+} + 2\text{F}^-$	10.3
Calcium orthophosphate	$\text{CaHPO}_4(\text{s}) \rightleftharpoons \text{Ca}^{2+} + \text{HPO}_4^{2-}$	6.6
Calcium sulfate (gypsum)	$\text{CaSO}_4(\text{s}) \rightleftharpoons \text{Ca}^{2+} + \text{SO}_4^{2-}$	4.6
Strontium sulfate	$\text{SrSO}_4(\text{s}) \rightleftharpoons \text{Sr}^{2+} + \text{SO}_4^{2-}$	6.2
Barium sulfate	$\text{BaSO}_4(\text{s}) \rightleftharpoons \text{Ba}^{2+} + \text{SO}_4^{2-}$	9.7
Silica, amorphous	$\text{SiO}_2(\text{s}) + 2\text{H}_2\text{O} \rightleftharpoons \text{Si}(\text{OH})_4(\text{aq})$	2.7

<sup>a</sup>From Stumm and Morgan (1996).

$[\text{Ca}^{2+}]$  = calcium concentration, mol/L

$[\text{SO}_4^{2-}]$  = sulfate concentration, mol/L

The ionic strength of feed solutions for RO is sufficiently high that ion products must be calculated using activity, rather than the common practice of assuming that activity is equal to concentration. Several factors in RO operation affect how much ions are concentrated. The system recovery is the most important factor because the concentration of the rejected solutes increases as more clean water is withdrawn from solution. In fact, precipitation is one of the important factors that limit recovery in RO systems (osmotic pressure being the other). The rate of ion or salt rejection is also important, as an ion with 99 percent rejection will be concentrated more than one with 10 percent rejection. Finally, the degree of concentration polarization is important because precipitation occurs in the more concentrated zone near the membrane surface. The inorganic scale that forms on the membrane surface can reduce water permeability or permanently damage the membrane.

In the absence of pretreatment, precipitation must be avoided by minimizing concentration polarization, limiting salt rejection, or limiting recovery. Concentration polarization is minimized by promoting turbulence in the feed channels and maintaining minimum velocity conditions specified by equipment manufacturers. Limiting rejection is impractical because it conflicts with process objectives. Limiting recovery, however, is often necessary to prevent precipitation. The highest recovery possible before any salts precipitate is the *allowable recovery*, and the salt that precipitates at this condition is the *limiting salt*. The most common scales encountered in water treatment applications are calcium carbonate ( $\text{CaCO}_3$ ) and calcium sulfate ( $\text{CaSO}_4$ ).

The allowable recovery without pretreatment that can be achieved in RO is determined by performing solubility calculations for each of the possible limiting salts. The highest solute concentrations occur in the final membrane element immediately prior to the feed water exiting the system as the concentrate stream, so concentrate stream concentrations are used to evaluate solubility limits. In addition, the concentration in the concentrate stream must be adjusted for the level of concentration polarization that is occurring. Incorporating the concentration polarization factor defined in Eq. 17-40 with the expression for the solute concentration in the concentrate stream defined by Eq. 17-15 yields

$$C_M = \beta C_F \left[ \frac{1 - (1 - \text{Rej})r}{1 - r} \right] \quad (17-47)$$

Allowable recovery is determined by substituting the activities at the membrane into a solubility product calculation (from Chap. 5) and solving for the recovery, as demonstrated in Example 17-4.

### Example 17-4 Allowable recovery from limiting salt calculations

Determine the limiting salt and allowable recovery for a brackish water RO system containing the following solutes: calcium 74 mg/L, barium 0.008 mg/L, and sulfate 68 mg/L. Assume 100 percent rejection of all solutes and a polarization factor of 1.15 and ignore activity coefficients (i.e., activity = concentration).

#### Solution

1. Calculate the molar concentration for each component:

$$[\text{Ca}^{2+}] = \frac{74 \text{ mg/L}}{(40 \text{ g/mol})(10^3 \text{ mg/g})} = 1.85 \times 10^{-3} \text{ mol/L}$$

$$[\text{Ba}^{2+}] = \frac{0.008 \text{ mg/L}}{(137.3 \text{ g/mol})(10^3 \text{ mg/g})} = 5.83 \times 10^{-8} \text{ mol/L}$$

$$[\text{SO}_4^{2-}] = \frac{68 \text{ mg/L}}{(96 \text{ g/mol})(10^3 \text{ mg/g})} = 7.08 \times 10^{-4} \text{ mol/L}$$

2. Simplify the expression for concentration at the membrane. Let  $y = 1 - r$ . Because  $\text{Rej} = 1$ , Eq. 17-47 becomes

$$C_M = \frac{\beta C_F}{y}$$

3. Substitute the concentrations at the membrane surface into the equation for solubility products and calculate recovery. Solubility product constants are available in Table 17-3.
  - a. For calcium sulfate,

$$K_{\text{sp}} = 10^{-4.6} = [\text{Ca}^{2+}]_M [\text{SO}_4^{2-}]_M = \left( \frac{\beta [\text{Ca}^{2+}]_F}{y} \right) \left( \frac{\beta [\text{SO}_4^{2-}]_F}{y} \right)$$

$$= \frac{\beta^2}{y^2} [\text{Ca}^{2+}]_F [\text{SO}_4^{2-}]_F$$

$$y = \left( \frac{\beta^2}{K_{\text{sp}}} [\text{Ca}^{2+}]_F [\text{SO}_4^{2-}]_F \right)^{1/2}$$

$$= \left[ \frac{(1.15)^2}{10^{-4.6}} (1.85 \times 10^{-3} \text{ mol/L})(7.08 \times 10^{-4} \text{ mol/L}) \right]^{1/2}$$

$$= 0.26$$

$$r = 1 - y = 1 - 0.26 = 0.74$$

b. For barium sulfate,

$$y = \left[ \frac{(1.15)^2}{10^{-9.7}} (5.83 \times 10^{-8} \text{ mol/L})(7.08 \times 10^{-4} \text{ mol/L}) \right]^{1/2}$$

$$= 0.52$$

$$r = 1 - y = 1 - 0.52 = 0.48$$

### Comments

1. The allowable recovery before barium sulfate precipitates is 48 percent, compared to 74 percent before calcium sulfate precipitates. Therefore, barium sulfate is the limiting salt and the allowable recovery is 48 percent.
2. Activity coefficients affect solubility calculations and, therefore, recovery. The ionic strength of the feed solution can be calculated from feed ion concentrations. However, the activity coefficients must be calculated from the ionic strength of the concentrate at the allowable recovery, so a simultaneous solution procedure must be used.

The complexity of limiting salt calculations is greatly oversimplified in Example 17-4. As noted above, activity coefficients cannot be ignored. The ionic strength is dependent on recovery and rejection, however, so the activity coefficients cannot be calculated until the recovery is determined. Ignoring ionic strength may yield a significantly lower value for allowable recovery than could actually be achieved. The assumption of 100 percent rejection is often justified because divalent ions typically have rejection near 100 percent. An assumption of 100 percent rejection yields a slightly conservative value for allowable recovery because lower rejection will produce concentrate stream concentrations that are actually slightly lower. For NF and low-pressure RO systems that have divalent ion rejection significantly below 100 percent, however, this assumption would be inappropriate.

Another complicating factor is the formation of ion complexes. For instance, calcium and sulfate form a neutral  $\text{CaSO}_4^0$  species that increases the solubility of  $\text{CaSO}_4(\text{s})$ . The solubility of calcium sulfate in distilled water would be calculated as 680 mg/L as  $\text{CaSO}_4$  using Eq. 17-48 if ionic strength and complexation were ignored. With ionic strength and complexation, the solubility of calcium sulfate in distilled water is 2170 mg/L, an error of over 200 percent.

Several models are available to calculate activity coefficients, and the applicability of each model depends on the ionic strength. Seawater has an ionic strength of about 0.7 M. Assuming 50 percent recovery, the ionic strength of the concentrate from a seawater RO plant would be about 1.4 M. This ionic strength is significantly above the range of applicability of the

extended Debye–Huckel or Davies equations. The specific interaction model or Pitzer model are suitable for calculating activity coefficients when the ionic strength is above 1 M (Pitzer, 1975).

Another complicating factor is that carbonate and phosphate concentrations are dependent on pH. As can be imagined, accounting for ionic strength, recovery, complexation, and pH in the calculations in Example 17-4, and then calculating activity coefficients with the Pitzer equations, would result in equations that cannot be easily manipulated algebraically.

Furthermore, the calculations must be repeated for each limiting salt in Table 17-3. Example 17-4 demonstrates that barium was a limiting solute even though its concentration in the feed water was very low. When alternative systems with different rejection capabilities are being evaluated, the calculations must be repeated for each rejection scenario. Temperature and supersaturation considerations further complicate the calculations. Clearly, the computational requirements of limiting salt calculations can be daunting and are rarely done manually. Membrane manufacturers provide computer programs to perform these calculations. These programs account for the concentration polarization factor and rejection capabilities of specific products, temperature and pH effects, and the degree of supersaturation that can be accommodated with various pretreatment strategies. Use of an equilibrium speciation program (Visual MINTEQ) to solve Example 17-4 reveals that the barium sulfate reaches saturation at 84 percent recovery instead of 48 percent recovery.

#### ACID ADDITION AND ANTISCALANTS TO PREVENT SCALING

Pretreatment is necessary in virtually all RO systems to prevent scaling due to precipitation of sparingly soluble salts. Calcium carbonate precipitation is common, and most systems require pretreatment for this compound. In addition to the limiting salt calculations presented in the above example, calcium carbonate solubility can also be expressed in terms of the Langelier saturation index (LSI) and Stiff and Davis stability index (ASTM, 2001a, 2001f), and manufacturers' solubility programs often report these values. Calcium carbonate precipitation can be prevented by adjusting the pH of the feed stream with acid to convert carbonate to bicarbonate and carbon dioxide. Sulfuric or hydrochloric acids are normally used, but using sulfuric acid can increase the sulfate concentration enough to cause precipitation of sulfate compounds. The pH of most RO feed waters is adjusted to a pH value of 5.5 to 6.0. At this pH, most carbonate is in the form of carbon dioxide and passes through the membrane.

Scaling of other limiting salts is commonly prevented with the addition of antiscalant chemicals. Antiscalants allow supersaturation without precipitation occurring by preventing crystal formation and growth. At one time, sodium hexametaphosphate (SHMP) was commonly used as an antiscalant, but it is rarely used anymore because it has limited ability to extend the supersaturation range and adds phosphate compounds to the concentrate,

which causes disposal problems. SHMP has been largely replaced with polymeric antiscalants. The degree of supersaturation allowed because of antiscalant addition depends on properties of the antiscalant, which are often proprietary, and characteristics of specific equipment configurations. It is appropriate to rely on the recommendations of equipment and antiscalant manufacturers when determining appropriate antiscalant selection and doses necessary for a specific feed water analysis and design recovery.

In addition to acid and antiscalant addition, newer installations are incorporating a variety of strategies to minimize scaling with the goal of reducing the quantity of waste concentrate that must be disposed and increasing the recovery of water. These strategies are discussed in more detail in Sec. 17-7 under the heading Concentrate Management.

#### **SILICA SCALING**

Silica scaling can be particularly problematic because silica chemistry is complex and silica can occur in several forms in groundwater, including monomeric, polymeric, and colloidal forms. Many brackish groundwater sources in the Southwestern United States have sufficiently high silica concentrations such that silica is the species that limits recovery. Silica precipitates in an amorphous rather than crystalline form; thus, antiscalants that prevent crystal growth are ineffective for preventing silica precipitation. The presence of metals can increase silica precipitation and change its form (Sahachaiyunta et al., 2002; Sheikholeslami and Bright, 2002), complicating the presence of silica in RO feed water. Recent advances and new antiscalant formulations are now available for both minimizing silica precipitation and cleaning silica from membranes, but these proprietary compounds have had varying degrees of success. When high silica concentrations are present, high-pH softening (resulting in co-precipitation with magnesium hydroxide) may be necessary to remove silica from the feed water to prevent precipitation on the membrane.

A cost trade-off exists between methods of preventing scaling: operating at a lower recovery or the use of pretreatment processes and chemicals. In some cases, it may be more cost effective to operate at a lower recovery to minimize pretreatment costs. Pretreatment and membrane equipment costs must be considered simultaneously and the design recovery set at the point that minimizes overall system costs.

Groundwater used as the source water for RO and NF systems is often anaerobic. Iron and manganese, soluble compounds in their reduced states, can oxidize, precipitate, and foul membranes if oxidants enter the feed water system. Iron fouling is more prevalent and can occur rapidly if any air enters the feed system. Fouling may be avoided by preventing oxidation or removing the iron or manganese after oxidation. If iron concentrations are low, precautions to prevent air from entering the feed system may be sufficient;

#### **Metal Oxide Fouling**

antiscalants often include additives to minimize fouling by low concentrations of iron. Pretreatment to control iron might include oxidation with oxygen or chlorine followed by adequate mixing and hydraulic detention time and granular media or membrane filtration or greensand filtration in which oxidation and filtration take place simultaneously. When oxidants are used, precautions must be made to prevent them from reaching the membranes, particularly for polyamide membranes or other materials that are not oxidant resistant. Iron-fouling deposits are usually removable from RO membrane surfaces by commercially available cleaning agents and procedures.

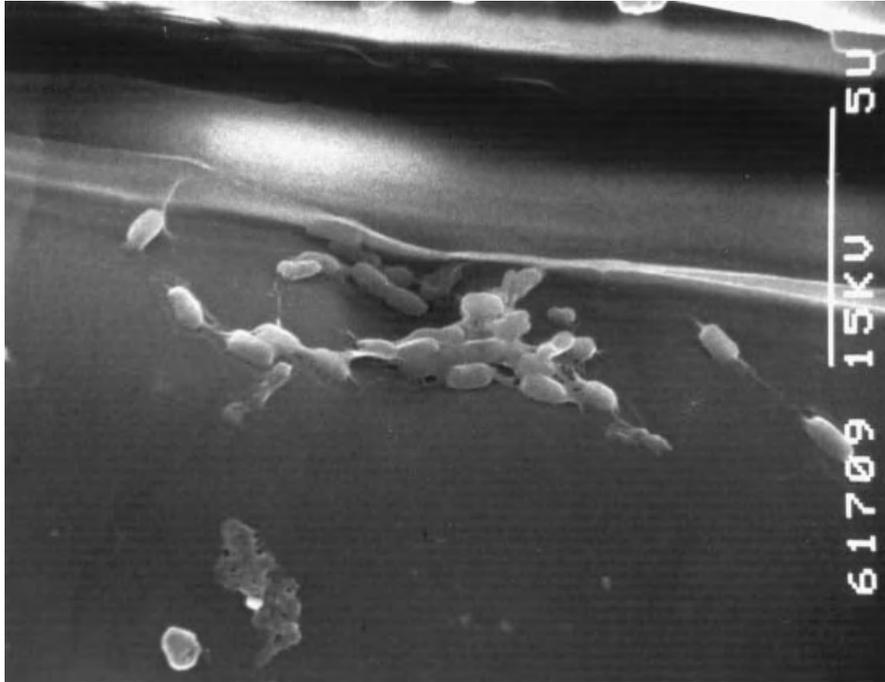

An additional constituent present in many anaerobic groundwaters is hydrogen sulfide. If air enters the feed water system, hydrogen sulfide can oxidize to colloidal sulfur, which can foul membranes. As with iron oxidation, precautions to prevent air from entering the feed system are important to prevent colloidal sulfur fouling. Sulfur deposits on membrane surfaces are typically irreversible.

### **Biological Fouling**

Biological fouling refers to the attachment or growth of microorganisms or extracellular soluble material on the membrane surface or in the membrane element feed channels. Biological fouling is common in many RO systems and can have a variety of negative effects on performance, including loss of flux, reduced solute rejection, increased head loss through the membrane modules, contamination of the permeate, degradation of the membrane material, and reduced membrane life (Ridgway and Flemming, 1996). An example of biological fouling is shown on Fig. 17-16. The primary source of microbial contamination is the feed water. Biological fouling is a significant problem in many RO systems.

Biological fouling is prevented by maintaining proper operating conditions, applying biocides, and flushing membrane elements properly when not in use. Many RO and NF feed waters (groundwater in many cases) have low microbial populations. When operated properly, the shear in the feed channels helps to keep bacteria from accumulating or growing to unacceptable levels. When membrane trains are out of service, however, bacteria can quickly multiply. To avoid this problem, membranes should be flushed with permeate periodically or filled with an approved biocide if out of service for any significant period. Chlorine solutions can be used as a biocide for cellulose acetate membranes within recommended limits, but other chemicals such as sodium bisulfite must be used with polyamide membranes because of their susceptibility to degradation by chlorine. An excellent review of the issues involved in biological fouling of membranes is provided in Ridgway and Flemming (1996).

The feed water to cellulose acetate membranes can be continuously chlorinated within limited concentrations to prevent biological growth, if necessary. Ultraviolet radiation, chloramination, or chlorination followed by dechlorination can sometimes be used for polyamide membranes.

## 17-7 Reverse Osmosis Process Design

---

During preliminary design of an RO system, the design engineer must perform the following activities:

1. Select the basic performance criteria: capacity, recovery, rejection, and permeate solute concentrations.
2. Evaluate alternatives for membrane equipment and operation, select the type of membrane element, and determine the array configuration (number of stages, number of passes, number of elements in a pressure vessel, number of vessels in each stage, feed pressure).
3. Select feed water pretreatment requirements (methods to control fouling).
4. Select permeate posttreatment requirements.
5. Select concentrate management and disposal requirements.
6. Select ancillary membrane system features such as permeate back-pressure control and interstage booster pumps.
7. Select equipment and procedures for process monitoring.

These elements of design are not independent of one another. For instance, recovery is often constrained by the solubility of limiting salts. As a result, selection of pretreatment requirements, recovery, and array design must be done simultaneously and iteratively to determine the most economical design.

The basis for design information typically includes characteristics of the feed water (solute concentrations, turbidity, SDI and MFI values) from laboratory or historical data, required treated-water quality (established by the client or regulatory limits), and required treated-water capacity (established by demand requirements). The process design criteria for a hypothetical brackish water RO facility are shown in Table 17-4. Frequently, pilot testing is part of the design process.

The following discussion focuses primarily on the design of the membrane components of an RO system. Design of additional components, such as intakes and pretreatment systems, are available in design manuals such as AWWA (2007).

### **Element Selection and Membrane Array Design**

Membrane array design involves determination of the quantity and quality of water produced by each membrane element in an array. This involves calculation of the flow, velocity, applied pressure, osmotic pressure, water flux, and solute flux in each element, which leads to the determination of the number of stages, number of passes, number of elements in each pressure vessel, and number of vessels in each stage. Membrane array design is a complex and iterative process using a large number of interrelated design parameters. Several important design parameters such as mass transfer coefficients are specific to individual products and available only from membrane manufacturers. Because of the complexity of the calculations and dependence on manufacturer information, array design is often done with design software provided by membrane manufacturers. Nevertheless, an understanding of the mechanics of the design procedure as described in the following paragraphs is important to interpreting the results from manufacturer design software.

#### **DESIGN CALCULATIONS**

The most common type of membrane element in use is the spiral-wound element. As described earlier, feed water enters one end of the pressure vessel and flows through several spiral-wound elements in series. As the water passes through each element, some water passes through the membrane into the permeate carrier channel, resulting in continuously changing conditions along the length of the membrane element. The net transmembrane pressure declines continuously across the length of a membrane element because of changes in both applied pressure (due to head loss in the feed channels) and osmotic pressure (due to concentration of salts). As a result, fluxes of both water and solute are dependent on the position

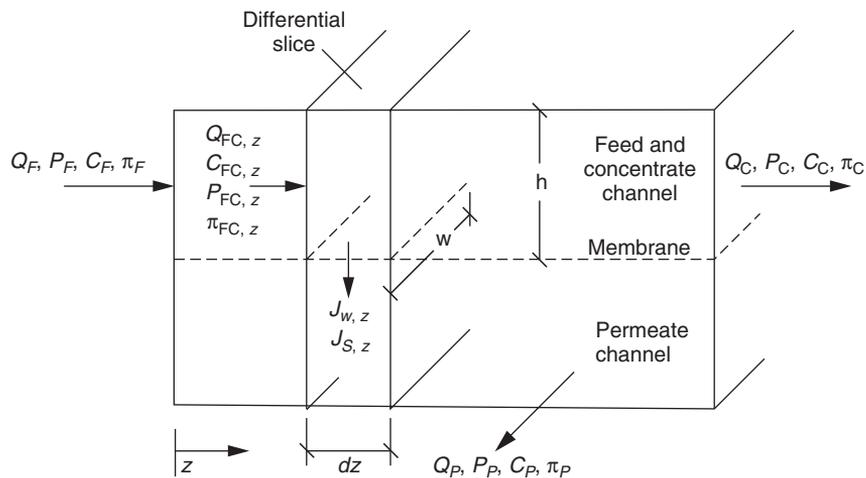

**Table 17-4**  
Design criteria for a hypothetical reverse osmosis facility

Operating Parameter	Units	Value
Feedwater pretreatment		
Capacity	m <sup>3</sup> /d	37,900
Strainers		
Number	Number	5
Nominal particle size rating	μm	5
Capacity, each	m <sup>3</sup> /d	9,480
Chemicals		
Sulfuric acid, max. dose	mg/L	200
Scale inhibitor, max. dose	mg/L	2
Feed pumps		
Number	Number	5
Capacity, each	m <sup>3</sup> /d	9,480
Pressure	bar	40
Membrane system		
Feed water flow rate	m <sup>3</sup> /d	37,900
Permeate flow rate	m <sup>3</sup> /d	30,300
Concentrate flow rate	m <sup>3</sup> /d	7,580
Recovery	%	80
Number of arrays	Number	4
Capacity per array	m <sup>3</sup> /d	9,480
Array design criteria		
Membrane area per element	m <sup>2</sup>	32.5
Elements per pressure vessel	Number	7
Number of stages per array	Number	2
Number of pressure vessels (stage 1)	Number	40
Stage 1 avg. permeate flux	L/m <sup>2</sup> · h	21
Number of pressure vessels (stage 2)	Number	20
Stage 2 avg. permeate flux	L/m <sup>2</sup> · h	17
Posttreatment <sup>a</sup>		
Caustic soda, max. dose	mg/L	10
Corrosion inhibitor, max. dose	mg/L	1
Chlorine, max. dose	mg/L	2
Fluoride, max. dose	mg/L	1
Concentrate disposal	Deep-well injection	

<sup>a</sup>Posttreatment may also include a countercurrent packed tower for hydrogen sulfide or carbon dioxide removal. See Chap. 14 for details of packed-tower design.

within a spiral-wound element, and the design procedure must integrate along the length of the membrane element.

A differential slice of a membrane element is shown on Fig. 17-17. In this figure, the center plane represents the membrane surface, with the feed–concentrate channel above the membrane and the permeate channel

**Figure 17-17**  
Differential slice of spiral-wound membrane element. Because the feed flows axially along the pressure vessel and the permeate flows spirally toward the center of the vessel, the feed and permeate flows are perpendicular to each other.

below the membrane. The fluxes of water and solute are described by Eqs. 17-9 and 17-10, but the applied pressure differential, osmotic pressure differential, and concentration differential depend on the location within the pressure vessel:

$$J_{W,Z} = k_W(\Delta P_Z - \Delta \pi_Z) = k_W[(P_{FC,Z} - P_{P,Z}) - (\pi_{M,Z} - \pi_{P,Z})] \quad (17-48)$$

$$J_{S,Z} = k_S(\Delta C_Z) = k_S(C_{M,Z} - C_{P,Z}) \quad (17-49)$$

where  $C_{M,Z}$  = concentration at the membrane surface,  
 $C_{M,Z} = \beta_Z C_{FC,Z}$ , mol/L  
 $\pi_{M,Z}$  = osmotic pressure at the membrane surface, bar

Other terms are defined on Fig. 17-17.

The water and solute mass transfer coefficients ( $k_W$  and  $k_S$ ) are dependent on the properties and configurations of specific membrane elements and cannot be generalized. These values are embedded in the manufacturer's design software and are typically not publicized but can be generated from pilot data if they cannot be obtained from the manufacturer.

Solute flux calculations are complicated by the presence of multiple solutes, which may have different value for the mass transfer coefficient. For instance, a low-pressure NF membrane has low rejection of monovalent ions but high rejection of divalent ions, and the mass transfer coefficients would reflect this difference in rejection.

The permeate flow and mass solute flow through the membrane are equal to the flux times the membrane area in the differential element, and the cumulative transfer of water and solute across the membrane is

determined by integrating the flow between the feed end and the position  $z$  within the pressure vessel, as shown in the following:

$$Q_{P,Z} = \int_0^z J_{W,Z} w \, dz \quad (17-50)$$

$$M_{S,Z} = \int_0^z J_{S,Z} w \, dz \quad (17-51)$$

where  $w$  = effective width of feed–concentrate flow channel, m  
 $M_{S,Z}$  = mass of solute transferred, mg/s

The water flow rate (and velocity) in the feed–concentrate channel declines as permeate is produced, and the flow rate at any point in the channel can be determined by subtracting the net permeate production up to that point from the feed water flow rate as follows:

$$Q_{FC,Z} = Q_F - Q_{P,Z} \quad (17-52)$$

Similarly, the solute concentration in the feed–concentrate channel can be determined by performing a mass balance on the solute as follows:

$$C_{FC,Z} = \frac{Q_F C_F - M_{S,Z}}{Q_{FC,Z}} \quad (17-53)$$

Water and solute flux are affected by concentration polarization and the concentration of solute at the membrane surface. Some manufacturers have developed relationships describing concentration polarization for specific element designs, and these relationships should be used if available. If no manufacturer information is available, the correlations presented earlier in this chapter can be used to estimate the concentration polarization factor. Because both flux and velocity are changing,  $\beta$  must be calculated using Eq. 17-41, but as a function of position, as shown in the equation

$$\beta_Z = \text{Rej}(e^{J_{W,Z}/k_{CP,Z}}) + (1 - \text{Rej}) \quad (17-54)$$

The mass transfer coefficient  $k_{CP}$  depends on velocity in the feed–concentrate channel, which can be calculated from the expression

$$v_Z = \frac{Q_{FC,Z}}{hw} \quad (17-55)$$

where  $h$  = height of feed–concentrate channel, m

The solute concentration at the membrane surface is defined by Eq. 17-40, using concentrations as a function of position.

$$C_{M,Z} = \beta_Z C_{FC,Z} \quad (17-56)$$

Pressure in the feed channel drops due to head loss, but head loss is not constant across the length of the membrane element. Turbulent

conditions are maintained, so head loss in the channel is proportional to the square of the velocity and the first power of length (consistent with the Darcy–Weisbach equation) as given by the expression

$$h_L = \delta_{HL} v^2 L \quad (17-57)$$

where  $h_L$  = head loss in feed–concentrate channel, bar  
 $\delta_{HL}$  = head loss coefficient, bar · s<sup>2</sup>/m<sup>3</sup>  
 $v$  = water velocity in feed–concentrate channel, m/s  
 $L$  = channel length, m

Finally, the permeate solute concentration can be calculated from the ratio of the solute and water fluxes per Eq. 17-11:

$$C_{P,Z} = \frac{J_{S,Z}}{J_{W,Z}} \quad (17-58)$$

Additional design calculations, such as the calculation of osmotic pressure from concentration, have been presented earlier in this chapter. The use of these equations in system array design is demonstrated in Example 17-5.

### Example 17-5 Calculation of permeate flux and concentration

Calculate the quantity and quality of water produced by a single membrane element (permeate concentration, rejection, and recovery) given the following information:

Parameter	Unit	Value
Membrane properties		
Element length	m	1
Element membrane area	m <sup>2</sup>	32.5
Effective feed channel height	mm	0.125
Water mass transfer coefficient ( $k_W$ )	L/m <sup>2</sup> · h · bar	2.87
Solute mass transfer coefficient ( $k_S$ )	m/h	$6.14 \times 10^{-4}$
Element head loss (at design velocity of 0.5 m/s)	bar	0.2
Operating conditions		
Feed flow ( $Q_F$ )	m <sup>3</sup> /d	270
Feed pressure ( $P_F$ )	bar	14.2
Feed concentration ( $C_F$ )	mg/L NaCl	2000
Feed temperature ( $T_F$ )	°C	20
Permeate pressure ( $P_P$ )	bar	0.3
Osmotic coefficient ( $\phi$ )		1.0

Assume  $D_{NaCl} = 1.35 \times 10^{-9}$  m<sup>2</sup>/s,  $\phi = 1$ , and  $MW_{NaCl} = 58.4$ .

**Solution**

The basic solution strategy is to (1) divide the membrane element into a number of increments; (2) determine  $P$ ,  $v$ ,  $C$ , and  $\pi$  on both sides of the membrane in the first increment; (3) calculate the water and solute flux across the membrane in the first increment; (4) determine  $Q$ ,  $P$ ,  $C$ ,  $v$ , and  $\pi$  on both sides of the membrane in the next increment; (5) calculate the water and solute flux across the membrane in the next increment; and (6) repeat steps 4 and 5 for all remaining increments.

**Part 1**

Divide the element into 10 increments 0.1 m length each. Determine  $v$ ,  $P$ ,  $C$ , and  $\pi$  on both sides of the membrane in the first increment. The subscript FC is used to designate the feed–concentrate side of the membrane, and the subscript  $P$  designates the permeate side of the membrane.

1. The following values are given in the problem statement:

$$Q_{FC,Z} = Q_F = 270 \text{ m}^3/\text{d}$$

$$P_{FC,Z} = P_F = 14.2 \text{ bar}$$

$$P_{P,Z} = 0.3 \text{ bar}$$

2. The feed channel velocity is determined by dividing the feed flow by the channel cross-sectional area. The effective channel height is given as 0.125 mm, but the width is not given. The width can be determined by dividing the membrane area by the element length, both of which are readily available information:

$$w = \frac{a}{L} = \frac{32.5 \text{ m}^2}{1 \text{ m}} = 32.5 \text{ m}$$

It should be noted that the element is not 32.5 m wide. Spiral-wound elements are typically 0.2 to 0.3 m in diameter, and 32.5 m is the unit width of the membrane surface (which includes multiple feed channels because multiple envelopes are used, see Sec. 17-4) as wrapped around the permeate tube. Then,

$$Q_{FC,Z} = \frac{270 \text{ m}^3/\text{d}}{86,400 \text{ s/d}} = 3.125 \times 10^{-3} \text{ m}^3/\text{s}$$

$$V_Z = \frac{Q_{FC,Z}}{hw} = \frac{(3.125 \times 10^{-3} \text{ m}^3/\text{s})(10^3 \text{ mm/m})}{(0.125 \text{ mm})(32.5 \text{ m})}$$

$$= 0.769 \text{ m/s}$$

3. Calculate the osmotic pressure in the feed channel using Eq. 17-7:

$$\pi_{FC,Z} = \frac{(2 \text{ mol ion/mol NaCl})(1.0)(2000 \text{ mg/L})(0.0831451 \text{ L} \cdot \text{bar/K} \cdot \text{mol})(293 \text{ K})}{(10^3 \text{ mg/g})(58.4 \text{ g/mol})}$$

$$= 1.67 \text{ bar}$$

4. The water and solute fluxes depend on the concentration and osmotic pressure in the permeate, which of course depend on the water and solute fluxes. Although a simultaneous numerical solution procedure could be used, it is acceptable to assume  $C_P$  and  $\pi_P$  are zero in the first increment for this example. Values calculated in the first increment will be used as an approximation of the values in the next increment.

### Part 2

Calculate the water and solute flux and flow rate across the membrane in the first increment.

1. The concentration and osmotic pressure at the membrane wall are higher than in the feed channel because of concentration polarization. However, the concentration polarization factor is dependent on permeate flux, so values for the concentration polarization factor and permeate flux must be determined concurrently by simultaneously solving Eqs. 17-48 and 17-54.

a. Calculate the Reynolds number, Schmidt number, and  $k_{CP}$  using Eqs. 17-37, 17-38, and 17-36. The hydraulic diameter is  $2h = 2 \times (0.125 \text{ mm}) = 0.25 \text{ mm}$ . Water density and viscosity at  $20^\circ\text{C}$  are  $\rho_W = 998 \text{ kg/m}^3$  and  $\mu_W = 10^{-3} \text{ kg/m} \cdot \text{s}$  (Table C-1, App. C):

$$\text{Re} = \frac{\rho v d_H}{\mu} = \frac{(998 \text{ kg/m}^3)(0.769 \text{ m/s})(0.25 \text{ mm})}{(1.0 \times 10^{-3} \text{ kg/m} \cdot \text{s})(10^3 \text{ mm/m})} = 192$$

$$\text{Sc} = \frac{\mu}{\rho D_L} = \frac{1.0 \times 10^{-3} \text{ kg/m} \cdot \text{s}}{(998 \text{ kg/m}^3)(1.35 \times 10^{-9} \text{ m}^2/\text{s})} = 742$$

$$k_{CP} = \frac{(0.023)(1.35 \times 10^{-9} \text{ m}^2/\text{s})(192)^{0.83}(742)^{0.33}}{(0.25 \text{ mm})(10^{-3} \text{ m/mm})}$$

$$= 8.64 \times 10^{-5} \text{ m/s}$$

b. The parameter  $\beta$  can be calculated using Eq. 17-34.  $\text{Re}_j$  is not yet known and is assumed to be 1.0 in the first increment.

In subsequent increments,  $Re_j$  will be taken as equal to the value calculated in the previous increment:

$$\begin{aligned}\beta_Z &= \exp\left(\frac{J_{W,Z}}{k_{CP}}\right) Re_j + (1 - Re_j) \\ &= \exp\left[\frac{(J_{W,Z} \text{ L/m}^2 \cdot \text{h})(10^{-3} \text{ m}^3/\text{L})}{(8.64 \times 10^{-5} \text{ m/s})(3600 \text{ s/h})}\right] \quad (\text{a})\end{aligned}$$

- c. The osmotic pressures in the feed water and at the membrane surface are related by  $\beta_Z$ :

$$C_{M,Z} = \beta_Z C_{FC,Z}$$

Therefore

$$\pi_{M,Z} = \beta_Z \pi_{FC,Z} \quad (\text{b})$$

- d. Substituting Eq. (b) into Eq. 17-48 yields

$$J_{W,Z} = k_W[(P_{FC,Z} - P_{P,Z}) - (\beta_Z \pi_{FC,Z} - \pi_{P,Z})] \quad (\text{c})$$

- e. Solving Eqs. (a) and (c) simultaneously using values given in the problem statement yields  $\beta_Z = 1.12$  and  $J_{W,Z} = 35.1 \text{ L/m}^2 \cdot \text{h}$ .
2. The permeate flow rate is calculated by multiplying the flux by the area of the increment:

$$\begin{aligned}Q_{P,Z} &= J_{W,Z}(w)(dz) = \frac{(35.1 \text{ L/m}^2 \cdot \text{h})(32.5 \text{ m})(0.1 \text{ m})}{(10^3 \text{ L/m}^3)(3600 \text{ s/h})} \\ &= 3.17 \times 10^{-5} \text{ m}^3/\text{s}\end{aligned}$$

3. The solute flux can be calculated using Eq. 17-49 after substituting in Eq. (b) (see step 1c above):

$$J_{S,Z} = k_S(\beta_Z C_{FC,Z} - C_{P,Z})$$

$$J_{S,Z} = (6.14 \times 10^{-4} \text{ m/h})[(1.12)(2000 \text{ mg/L}) - 0 \text{ mg/L}](10^3 \text{ L/m}^3)$$

$$J_{S,Z} = 1375 \text{ mg/m}^2 \cdot \text{h}$$

4. Calculate the solute transport across the membrane:

$$M_{S,Z} = J_{S,Z}(w)(dz) = \frac{(1375 \text{ mg/m}^2 \cdot \text{h})(32.5 \text{ m})(0.1 \text{ m})}{3600 \text{ s/h}} = 1.24 \text{ mg/s}$$

### Part 3

Determine  $P$ ,  $C$ , and  $\pi$  on both sides of the membrane in the next increment along with  $v$  in the feed channel.

1. The flow in the feed channel is equal to the influent flow minus any permeate production and is calculated using Eq. 17-52:

$$\begin{aligned} Q_{FC,Z} &= Q_F - Q_{P,Z} = 3.125 \times 10^{-3} \text{ m}^3/\text{s} - 3.17 \times 10^{-5} \text{ m}^3/\text{s} \\ &= 3.09 \times 10^{-3} \text{ m}^3/\text{s} \end{aligned}$$

2. Calculate feed channel velocity:

$$v_Z = \frac{Q_{FC,Z}}{hw} = \frac{(3.09 \times 10^{-3} \text{ m}^3/\text{s})(10^3 \text{ mm/m})}{(0.125 \text{ mm})(32.5 \text{ m})} = 0.761 \text{ m/s}$$

3. The solute concentration in the feed channel of the next increment can be calculated using Eq. 17-53:

$$\begin{aligned} C_{FC,Z} &= \frac{Q_F C_F - M_{S,Z}}{Q_{FC,Z}} \\ &= \frac{[(3.125 \times 10^{-3} \text{ m}^3/\text{s})(2000 \text{ mg/L})(10^3 \text{ L/m}^3)](-1.24 \text{ mg/s})}{(3.09 \times 10^{-3} \text{ m}^3/\text{s})(10^3 \text{ L/m}^3)} \\ &= 2020 \text{ mg/L} \end{aligned}$$

4. The solute concentration in the permeate of the next increment can be calculated from the water and solute fluxes in the first increment using Eq. 17-58:

$$C_{P,Z} = \frac{J_{S,Z}}{J_{W,Z}} = \frac{1371 \text{ mg/m}^2 \cdot \text{h}}{35.1 \text{ L/m}^2 \cdot \text{h}} = 39.2 \text{ mg/L}$$

5. Calculate the feed channel and permeate osmotic pressures using Eq. 17-7:

$$\pi_{FC,Z} = \frac{(2 \text{ mol ion/mol NaCl})(1.0)(2020 \text{ mg/L})(0.0831451 \text{ L} \cdot \text{bar/K} \cdot \text{mol})(293 \text{ K})}{(10^3 \text{ mg/g})(58.4 \text{ g/mol})}$$

$$= 1.68 \text{ bar}$$

$$\pi_{P,Z} = \frac{(2 \text{ mol ion/mol NaCl})(1.0)(39.2 \text{ mg/L})(0.0831451 \text{ L} \cdot \text{bar/K} \cdot \text{mol})(293 \text{ K})}{(10^3 \text{ mg/g})(58.4 \text{ g/mol})}$$

$$= 0.03 \text{ bar}$$

6. The pressure in the feed channel drops due to head loss through the channel, and the head loss is a function of the feed velocity. The head loss in the first increment and pressure in the next increment can be calculated:

- a. The head loss in an incremental length of the membrane element as a function of velocity must be determined from the given head

loss information using Eq. 17-57 rearranged as follows:

$$\delta_{HL} = \frac{h_L}{v^2 L} = \frac{0.2 \text{ bar}}{(0.5 \text{ m/s})^2 (1 \text{ m})} = 0.8 \text{ bar} \cdot \text{s}^2/\text{m}^3$$

b. Determine the head loss in the increment using Eq. 17-57:

$$h_{L,Z} = \delta_{HL} v_Z^2 dz = (0.8 \text{ bar} \cdot \text{s}^2/\text{m}^3)(0.769 \text{ m/s})^2(0.1 \text{ m}) = 0.047 \text{ bar}$$

c. Determine pressure in the next increment:

$$P_{FC,Z} = 14.2 \text{ bar} - 0.047 \text{ bar} = 14.15 \text{ bar}$$

#### Part 4

Repeat Parts 2 and 3 for the second and subsequent increments. The results are shown in the table below:

Increment (z)	Unit	1	2	3	4	5	...	10
$Q_{FC,Z}$	m <sup>3</sup> /s	$3.125 \times 10^{-3}$	$3.093 \times 10^{-3}$	$3.062 \times 10^{-3}$	$3.030 \times 10^{-3}$	$2.999 \times 10^{-3}$		$2.845 \times 10^{-3}$
$v_Z$	m/s	0.7692	0.7614	0.7536	0.7459	0.7382		0.7003
$P_{FC,Z}$	bar	14.20	14.15	14.11	14.06	14.02		13.81
$h_{L,Z}$	bar	0.047	0.046	0.045	0.045	0.044		0.039
$C_{FC,Z}$	mg/L	2000	2020	2041	2062	2084		2196
$\pi_{FC,Z}$	bar	1.67	1.68	1.70	1.72	1.74		1.83
$Q_{P,Z}$	m <sup>3</sup> /s	$3.17 \times 10^{-5}$	$3.16 \times 10^{-5}$	$3.14 \times 10^{-5}$	$3.13 \times 10^{-5}$	$3.11 \times 10^{-5}$		$3.03 \times 10^{-5}$
$P_{P,Z}$	bar	0.3	0.3	0.3	0.3	0.3		0.3
$C_{P,Z}$	mg/L	0	39.2	39.0	39.6	40.3		43.6
$\pi_{P,Z}$	bar	0	0.03	0.03	0.03	0.03		0.04
$k_{CP,Z}$	m/s	$8.64 \times 10^{-5}$	$8.56 \times 10^{-5}$	$8.49 \times 10^{-5}$	$8.42 \times 10^{-5}$	$8.35 \times 10^{-5}$		$7.99 \times 10^{-5}$
$\beta_Z$		1.120	1.120	1.121	1.121	1.122		1.124
$J_{W,Z}$	L/m <sup>2</sup> · h	35.1	35.0	34.8	34.7	34.5		33.6
$J_{S,Z}$	mg/m <sup>2</sup> · h	1374.77	1365.46	1380.43	1395.16	1410.15		1489.01
$M_Z$	mg/s	1.24	1.23	1.25	1.26	1.27		1.34
$Re_{jZ}$		0.980	0.981	0.981	0.981	0.981		0.981

#### Part 5

After calculating Part 4 for all increments in the element, the overall performance can be determined.

1. Permeate production from the element is the sum of the permeate produced in each increment:

$$Q_P = \sum_{Z=1}^{10} Q_{P,Z} = 3.1 \times 10^{-4} \text{ m}^3/\text{s}$$

2. Salt transfer from the element is the sum of the salt transferred in each increment:

$$M_S = \sum_{Z=1}^{10} M_{S,Z} = 12.8 \text{ mg/s}$$

3. Permeate concentration:

$$C_P = \frac{M_S}{Q_P} = \frac{12.8 \text{ mg/s}}{(3.10 \times 10^{-4} \text{ m}^3/\text{s})(10^3 \text{ L/m}^3)} = 41.3 \text{ mg/L}$$

4. Rejection (Eq. 17-1):

$$\text{Rej} = 1 - \frac{C_P}{C_F} = 1 - \frac{41.3 \text{ mg/L}}{2000 \text{ mg/L}} = 0.98$$

5. Recovery (Eq. 17-12):

$$r = \frac{Q_P}{Q_F} = \frac{3.1 \times 10^{-4} \text{ m}^3/\text{s}}{3.12 \times 10^{-3} \text{ m}^3/\text{s}} = 0.099$$

### Comment

In this example, the performance of a single membrane element has been determined. The concentrate from this element becomes the feed to the next element in series; that is,  $Q_{C,1}$ ,  $P_{C,1}$ , and  $C_{C,1}$  are  $Q_{F,2}$ ,  $P_{F,2}$ , and  $C_{F,2}$ . The system permeate flow rate is the sum of the permeate flow from each element. The system permeate concentration is the flow-averaged permeate concentration from each element.

### MANUFACTURER SOFTWARE

In Example 17-5 pressure was used as an input variable and a value for recovery was generated. Normally, the desired recovery is determined from limiting salt calculations (taking acid and antiscalant addition into account), and design calculations generate the feed pressure required for a particular membrane element. Using these equations, an iterative solution would be necessary. The design calculations are also repeated with varying membrane elements and array configurations. In addition, other process parameters, such as permeate backpressure and interstage booster pumps, can affect system design and performance. Thus, design is an iterative process and typically takes place with the cooperation of several membrane system manufacturers. Manufacturers provide design software to perform these calculations, which are based on the principles presented in this chapter, and incorporate issues such as osmotic pressure, limiting salt solubility, mass transfer rates, concentration polarization, and permeate water quality. As such, manufacturers' software is reliable for predicting effluent water

quality from a specific membrane system design and a given set of operating conditions. An example of the output from a vendor-supplied RO design program is shown in Table 17-5.

#### **FUNCTIONAL SPECIFICATIONS**

Because design criteria cannot be developed independently of manufacturer data, procurement of RO systems is often accomplished by means of a functional specification. By this method, an engineer develops the system requirements, designs the pretreatment processes, designs the RO system support facilities, and defines the basic requirements of the RO system. The functional specifications outline the operating requirements of the system, physical constraints of the system, and warranty agreements between the manufacturer and the owner. Bid proposals are returned by the interested manufacturers that outline the particulars of the system being supplied, estimates of system product quality as a function of time, system capital costs, and system operating costs as a function of time. The proposals are typically reviewed by the engineer to determine the optimum life-cycle cost.

An important aspect of long-term RO operation is loss of performance due to compaction, fouling, or degradation of the membrane. Limiting salt calculations can be a good predictor of the recovery that can be achieved without causing scaling. Antiscalants can allow supersaturation (i.e., higher recovery) without scaling, but their effectiveness might be dependent on other water quality parameters. SDI and MFI tests can indicate when feed water quality is unacceptable, but low values do not assure that fouling will be minimal. Therefore, it is necessary to perform pilot testing for nearly all RO installations. Pilot testing is guided by membrane system selection and operating conditions developed during array design and serves to verify the array design criteria and identify pretreatment requirements to prevent excessive fouling.

#### **Pilot Testing**

#### **COMMERCIAL RO PILOT PLANTS**

Reverse osmosis pilot plant systems are typically available from membrane manufacturers or consulting engineering firms. A typical commercially available skid-mount system is shown on Fig. 17-18. This skid unit contains six pressure vessels, each containing spiral-wound membrane elements in series. The pressure vessels can be operated as two independent systems, with each system containing three pressure vessels that can be piped as a  $2 \times 1$  array, which allows membranes from two manufacturers to be tested simultaneously. The pilot plant system is operated with a programmable logic controller (PLC). Chemicals are added to the feed water to prevent fouling of the membrane. Manufacturer-supplied specifications for pilot plant systems are usually provided so that the pilot unit can be properly operated. These specifications are usually obtained from the manufacturer

Typical reverse osmosis pilot plant.

and provide useful guidelines when planning and operating the pilot plant units.

#### **PILOT TEST PARAMETERS**

For most RO pilot studies, the following parameters should be recorded:

1. Date and time of sample analysis
2. Flow rates (feed, concentrate, and permeate)
3. Pressure (feed, concentrate, and permeate)
4. Feed water temperature
5. Conductivity (online reading recommended)
6. Power consumption
7. Chemical usage
8. pH (feed, concentrate, and permeate)

Additional reporting and recording requirements are available elsewhere (ASTM, 2001c, 2001d).

### **Pretreatment**

Pretreatment is necessary to prevent scaling and fouling. The common pretreatment strategies include the injection of acids and antiscalants to prevent the precipitation of sparingly soluble salts and filtration to prevent plugging by particulate matter. Very clean source water (such as groundwater) often can operate with only cartridge filtration prior to the membrane units, but more advanced filtration methods, including coagulation, flocculation, sedimentation, and granular filtration, or membrane filtration, are commonly required with surface water intake facilities. Pretreatment must be selected and designed in concert with the array design because the membrane element performance is dependent on the level of pretreatment. Additional details on the design of pretreatment systems is available in design manuals such as AWWA (2007).

### **Posttreatment**

The permeate from an RO facility typically requires additional treatment. Feed water pH adjustment prior to RO, along with extensive removal of divalent ions by the RO process, produces treated water with low pH, low alkalinity, and low hardness, which are conditions that cause water to be corrosive. Anaerobic groundwater frequently contains hydrogen sulfide, which passes through the membrane and causes odor problems in the treated water. Finally, residual disinfection is always required for municipal water distribution.

**PERMEATE STABILITY**

A number of strategies can be used to increase the stability (reduce the corrosivity) of the water. When the feed water is acidified for scale control, carbonate alkalinity in the raw water is converted to carbonic acid, which passes through the membrane. Thus, addition of a base such as caustic soda can restore both pH and alkalinity to acceptable levels. Without additional measures, however, such water will still be corrosive. Stability can be improved by adding hardness ions to the water, so base addition with chemicals containing calcium is sometimes preferred over caustic soda. Lime and soda ash are common chemicals for increasing the stability of RO permeate. Small systems sometimes can add an acceptable amount of hardness by passing the permeate through a bed of calcareous media such as dolomite or calcite. In lieu of adding hardness to the water, corrosion inhibitors may be effective. Another strategy for producing a stable finished water is to blend the permeate with a bypass stream of raw water that meets all other water treatment requirements (such as filtration if a surface water source is used). Proper blending of raw and permeate water may produce a finished water with the desired pH, alkalinity, and hardness. However, DBP precursor concentration in the raw water and the potential for DBP formation need to be evaluated when considering blending options. The importance of finished-water stability is discussed in additional detail in Chap. 22.

**HYDROGEN SULFIDE**

Anaerobic groundwater can contain hydrogen sulfide, a highly odorous compound that is not removed during RO. Hydrogen sulfide can be removed by oxidation or aeration. Oxidation to sulfate can be accomplished with oxidants such as chlorine, but large doses are needed (the stoichiometric chlorine requirement is about 9 times the hydrogen sulfide concentration on a mass basis and insufficient amounts can oxidize sulfide to elemental sulfur, which is equally undesirable). Thus, hydrogen sulfide is commonly removed after the membrane process in an air-stripping process using countercurrent packed towers, which are discussed in Chap. 14. Since hydrogen sulfide is a weak acid, the pH of the water will have a significant impact on its removal efficiency (Howe and Lawler, 1989). Odor control can be a significant issue when stripping water that contains sulfide.

It is necessary to consider all posttreatment goals simultaneously and select treatment options that achieve all objectives. For instance, air stripping to remove sulfide before base addition will strip carbon dioxide and increase the permeate pH; subsequent pH adjustment with caustic soda will not restore alkalinity because the carbonate will be gone. Alternatively, pH adjustment before stripping can prevent effective stripping because

sulfide is present as ionic hydrogen bisulfide rather than gaseous hydrogen sulfide.

#### **DISINFECTION**

Chlorine is commonly used for disinfection and is discussed in Chap. 13. The RO process is effective at removing DBP precursors; thus, free chlorination can typically be practiced without forming significant quantities of DBPs. However, care must be used if the RO permeate is to be blended with either raw water (for stability, see above) or a fresh water supply. Blending may increase DBP formation when using free chlorine. Cases have been observed when the blending of desalinated seawater into freshwater can increase the DBP formation of the freshwater, even though the desalinated water has a very low DBP formation potential on its own. Desalinated seawater can have a higher bromide concentration than freshwater sources, so that interactions between bromide from the desalinated seawater and NOM from the freshwater can increase overall DBP formation after chlorination to above what it would be with either water source individually. Thus, bromide removal can be one of the factors that controls the design of RO facilities.

#### **Concentrate Management**

A significant concern in the design and operation of inland brackish water RO facilities is the low product water recovery compared to other water treatment processes. Recovery is limited by osmotic pressure in seawater systems and by scaling from sparingly soluble salts in inland brackish water systems. For inland systems, the low recovery has two negative consequences. First, brackish water desalination is typically considered because of a lack of adequate freshwater resources, and inability to recover a high fraction of the feed water is simply a poor use of scarce natural resources. Second, the unrecovered water becomes the concentrate stream and must be disposed of. The increase salinity of the concentrate stream greatly limits available disposal options because of the potential for contaminating the scarce freshwater resources. Thus, there is significant interest in increasing recovery of product water and decreasing the volume of concentrate that must be disposed of.

Increasing recovery from inland brackish water RO facilities involves preventing the precipitation of sparingly soluble salts. As noted earlier, scale inhibitors are used to prevent precipitation and increase recovery up to a point. However, scale inhibitors are limited in their effectiveness, and more aggressive strategies typically must be employed to achieve recovery of greater than 90 percent.

One strategy is to provide an intermediate treatment process between two stages of RO membranes. Since calcium is often the limiting cation,

lime softening can be an effective intermediate strategy. Softening can also be effective at removing other scale-causing constituents. Gabelich et al. (2007) found that increasing pH to between 10.5 and 11.5 with NaOH was able to remove 88 to 98 percent of  $\text{Ca}^{2+}$ ,  $\text{Ba}^{2+}$ ,  $\text{Sr}^{2+}$ , and 67 percent of silica. However, the high alkalinity and hardness present after a first stage of RO can lead to high doses of lime or NaOH; doses in excess of 1000 mg/L have been reported in experimental studies. Similarly high doses of acid can be necessary to reduce the pH after softening. The high doses also lead to a large amount of waste production. Seeding with calcite or gypsum crystals has also been explored as a way of improving the effectiveness of the intermediate precipitation process (Rahardianto et al., 2007). Fluidized bed crystallization using sand as a seed material has also proved effective in bench-scale testing (Sethi et al., 2008). Ion exchange is another possibility for interstage treatment for the removal of scale-causing constituents that may result in less waste production (Howe et al., 2010).

Several patented or proprietary processes have been developed to increase recovery from brackish RO systems. The patented high-efficiency reverse osmosis (HERO) process involves pretreatment to reducing scaling, followed by pH adjustment and additional stages of reverse osmosis. Hardness is typically removed using a cation exchange column that removes calcium and magnesium, and carbonate is removed by stripping carbon dioxide in a countercurrent packed column (see Chap. 14). The pH is then increased using caustic soda, typically above  $\text{pH} = 10$ . Since calcium and carbonate have been removed, calcium carbonate scaling at high pH is no longer a concern and the concentrate is fed into another stage of reverse osmosis. At pH above 10, silica and borate are transformed from neutral to ionic species, the solubility of silica is increased and scaling potential is reduced, the rejection of silica and borate is increased, the potential for organic fouling or biofouling is decreased, and cleaning costs are reduced. Recovery of 90 to 98 percent has been achieved.

Another proprietary system is the SAL-PROC system developed by Geo-Processors, Inc. This process uses a variety of treatment steps, including chemical addition, heating, cooling, and sequential concentration steps that may include more RO or evaporation. The SAL-PROC system is potentially capable of producing usable and possibly sellable salt products and slurries from the RO concentrate.

Another option that has been explored in research to prevent scaling and potentially increase recovery include the vibratory shear-enhanced process (VSEP) in which a membrane system is vibrated to prevent scale from forming on the membrane surface (Chang, 2008). Researchers have also explored other electrodialysis reversal, membrane distillation, or other desalination processes as a second-state desalination system after an intermediate-scale reduction process (Sethi et al., 2008).

Brine concentrators and crystallizers are additional technologies to reduce the volume of concentrate, and can lead to zero liquid discharge (ZLD), in which the only residuals from the facility are solids, which are then easier to dispose of (Mickley, 2006). While brine concentrators and crystallizers are used in some industrial processes such as the power generation industry, they are expensive, energy intensive, and have not yet been used in municipal water treatment industry. Brine concentrators and crystallizers are discussed in more detail in Chap. 21.

### Disposal of Residuals

Disposal of the concentrate stream is frequently a challenge in RO plant design. The factors that contribute to this problem are identified in Table 17-6. In addition to the concentrate stream, RO plants must also dispose of spent cleaning solutions. Both of these residuals are discussed in this section.

#### CONCENTRATE

Several surveys of concentrate disposal methods are available (Kenna and Zander, 2001; Mickley et al., 1993; Truesdall et al., 1995). The most common concentrate disposal options in the United States are (1) discharge to a brackish surface water (include oceans, brackish rivers, or estuaries),

**Table 17-6**  
Factors affecting concentrate disposal

Issue	Description
Volume	The waste stream volume from many water treatment processes is less than 5% of the feed stream volume. In RO, the waste stream volume ranges from 15 to 50% of the feed stream volume.
Salinity/toxicity	The high salinity of the concentrate stream makes it toxic to many plants and animals, limiting options for land application or surface water discharge and rendering it unusable for recycling or reuse. Many concentrate streams are anaerobic, which can be toxic to fish without sufficient dilution. In addition, RO processes used for specific contaminant removal (i.e., arsenic, radium) may produce concentrate streams that can be classified as a hazardous material.
Regulations	Concentrate is classified as an industrial waste by the U.S. EPA. Concentrate disposal is regulated under several different federal, state, and local laws, and the interaction between these regulatory requirements can be complex (Kimes, 1995; Pontius et al., 1996). Regulatory considerations are often as important as cost and technical considerations for determining viable concentrate disposal options.

(2) discharge to a municipal sewer, and (3) deep-well injection. In the United States, about half of all plants discharge concentrate to a surface water, a third discharge to a municipal sewer, and about 10 percent discharge to a deep well. Deep-well injection is most common in Florida. Evaporation ponds are used by a small number of facilities. Concentrate disposal is an integral part of the design of RO facilities and disposal options are discussed in more detail in Chap. 21 of this text.

An alternative to disposal of concentrate is to identify beneficial uses for the concentrate or its constituent salts and minerals. Possible beneficial uses that have been explored in various research projects include (1) land application or irrigation of salt-tolerant crops, (2) saline aquaculture, farming of brine shrimp or other saltwater species, (3) restoration of brackish waterways or development of saltwater marshes, wetlands, or habitats, (4) energy generation using solar gradient ponds, (5) industrial uses as feedstock or process stream, (6) production of marketable salts or mineral commodities (Ahuja and Howe, 2005; Everest and Murphree, 1995). At the current time, however, beneficial uses for the concentrate have not been identified at most facilities.

#### **CLEANING SOLUTIONS**

Spent cleaning solutions from RO plants are frequently acidic or basic solutions and contain detergents or surfactants. In many cases, the cleaning solution volume is small compared to the concentrate stream and can be diluted into and disposed of with the concentrate. In some cases, treatment of the cleaning solution may be required prior to disposal, but treatment may consist only of pH neutralization. Detergents and surfactants should be selected with disposal issues in mind.

Reverse osmosis is an energy-intensive process. The theoretical thermodynamic minimum energy requirement for desalinating seawater, based solely on the pressure required to overcome the osmotic pressure, is  $0.70 \text{ kWh/m}^3$ . This value is significantly higher than the typical energy required for the treatment of freshwater. A significant component of operating costs is electrical power for the feed pumps because of the high pressure necessary to operate RO membranes. Although pressure drops significantly as permeate passes through the membrane, the head loss through the feed channels is relatively small, and the concentrate exits the final membrane element at 80 to 90 percent of the feed pressure, with backpressure maintained by a concentrate control valve. If concentrate is discharged to a deep well, a portion of this pressure can be used to drive the disposal process. If, however, the concentrate is discharged to a surface water, this pressure must be dissipated prior to discharge. Pressure in the concentrate stream

#### **Energy Recovery**

dissipated across the concentrate control valve is wasted energy because it performs no useful work in the treatment system. Because the concentrate stream is both high energy and relatively high volume, the amount of wasted energy is substantial.

Energy recovery devices are being used more frequently to reclaim the wasted energy in the concentrate stream. Several types of devices are available, including reverse-running turbines, Pelton wheels, pressure exchangers, and electric motor drives (Geisler et al., 1999; Harris, 1999; Oklejas and Pergande, 2000; Tomkins and Nemeth, 2001). Typically, recovered energy from the residual pressure of the concentrate stream is used to pressurize the feed stream. In some systems, the concentrate stream spins a rotor, losing energy in the process, and exits the energy recovery device at a significantly lower pressure. In the reverse-running turbine and pressure exchanger, the energy recovery device is in contact with both the feed and concentrate streams, with a single rotor transferring pressure from the concentrate to the feed stream. Pressure exchangers allow direct contact between the feed and concentrate streams via a rotating rotor, and are thus able to transfer the pressure from the concentrate stream directly to the feed stream. Pelton wheel devices use a rotor connected directly to the feed pump via an extended shaft, and the energy recovered from the concentrate stream provides hydraulic assistance to the operation of the feed pumps. The main moving part is the Pelton wheel and shaft. Electric motor drives are more complex, utilizing a hydraulic drive system connected to the pump motor.

More than 90 percent of the energy expended to pressurize the concentrate stream can be recovered. Depending on the price for electricity, capital costs of energy recovery equipment may be recouped within 3 to 5 years. Energy recovery devices were first utilized on seawater RO systems because they operate at high pressure and low recovery, compounding the energy loss. Recent trends and improvements in energy recovery equipment and rising electricity prices suggest that energy recovery will be applied in more and more low-pressure systems.

In addition to providing pressure to the feed stream, another application is to use the energy recovery system to add pressure between stages (Duranceau et al., 1999). In normal operation, the second or later stages produce less permeate because of lower applied pressure (due to pressure drop in the first stage) and higher osmotic pressure (due to concentration of the feed stream in the first stage). The lower permeate flow and higher feed concentration also increase salt passage and degrade permeate quality. These effects are sometimes counteracted by installing booster pumps between stages, so that a higher feed pressure is available to offset

the higher osmotic pressure. By using energy recovery devices to boost pressure between stages, the booster pumps can be eliminated, which offsets a portion of the capital cost of the energy control device.

## Problems and Discussion Topics

---

- 17-1 Discuss key similarities and differences between membrane filtration and RO.
- 17-2 Explain why dissolved gases such as  $\text{CO}_2$  and  $\text{H}_2\text{S}$  are poorly rejected by RO membranes.
- 17-3 Calculate the total osmotic pressure of seawater at a temperature of  $20^\circ\text{C}$  using the ion concentrations shown in Table 17-2 and  $\phi = 1$ . Calculate the osmotic pressure of a solution containing an equivalent concentration of sodium chloride (i.e., 35,200 mg/L NaCl) also using  $\phi = 1$ . Explain and discuss the difference between the two results and discuss Fig. 17-9 in the context of these results.
- 17-4 The following solutions are representative of common applications of reverse osmosis. Calculate the osmotic pressure of each at  $20^\circ\text{C}$ . Discuss the importance of osmotic pressure and how it affects the applied pressure for these applications.
- NaCl = 35,000 mg/L (representative of seawater RO).
  - NaCl = 8000 mg/L (representative of brackish water RO).
  - Hardness = 400 mg/L as  $\text{CaCO}_3$  (representative of softening NF).
  - Dissolved organic carbon (DOC) = 25 mg/L (representative of using NF to control DBP formation by removing DBP precursors. Assume an average MW of 1000 g/mol.).
- 17-5 Seawater RO facilities are restricted to a maximum applied pressure of about 85 bar (1200 psi) because of equipment limitations. Using the seawater composition shown in Table 17-2, calculate the maximum recovery that can be achieved before the osmotic pressure at the membrane surface (at the exit from a membrane module) is equal to the applied pressure. Assume 100 percent rejection, a temperature of  $15^\circ\text{C}$ , and a concentration polarization factor of 1.12. Discuss how the results of this calculation compare to the typical recovery achieved by seawater RO facilities. Does osmotic pressure lead to any practical limitations on the size of the waste stream from a seawater RO facility?

- 17-6 Operating data for a low-pressure RO system on two different days are shown in the table below:

	Unit	Day 1	Day 2
Water temperature	°C	13	22
Water flux	L/m <sup>2</sup> · h	17.5	18.8
Feed pressure	bar	41.9	38.7
Concentrate pressure	bar	39.0	35.8
Permeate pressure	bar	0.25	0.25
Feed TDS concentration	mg/L	10,500	10,200
Permeate TDS concentration	mg/L	120	120
Recovery	%	66	68

Performance data for this membrane element were developed using the following standard conditions:

	Unit	Standard
Temperature	°C	20
Feed pressure	bar	40
Permeate pressure	bar	0
Head loss per element	bar	0.4
Number of elements	no.	7
Feed TDS concentration	mg/L	10,000
Permeate TDS concentration	mg/L	100
Recovery	%	70

Determine the difference in system performance (water flux and rejection) between the two days using the temperature correction formula in this text and an arithmetic average for the solute concentration in the feed–concentrate channel. Assume the salts in the feed water are sodium chloride for the purpose of calculating osmotic pressures.

- 17-7 In Eq. 17-10 the solute flux is dependent on the concentration gradient and independent of pressure; also it was noted that solute flux is dependent on temperature. However, Eq. 17-26 includes a correction factor for pressure and not temperature, from which it appears that rejection is dependent on pressure and independent of temperature. Show mathematically and explain (1) how rejection can be dependent on pressure when solute flux is independent of pressure and (2) why there is no temperature correction factor for rejection when there is a temperature correction factor for water flux.
- 17-8 Examine the importance of the diffusion coefficient on concentration polarization by plotting  $\beta$  as a function of the diffusion coefficient for diffusion coefficient values between  $10^{-10}$  m<sup>2</sup>/s

(typical of NOM with a diameter of 5 nm) and  $1.35 \times 10^{-9} \text{ m}^2/\text{s}$  (sodium chloride). Use feed channel velocity 0.65 m/s, permeate flux  $25 \text{ L}/\text{m}^2 \cdot \text{h}$ , hydraulic diameter 0.5 mm, and temperature  $20^\circ\text{C}$ . Discuss the implications that this graph has on the accumulation of material at the membrane surface.

- 17-9 Examine the importance of temperature on concentration polarization by plotting  $\beta$  as a function of temperature for values between 1 and  $30^\circ\text{C}$ . Use feed channel velocity 0.65 m/s, permeate flux  $25 \text{ L}/\text{m}^2 \cdot \text{h}$ , hydraulic diameter 0.5 mm, and calculate the diffusion coefficient from the Nernst–Haskell equation given in Chap. 7 (Eq. 7-36) for sodium chloride. Discuss how temperature will impact water and solute flux across the membrane from the perspective of concentration polarization.
- 17-10 An SDI test was performed to evaluate the fouling tendency of potential RO source water. The time to collect 500 mL of water was measured as 24 s. Filtration continued for a total of 15 min, and then a second 500 mL was collected. The time necessary to collect the second 500-mL sample was 32 s. Calculate the SDI.
- 17-11 Calculate the MFI from the following experimental data:

Time, min	Volume Filtered, L	Time, min	Volume Filtered, L	Time, min	Volume Filtered, L
0	0	5.5	5.37	11.0	9.86
0.5	0.63	6.0	5.80	11.5	10.24
1.0	1.17	6.5	6.23	12.0	10.61
1.5	1.68	7.0	6.65	12.5	10.98
2.0	2.16	7.5	7.07	13.0	11.35
2.5	2.64	8.0	7.48	13.5	11.71
3.0	3.11	8.5	7.89	14.0	12.06
3.5	3.58	9.0	8.29	14.5	12.41
4.0	4.03	9.5	8.69	15.0	12.75
4.5	4.48	10.0	9.08		
5.0	4.93	10.5	9.47		

- 17-12 An RO facility is being designed to treat groundwater containing the ions given below. Calculate the allowable recovery before scaling occurs and identify the limiting salt. Assume 100 percent rejection, a concentration polarization factor of 1.08, and  $T = 25^\circ\text{C}$ , and ignore the impact of ionic strength. The water contains calcium = 105 mg/L, strontium = 2.5 mg/L, barium = 0.0018 mg/L, sulfate = 128 mg/L, fluoride = 1.3 mg/L, and silica = 9.1 mg/L as Si.
- 17-13 A groundwater has a calcium concentration of 125 mg/L, alkalinity of 180 mg/L as  $\text{CaCO}_3$ , and pH of 7.1. Calculate the degree of

- supersaturation of calcium carbonate (ratio of actual concentration to the saturated concentration for each ion) at 60 percent recovery. Calculate the adjusted pH value and acid (HCl) dose necessary to prevent calcium carbonate precipitation at this recovery. Assume 100 percent rejection,  $\beta = 1.12$ , and  $T = 25^\circ\text{C}$ , and ignore ionic strength.
- 17-14 Feed water to a proposed low-pressure RO facility has a barium concentration of  $0.2\ \mu\text{g/L}$  and a sulfate concentration of  $420\ \text{mg/L}$ . The planned recovery is 80 percent. Calculate the concentration polarization allowable before the solubility of barium sulfate is exceeded. Assume 100 percent rejection and  $T = 25^\circ\text{C}$ , and ignore the impact of ionic strength.
- 17-15 Reverse osmosis facilities can be designed with multiple stages (concentrate from one stage is fed to the next stage) or multiple passes (permeate from one stage is fed to the next stage). Explain the difference in permeate quantity and quality expected from these systems.
- 17-16 Concentrate-staged membrane arrays can be designed with a booster pump in the concentrate line between stages. Explain the benefits of this interstage booster pump and the impact it has on permeate quantity and quality.
- 17-17 Design criteria for an RO system are given in the following table:

Item	Unit	Value
Membrane properties		
Element length	m	1
Element membrane area	$\text{m}^2$	32.5
Feed channel height (spacer thickness)	mm	0.125
Water mass transfer coefficient ( $k_W$ )	$\text{L}/\text{m}^2 \cdot \text{h} \cdot \text{bar}$	1.25
Solute mass transfer coefficient ( $k_S$ )	m/h	$3.29 \times 10^{-4}$
Element head loss (at design velocity of 0.5 m/s)	bar	0.1
Operating conditions		
Feed flow ( $Q_F$ )	$\text{m}^3/\text{d}$	19,000
Feed pressure ( $P_F$ )	bar	34
Feed concentration ( $C_F$ )	mg/L NaCl	8500
Feed temperature ( $T_F$ )	$^\circ\text{C}$	20
Permeate pressure ( $P_P$ )	bar	0.3

The system is to be designed as a  $2 \times 1$  array with 80 pressure vessels in the first stage and 40 pressure vessels in the second stage, and with 7 membrane elements in each pressure vessel.

- a. Using a spreadsheet or computer program, calculate and graph (1) the feed flow rate entering each element, (2) the feed concentration entering each element, (3) the concentration

- polarization factor  $\beta$  at each element, (4) the permeate flow rate produced by each element, and (5) permeate salt concentration produced by each element. For the purposes of this problem, assume that the operating conditions are constant across the length of each individual element. Assume that the feed water salinity is due entirely to NaCl,  $\phi = 0.94$ , and  $D_{\text{NaCl}} = 1.58 \times 10^{-9} \text{ m}^2/\text{s}$  (from Table 7-1 in Chap. 7).
- Calculate the average permeate flow rate and concentration for each stage and for the whole array.
  - Calculate overall recovery, rejection, and average water flux.
  - Discuss any observations about the quantity and quality of water produced by the first element compared to the last element, and explain the observed trend in  $\beta$ .
- 17-18 Calculate and plot water flux and salt rejection as a function of recovery, for recovery ranging from 50 to 85 percent, given  $C_F = 10,000 \text{ mg/L NaCl}$ ,  $\Delta P = 50 \text{ bar}$ ,  $k_W = 2.2 \text{ L/m}^2 \cdot \text{h} \cdot \text{bar}$  and  $k_S = 0.75 \text{ L/m}^2 \cdot \text{h}$ ,  $\phi = 1$ , and  $T = 20^\circ\text{C}$ . Comment on the effect of recovery on RO performance.
- 17-19 A new brackish water RO system is being proposed. The water quality is as shown in the table below. Using RO manufacturer design software (provided by the instructor or obtained from a membrane manufacturer website), develop the process design criteria for the plant. The required water demand is  $38,000 \text{ m}^3/\text{d}$  and the finished-water TDS should be  $500 \text{ mg/L}$  or lower.

Constituent	Concentration, mg/L	Constituent	Concentration, mg/L
Ammonia	1.3	Bicarbonate	680
Barium	0.04	Chloride	890
Calcium	20	Fluoride	0.7
Iron	0.5	Orthophosphate	0.7
Magnesium	2.5	Sulfate	105
Manganese	0.02	Silica	21.5
Potassium	17	Nitrate	1.2
Sodium	875	Hydrogen sulfide	0.3
Strontium	2.17		
pH	7.8	Turbidity	0.3 NTU
SDI	$<1 \text{ min}^{-1}$	Temperature	$15^\circ\text{C}$

- 17-20 A new seawater RO system is being proposed. The water quality is as shown in the table below. Using RO manufacturer design software (provided by the instructor or obtained from a membrane manufacturer website), develop the process design criteria for

the plant. The required water demand is 4000 m<sup>3</sup>/d and the finished-water TDS should be 500 mg/L or lower.

Constituent	Concentration, mg/L	Constituent	Concentration, mg/L
Aluminum	0.15	Strontium	6.6
Ammonia	0.092	Bromide	51
Barium	0.00	Bicarbonate	112
Boron	4.3	Chloride	18,900
Calcium	439	Fluoride	0.61
Iron	0.1	Phosphate	0.12
Magnesium	1,240	Sulfate	2380
Potassium	425	Silica	0.86
Sodium	10,100	Hydrogen sulfide	0.0
Strontium	6.6		
pH	8.0	Turbidity	3.3 NTU
SDI	<1 min <sup>-1</sup>	UV <sub>254</sub>	0.03/cm
Temperature	15°C		

17-21 A new membrane softening system is being proposed. The water quality is as shown in the table below. Using RO manufacturer design software (provided by the instructor or obtained from a membrane manufacturer website), develop the process design criteria for the plant. The required water demand is 14,200 m<sup>3</sup>/d and the finished-water hardness should be between 50 and 75 mg/L as CaCO<sub>3</sub>.

Constituent	Concentration, mg/L	Constituent	Concentration, mg/L
Ammonia	1.5	Bicarbonate	135.1
Barium	0.0	Bromide	0.0
Calcium	100	Carbonate	0.11
Magnesium	10	Chloride	98.8
Manganese	0.002	Fluoride	0.5
Sodium	60	Phosphate	0.5
Strontium	1.0	Sulfate	167.6
		Silica	15.0
pH	7.0	Temperature	20°C
SDI	<1 min <sup>-1</sup>

# 18 Advanced Oxidation

## 18-1 Introduction to Advanced Oxidation

- Types of Advanced Oxidation Processes
- Estimating Performance of AOPs
- By-products of AOPs
- Major Factors Affecting AOPs
- Assessing Feasibility of AOPs

## 18-2 Ozonation as an Advanced Oxidation Process

- Hydroxyl Radical Production from  $\text{OH}^-$
- Hydroxyl Radical Production from NOM
- Determination of Destruction of Target Compounds from Bench-Scale Tests

## 18-3 Hydrogen Peroxide/Ozone Process for Potable Water

- Reaction Mechanisms
- Proper Dosage of Hydrogen Peroxide and Ozone
- Elementary Reactions for  $\text{H}_2\text{O}_2/\text{O}_3$  Process
- Simplified Model for  $\text{H}_2\text{O}_2/\text{O}_3$  Process
- Comparison of Simplified Model to Data and Its Limitations
- Disadvantages of  $\text{H}_2\text{O}_2/\text{O}_3$  Process

## 18-4 Hydrogen Peroxide/UV Light Process

- Elementary Reactions for the Hydrogen Peroxide/UV Process
- Describing Reactor Performance
- Comparison of the Simplified Model to Data and Its Limitations
- Impact of NOM and Compound Type on Target Compound Destruction

## 18-5 Other Advanced Oxidation Processes

- Ozone/UV Light
- Photocatalysis with Titanium Dioxide
- Reactions with Iron (Fenton's Reactions)
- Sonolysis

## Problems and Discussion Topics

## Terminology for Advanced Oxidation

---

Term	Definition
Advanced oxidation process	Oxidation process that produces hydroxyl radicals at room temperature and pressure.
Electrical efficiency per log order reduction (EE/O)	Electrical energy (in kWh/m <sup>3</sup> ) required to reduce the concentration of a pollutant by one order of magnitude.
Extinction coefficient	Measure of how strongly a substance absorbs light at a given wavelength per mass unit.
Hydroxyl radical	Chemical species containing hydrogen and oxygen, differentiated from hydroxide ion (OH <sup>-</sup> ) because it has an unpaired electron in its outer shell. The unpaired electron makes it a powerful, unselective electrophile that is able to oxidize a wide range of organic compounds.
Photocatalysis	Acceleration of a photolysis reaction due to the presence of a catalyst.
Photolysis	Process in which compounds absorb photons and release energy that is able to initiate advanced oxidation.
Photon	Small packet of energy that carries electromagnetic radiation.
Quantum yield	Ratio of the number of molecules degraded in a photolysis reaction to the number of adsorbed photons.
Relative quenching rate ( $Q_R$ )	Ratio of the rate of target compound destruction by hydroxyl radical reaction to the rate of all hydroxyl radical reactions in solution.
Second-order hydroxyl radical rate constant	Indicator of the speed of an advanced oxidation process (AOP) reaction. AOP reactions tend to be quite rapid with second-order hydroxyl radical rate constants on the order of 10 <sup>8</sup> to 10 <sup>10</sup> L/mol · s.
Sonolysis	Formation of radicals using ultrasound to break apart chemical bonds of organic compounds, causing oxidation.
Ultraviolet light (UV)	Electromagnetic radiation with wavelengths between 100 and 400 nm.

---

Three types of oxidation processes are used in water treatment. They include (1) conventional chemical oxidation processes, (2) oxidation processes carried out at elevated temperatures and/or pressure, and (3) advanced oxidation processes. Conventional chemical oxidation processes

employ oxidants such as chlorine, chlorine dioxide, and potassium permanganate and do not produce highly reactive species such as the hydroxyl radical ( $\text{HO}\cdot$ ), which are produced in the other two types of oxidation processes. The “dot” written as part of the hydroxyl and other radical species indicates that the outer electron orbital has an unpaired electron. Hydroxyl radicals are reactive electrophiles that readily react with most organic compounds by undergoing addition reactions with double bonds or extracting hydrogen atoms from organic compounds. The reaction rates for conventional oxidants are much slower than the reaction rates involving  $\text{HO}\cdot$ , and conventional chemical oxidants are more selective in terms of the types of organic molecules that they oxidize. Oxidation processes carried out at elevated temperatures and/or pressures such as wet oxidation, supercritical oxidation, gas-phase combustion, and catalytic oxidation processes can oxidize organic matter by free-radical reactions involving  $\text{HO}\cdot$ . In advanced oxidation processes (AOPs),  $\text{HO}\cdot$  radicals are generated at ambient temperature and atmospheric pressure.

The purpose of this chapter is to introduce the general subject of advanced oxidation. Topics to be considered include (1) an introduction to advanced oxidation processes, (2) ozonation as an advanced oxidation process, (3) the hydrogen peroxide/ozone process for potable water, and (4) other advanced oxidation processes.

## 18-1 Introduction to Advanced Oxidation

---

Some water supplies may contain toxic synthetic organic compounds (SOCs) that must be removed or destroyed to protect public health. These chemicals include agricultural pesticides and herbicides, fuels, solvents, human and veterinary drugs, and other potential endocrine disruptors. Given the uncertainty of the toxicity of the by-products of chemical oxidation, any oxidation process that is used to remove these compounds must oxidize the SOCs completely into carbon dioxide, water, and mineral acids (e.g.,  $\text{HCl}$ ). Conventional oxidants, such as chlorine, are selective as to which compounds they can degrade, whereas AOPs are able to completely convert organic compounds into carbon dioxide, water and mineral acids, making AOPs a viable option to destroy SOCs. Advanced oxidation processes also have several inherent advantages over other processes, such as adsorption onto activated carbon or air stripping: (1) the contaminants can be destroyed completely, (2) contaminants that are not adsorbable or volatile can be destroyed, and (3) mass transfer processes such as adsorption or stripping only transfer the contaminant to another phase, which becomes a residual and may require additional treatment.

Advanced oxidation processes are feasible for full-scale use to destroy organic compounds because they generate hydroxyl radicals at ambient temperature and atmospheric pressure (Glaze et al., 1987), whereas other

processes that generate hydroxyl radicals (wet oxidation, supercritical oxidation, gas-phase combustion, and catalytic oxidation processes) require elevated temperatures and/or high pressures and are mediated by free-radical chain reactions involving hydroxyl radicals ( $\text{HO}\cdot$ ). As noted in the introduction to the chapter, a dot is often given after each radical species indicating that there is an unpaired electron in the outer orbital. This notation is an abbreviated version of the Lewis structure, which normally is used to denote whether all eight electrons in the outer orbitals of carbon, oxygen, and nitrogen are filled. In the case of  $\text{HO}\cdot$ , there are three sets of paired electrons that are not shown and one unpaired electron, which is shown as the dot.

Hydroxyl radicals are effective in destroying organic chemicals because they are reactive electrophiles (electron preferring) that react rapidly and nonselectively with nearly all electron-rich organic compounds. Moreover, the second-order hydroxyl radical rate constants for most organic pollutants in water are on the order of  $10^8$  to  $10^9$  L/mol·s (Buxton and Greenstock, 1988), which is about the magnitude of diffusion-limited acid–base reactions ( $\sim 10^9$ ; Stumm and Morgan, 1972). Acid–base reactions are considered to be the fastest aqueous-phase chemical reactions because they only involve the transfer of a hydrated proton. These rate constants are three to four orders of magnitude greater than any of the second-order rate constants reported for other oxidants.

### **Types of Advanced Oxidation Processes**

The major advantages and disadvantages of various AOPs are provided in Table 18-1. Of the processes listed only the commercially available AOPs can be considered for full-scale water treatment, which are (1) ozone and hydrogen peroxide, (2) UV light and ozone, (3) UV light and hydrogen peroxide, (4) UV light and titanium dioxide, and (5) combinations of the aforementioned technologies.

### **Estimating Performance of AOPs**

One of the most important considerations in advanced oxidation is the quantity of oxidants that are required to destroy the organics targeted for destruction and that are scavenged ( $\text{HO}\cdot$  radicals) by background organic and inorganic matter. The influence of background matter on AOP performance is discussed later, but insight into the type of compounds that may be degraded in a reasonable time can be evaluated by using typical  $\text{HO}\cdot$  concentrations and reported rate constants.

Advanced oxidation processes that operate in the field generate  $\text{HO}\cdot$  concentrations between  $10^{-11}$  and  $10^{-9}$  mol/L (Glaze and Kang, 1988; Glaze et al., 1987). The second-order hydroxyl radical rate constants for several commonly encountered water pollutants are provided in Table 18-2. A more comprehensive list is provided in the electronic Table E-4 at the website listed in App. E. The reaction mechanism and the rate law for  $\text{HO}\cdot$  that

**Table 18-1**

Advantages and disadvantages of various oxidation processes that produce hydroxyl radicals in decreasing order of preference

Advanced Oxidation Process	Advantages	Disadvantages
Hydrogen peroxide/UV light	<ul style="list-style-type: none"> <li><input type="checkbox"/> H<sub>2</sub>O<sub>2</sub> is quite stable and can be stored onsite for long periods prior to use.</li> </ul>	<ul style="list-style-type: none"> <li><input type="checkbox"/> H<sub>2</sub>O<sub>2</sub> has poor UV absorption characteristics, and if the water matrix absorbs a lot of UV light energy, then most of the light input to the reactor will be wasted.</li> <li><input type="checkbox"/> Special reactors designed for UV illumination are required.</li> <li><input type="checkbox"/> Residual H<sub>2</sub>O<sub>2</sub> must be addressed.</li> </ul>

**Table 18-1** (Continued)

Advanced Oxidation Process	Advantages	Disadvantages
Ozone/TiO <sub>2</sub>	<input type="checkbox"/> Process may have faster destruction rates as compared to TiO <sub>2</sub> alone.	<input type="checkbox"/> There are no commercial applications.
Ozone/TiO <sub>2</sub> /H <sub>2</sub> O <sub>2</sub>	<input type="checkbox"/> Process may have faster destruction rates as compared to TiO <sub>2</sub> alone.	<input type="checkbox"/> There are no commercial applications.
Pulsed corona discharges/ nonthermal plasma	<input type="checkbox"/> Process does not require elevated temperatures.	<input type="checkbox"/> Works only in the gas phase.
Catalytic oxidation	<input type="checkbox"/> For gas-phase applications, process does not require temperatures that are as high as thermal incineration. <input type="checkbox"/> For aqueous-phase applications, process does not require temperatures that are as high as supercritical water oxidation.	<input type="checkbox"/> Only certain compounds in the aqueous phase may be degraded. <input type="checkbox"/> For gas-phase applications, the production of dioxins and furans must be avoided.
Electron beam irradiation	<input type="checkbox"/> Process does not require elevated temperatures.	<input type="checkbox"/> There are no commercial applications. <input type="checkbox"/> Requires specialized reactor and significant amount of energy.
Ozone/electron beam irradiation	<input type="checkbox"/> Process does not require elevated temperatures. <input type="checkbox"/> Process may have faster destruction rates as compared to electron process alone.	<input type="checkbox"/> Same as electron beam.
Gamma radiation	<input type="checkbox"/> Process does not require elevated temperatures.	<input type="checkbox"/> Same as electron beam.
Electrohydraulic cavitation	<input type="checkbox"/> Process does not require elevated temperatures.	<input type="checkbox"/> Same as electron beam.

reacts with an organic compound is given by the expressions

$$r_{\text{R}} = -k_{\text{R}} C_{\text{HO}\cdot} C_{\text{R}} \quad (18-2)$$

where  $r_{\text{R}}$  = destruction rate of R with HO• radicals, mol/L · s  
 $k_{\text{R}}$  = second-order rate constant for destruction of R with HO• radicals, L/mol · s

Source: Adapted from Buxton and Greenstock (1988), Lal et al. (1988), and Mao et al. (1991).

$C_{\text{HO}\cdot}$  = concentration of hydroxyl radical, mol/L

$C_{\text{R}}$  = concentration of target organic R, mol/L

The half-life of the target organic compounds may be calculated assuming that the concentration of  $\text{HO}\cdot$  is constant and equal to a typical value that is encountered in the field. The expression for the half-life of an organic compound is obtained by substituting the rate expression into a mass balance on a batch reactor whose contents are mixed completely and solving and rearranging the result, as follows:

$$\frac{dC_{\text{R}}}{dt} = -k_{\text{R}} C_{\text{HO}\cdot} C_{\text{R}} \quad (18-3)$$

$$t_{1/2} = \frac{\ln(2)}{k_{\text{R}} C_{\text{HO}\cdot}} \quad (18-4)$$

where  $t_{1/2}$  = half-life of organic compound R, s

The half-lives of the target organic compounds for  $\text{HO}\cdot$  concentrations of  $10^{-9}$ ,  $10^{-10}$ , and  $10^{-11}$  mol/L are also provided in Table 18-2. Based on the reported half-life, it is possible to mineralize many organic compounds completely within a matter of minutes. However, it is clear that if background matter reduces the  $\text{HO}\cdot$  concentration to  $10^{-11}$  mol/L, then AOPs may not be effective. The influences of NOM, carbonate, bicarbonate, and pH on AOPs are considered later in this chapter.

### Example 18-1 Half life and detention time in a PFR for advanced oxidation of MTBE

Methyl *tert*-butyl ether (MTBE) was used as an octane enhancer that has been found in groundwater underneath a gasoline station at a concentration of 100  $\mu\text{g/L}$ . From Table 18-2, the second-order rate constant of  $\text{HO}\cdot$  for MTBE is  $1.6 \times 10^9$  L/mol  $\cdot$  s. Calculate the half-life and the time it would take to lower the concentration of MTBE to 5  $\mu\text{g/L}$  for a  $\text{HO}\cdot$  concentration of  $10^{-11}$  mol/L in a completely mixed batch reactor (CMBR). Determine the detention time for an ideal plug flow reactor (PFR) to achieve a treatment objective of 5  $\mu\text{g/L}$ .

#### Solution

1. Obtain an expression of the concentration of MTBE as a function of time in a CMBR. The following expression can be written for a CMBR, where  $C_{\text{R}}$  represents the concentration of MTBE:

$$\frac{dC_{\text{R}}}{dt} = r_{\text{R}} = -k_{\text{R}} C_{\text{HO}\cdot} C_{\text{R}}$$

Let  $k = k_{\text{R}}C_{\text{HO}\cdot} = (1.6 \times 10^9 \text{ L/mol} \cdot \text{s})(10^{-11} \text{ mol/L}) = 1.6 \times 10^{-2} \text{ s}^{-1}$ . The rate expression can be rewritten as

$$\frac{dC_{\text{R}}}{dt} = -kC_{\text{R}}$$

Integrating the above expression yields

$$\int_{C_{\text{R}0}}^{C_{\text{R}}} \frac{dC_{\text{R}}}{C_{\text{R}}} = - \int_0^t kt \quad C_{\text{R}} = C_{\text{R}0}e^{-kt}$$

2. Calculate the half-life of MTBE: Substituting  $C_{\text{R}} = C_{\text{R}0}/2$  into the equation  $C_{\text{R}} = C_{\text{R}0}e^{-kt}$  and defining  $t$  for  $C_{\text{R}} = C_{\text{R}0}/2$  as the half-life  $t_{1/2}$  yields

$$\frac{1}{2} = e^{-kt_{1/2}}$$

$$t_{1/2} = \frac{\ln(2)}{k} = \frac{0.693}{(1.6 \times 10^{-2} \text{ s}^{-1})} = 43.3 \text{ s}$$

3. Calculate the time it would take to achieve a concentration of  $5 \mu\text{g/L}$ . Rearranging the equation  $C_{\text{R}} = C_{\text{R}0}e^{-kt}$  and solving for  $t$ ,

$$t = \frac{1}{k} \ln \frac{C_{\text{R}0}}{C_{\text{R}}}$$

$$t = \frac{1}{1.6 \times 10^{-2}} \ln \left( \frac{100}{5} \right) = 187 \text{ s} \quad (3.12 \text{ min})$$

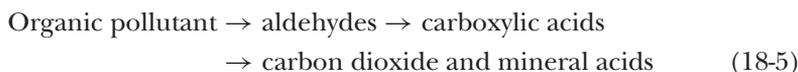

4. The residence time for an ideal PFR would also be 3.12 min because the elapsed time in a CMBR is equivalent to residence time in an ideal PFR.

### Comment

Many AOPs have much shorter residence times than 3 min. Consequently, the hydroxyl radical concentration must be much higher than  $10^{-11} \text{ M}$  for AOPs to be feasible.

Two common reactions of  $\text{HO}\cdot$  with organic compounds are addition reactions with double bonds and extraction of hydrogen atoms. Double-bond addition is much more rapid than hydrogen abstraction. For example, TCE reacts much more rapidly than 1,1,2-trichloroethane, as shown in Table 18-2. Some toxic organic compounds of interest, such as halogenated organic contaminants that do not contain double bonds, are more difficult to degrade. For example, as reported in Table 18-2, chloroform, 1,1,2-trichloroethane, and 1,1,1-trichloroethane react more slowly with  $\text{HO}\cdot$ , and these compounds will require longer reaction times and/or high concentrations of  $\text{HO}\cdot$ .

Both hydrogen abstraction and double-bond addition produce reactive organic radicals that rapidly undergo subsequent oxidation and most often combine with dissolved oxygen to form peroxy organic radicals (ROO•). These peroxy organic radicals undergo radical chain reactions that produce a variety of oxygenated by-products. The following general pattern of oxidation is observed for AOPs (Bolton and Carter, 1994):

Some of the significant by-products and the highest yields observed are listed in Table 18-3. The most significant observed by-products are the carboxylic acids, due to the fact that the second-order rate constants for these compounds are much lower than those for most other organics. However, if adequate reaction time is provided, all by-products (>99 percent as measured by a TOC mass balance) are destroyed (Stefan and Bolton, 1998, 1999, 2002; Stefan et al., 2000). Other by-products of concern are the halogenated acetic acids, formed from the oxidation of halogenated alkenes such as trichloroethylene. The rate constant and half-life for chloroacetic

**Table 18-3**

By-products observed following advanced oxidation for four selected organic compounds

Target Compound	Observed By-products	Approximate Yield: Mole By-product per Mole Compound, %

acid is reported in Table 18-2, and longer retention time and/or higher HO• radical concentrations are needed to destroy this compound. For example, it has been demonstrated that it is possible to completely mineralize TCE using an AOP that utilizes TiO<sub>2</sub>, O<sub>3</sub>, and UV light in a few minutes of reaction time (Zhang et al., 1994).

Another problem with advanced oxidation processes (and processes that use ozone) is the production of brominated by-products and bromate in waters containing bromide ion. A complete discussion of ozone by-products is contained in Chap. 19.

### Major Factors Affecting AOPs

The following chemical and physical properties of the water matrix have a major impact on AOPs because they either scavenge HO• radicals or absorb UV light that is used to produce HO• from hydrogen peroxide or ozone: (1) carbonate species (HCO<sub>3</sub><sup>-</sup> and CO<sub>3</sub><sup>2-</sup>), (2) pH, (3) NOM, (4) reduced metal ions (iron and manganese), (5) reactivity of the parent component with hydroxyl radical, and (6) UV light transmission of the water matrix. The first five of these factors are considered briefly in the following discussion. The effect of UV light transmission has been discussed previously in Sec. 8-4.

#### IMPACT OF CARBONATE SPECIES

Bicarbonate and carbonate ions are known scavengers of HO• radicals and significantly reduce the rate of organics destruction. As shown in Table 18-2, the rate constants between HO• and HCO<sub>3</sub><sup>-</sup> and CO<sub>3</sub><sup>2-</sup> are much lower than for many organic compounds. Unfortunately, the concentrations of HCO<sub>3</sub><sup>-</sup> and CO<sub>3</sub><sup>2-</sup> are often three orders of magnitude higher than the organic pollutants targeted for destruction. The degree of quenching of the AOP oxidation rate can be estimated from the expression

$$Q_R = \frac{k_R C_R}{k_R C_R + k_{\text{HCO}_3^-} C_{\text{HCO}_3^-} + k_{\text{CO}_3^{2-}} C_{\text{CO}_3^{2-}}} \quad (18-6)$$

where  $Q_R$  = target organics (R) reaction rate with hydroxyl radical divided by total reaction rate of hydroxyl radical with both R and alkalinity ( $1/Q_R$  equals the reduction in reaction due to presence of carbonate species), dimensionless

$k_R$  = second-order rate constant for destruction of R with HO• radicals, L/mol · s

$k_{\text{HCO}_3^-}$  = second-order hydroxyl radical rate constants for HCO<sub>3</sub><sup>-</sup>, L/mol · s

$k_{\text{CO}_3^{2-}}$  = second-order hydroxyl radical rate constants for CO<sub>3</sub><sup>2-</sup>, L/mol · s

$C_R$  = concentration of target organic R, mol/L

**Table 18-4**

Relative rates of destruction of TCE ( $Q_{\text{TCE}}$  at concentration of 0.100 mg/L) for various pH values and alkalinities

Relative rate $Q_{\text{TCE}}$ , %	pH	$C_{\text{T,CO}_3}$ , mM	$\text{HCO}_3^-$ , mM	$\text{CO}_3^{2-}$ , mM
10.9	7.0	1	0.997	0.003
5.78	7.0	2	1.994	0.006
2.98	7.0	4	3.988	0.012
2.00	7.0	6	5.982	0.018
1.51	7.0	8	7.976	0.024
5.55	8.0	2	1.990	0.010

0.754	10.0	2	1.333	0.667

Source: Adapted from Glaze and Kang (1988).

$C_{\text{HCO}_3^-}$  = concentration of bicarbonate, mol/L  
 $C_{\text{CO}_3^{2-}}$  = concentration of carbonate, mol/L

The relative rates of destruction of TCE for various pH values and total carbonate concentration are provided in Table 18-4. If only the influence of alkalinity is considered, it appears that even low alkalinities (50 mg/L) reduce the rate of TCE destruction by a factor of 10 at pH 7. However, at high pH, the alkalinity is more detrimental because the second-order rate constant with  $\text{CO}_3^{2-}$  is much larger than  $\text{HCO}_3^-$ . In summary, water matrices with high pH and alkalinity are more difficult to treat using AOPs, and AOPs are more effective if pretreatment processes such as softening are used to remove the alkalinity. However, NOM as discussed later has a much greater influence on quenching the reaction rate than alkalinity.

#### IMPACT OF PH

The performance of AOPs is affected by pH in three ways: (1) pH affects the concentration of  $\text{HCO}_3^-$  and  $\text{CO}_3^{2-}$  as discussed above; (2) the concentration of  $\text{HO}_2^-$  ( $\text{H}_2\text{O}_2$  has a  $pK_a$  of 11.6), which is important in the UV/ $\text{H}_2\text{O}_2$ , UV/ $\text{O}_3$ , and  $\text{H}_2\text{O}_2/\text{O}_3$  advanced oxidation processes, is a function of pH; and (3) pH affects the charge on the organic compounds if they are weak acids or bases.

For the  $\text{O}_3/\text{UV}$  and  $\text{H}_2\text{O}_2/\text{O}_3$  processes,  $\text{O}_3$  reacts with  $\text{HO}_2^-$  to form  $\text{HO}\cdot$ , which is the rate-limiting step, especially for the  $\text{H}_2\text{O}_2/\text{O}_3$  AOP. Accordingly, low pH (<5.0) greatly reduces the rate of production of  $\text{HO}\cdot$  and the AOP reactions. High pH (11) is also thought to catalyze the formation of  $\text{HO}\cdot$  radicals directly from  $\text{O}_3$ , but significant rates of organics destruction have not been observed with  $\text{O}_3$  at high pH (Hoigné and Bader, 1976).

The reactivity and light absorption properties of the compound can be affected by its charge. For example, in the  $\text{H}_2\text{O}_2/\text{UV}$  process,  $\text{HO}_2^-$  has

about 10 times the UV molar absorptivity at 254 nm (228 L/mol·cm) than does H<sub>2</sub>O<sub>2</sub>; consequently, H<sub>2</sub>O<sub>2</sub>/UV may be more effective at higher pH, especially if the background water matrix absorbs a lot of UV light (this would only be practical if the pH was raised for other purposes and carbonate was removed, such as softening).

#### IMPACT OF NOM

Natural organic matter reacts with hydroxyl radicals and quenches the reaction. The quenching of the reaction rate can be estimated using the expression

$$Q_R = \frac{k_R C_R}{k_{\text{NOM}} C_{\text{DOC}} + k_R C_R} \quad (18-7)$$

where  $Q_R$  = target organics (R) reaction rate with hydroxyl radical divided by total reaction rate of hydroxyl radical with both R and NOM ( $1/Q_R$  equals the reduction in reaction due to presence of NOM), dimensionless

$k_R$  = second-order rate constant for destruction of R with HO· radicals, L/mol·s

$k_{\text{NOM}}$  = second-order hydroxyl radical rate constants for NOM, L/mol NOM C·s

$C_R$  = concentration of target organic R, mol/L

$C_{\text{DOC}}$  = concentration of NOM, mol/L

In a survey of the reactivity of NOM with hydroxyl radicals, it was found that most values for NOM were between 1.4 and  $4.5 \times 10^8$  L/s·mol NOM carbon (Westerhoff et al., 2007). The average value for 17 water sources was  $3.9 \times 10^8$  and the standard deviation was  $1.2 \times 10^8$  (Westerhoff et al., 1999).

### Example 18-2 Quenching of the AOP reaction rate due to NOM

Examine the difference in the rate of oxidation of trichloroethylene (TCE) and chloroacetic acid (CAA) in distilled deionized water versus the rate in a typical tap water. The rate constants are (1)  $k_{\text{NOM}} = 3 \times 10^8$  L/mol NOM C·s,  $k_{\text{TCE}} = 4.2 \times 10^9$  L/mol·s, and  $k_{\text{CAA}} = 4.3 \times 10^7$  L/mol·s. The NOM concentrations in distilled water and tap water are 0.05 and 3 mg/L, respectively. The initial concentrations of TCE and CAA are 35 and 48 μg/L. Estimate  $Q_R$  for each compound in distilled water and then in tap water. Can rates observed in distilled water be used to estimate the rate of oxidation that will be observed in the field?

**Solution**

1. Determine  $Q_R$  for TCE and chloroacetic acid in distilled water using Eq. 18-7

a. Convert concentration of NOM in mg/L to mol/L:

$$C_{\text{DOC}} = \frac{0.05 \text{ mg C/L}}{(12 \text{ g/mol})(1000 \text{ mg/g})} = 4.167 \times 10^{-6} \text{ mol C/L}$$

$$k_{\text{NOM}} = 3.0 \times 10^8 \text{ L/mol C} \cdot \text{s}$$

b.  $Q_R$  for TCE:

$$C_R = \frac{35 \text{ } \mu\text{g/L}}{(131.39 \text{ g/mol})(10^6 \text{ } \mu\text{g/g})} = 2.66 \times 10^{-7} \text{ mol/L}$$

$$Q_R = \frac{(4.2 \times 10^9 \text{ L/mol} \cdot \text{s})(2.66 \times 10^{-7} \text{ mol/L})}{(3.0 \times 10^8 \text{ L/mol} \cdot \text{s})(4.167 \times 10^{-6} \text{ mol/L}) + (4.2 \times 10^9 \text{ L/mol} \cdot \text{s})(2.66 \times 10^{-7} \text{ mol/L})}$$

$$= 0.472$$

c.  $Q_R$  for chloroacetic acid:

$$C_R = \frac{48 \text{ } \mu\text{g/L}}{(81.5 \text{ g/mol})(10^6 \text{ } \mu\text{g/g})} = 5.89 \times 10^{-7} \text{ mol/L}$$

$$k_R = 4.3 \times 10^7 \text{ L/mol} \cdot \text{s}$$

$$Q_R = \frac{(4.3 \times 10^7 \text{ L/mol} \cdot \text{s})(5.89 \times 10^{-7} \text{ mol/L})}{(3.0 \times 10^8 \text{ L/mol} \cdot \text{s})(4.167 \times 10^{-6} \text{ mol/L}) + (4.3 \times 10^7 \text{ L/mol} \cdot \text{s})(5.89 \times 10^{-7} \text{ mol/L})}$$

$$= 0.0199$$

2. Determine  $Q_R$  for TCE and chloroacetic acid in tap water.

a. Convert concentration of NOM in mg/L to mol/L:

$$C_{\text{DOC}} = \frac{3.0 \text{ mg C/L}}{(12 \text{ g/mol})(1000 \text{ mg/g})} = 2.5 \times 10^{-4} \text{ mol C/L}$$

b.  $Q_R$  for TCE:

$$Q_R = \frac{(4.2 \times 10^9 \text{ L/mol} \cdot \text{s})(2.66 \times 10^{-7} \text{ mol/L})}{(3.0 \times 10^8 \text{ L/mol} \cdot \text{s})(2.5 \times 10^{-4} \text{ mol/L}) + (4.2 \times 10^9 \text{ L/mol} \cdot \text{s})(2.66 \times 10^{-7} \text{ mol/L})}$$

$$= 0.0147$$

c.  $Q_R$  for chloroacetic acid:

$$Q_R = \frac{(4.3 \times 10^7 \text{ L/mol} \cdot \text{s})(5.89 \times 10^{-7} \text{ mol/L})}{(3.0 \times 10^8 \text{ L/mol} \cdot \text{s})(2.5 \times 10^{-4} \text{ mol/L}) + (4.3 \times 10^7 \text{ L/mol} \cdot \text{s})(5.89 \times 10^{-7} \text{ mol/L})}$$

$$= 0.000338$$

### Comment

The amount of quenching ( $1/Q_R$ ) for TCE and CAA is about 32 ( $0.472/0.0147$ ) and 59 ( $0.0199/0.000338$ ) times higher in tap water than in distilled deionized water due to the quenching effect of the NOM. Hence, the results of tests in distilled water cannot be used directly to estimate oxidation rates in the field. Bench tests should be conducted in the same water that is to be treated in the field.

### IMPACT OF REDUCED METAL IONS

Metal ions in reduced oxidation states such as Fe(II) and Mn(II) are often found in groundwater due to the anoxic conditions typically present in groundwater. These inorganic species can consume a significant quantity of chemical oxidants as well as scavenge  $\text{HO}\cdot$  radicals. Consequently, the concentration of reduced metal ions should be measured as part of any treatability study, and the dosages of oxidants should be based on a consideration of the chemical oxygen demand (COD) of the reduced metal species. Similar to NOM, the amount of quenching can be estimated using the expression

$$Q_R = \frac{k_R C_R}{k_R C_R + k_{\text{Fe(II)}} C_{\text{Fe(II)}} + k_{\text{Mn(II)}} C_{\text{Mn(II)}}} \quad (18-8)$$

where  $k_{\text{Fe(II)}}$  = second-order hydroxyl rate constants for Fe(II),  
L/mol · s

$k_{\text{Mn(II)}}$  = second-order hydroxyl rate constants for Mn(II),  
L/mol · s

$C_{\text{Fe(II)}}$  = concentration of Fe(II), mol/L

$C_{\text{Mn(II)}}$  = concentration of Mn(II), mol/L

The second-order rate constants reported for Fe(II) and Mn(II) are  $3.3 \times 10^8$  and  $3.0 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ , respectively (Buxton et al., 1988).

### Example 18-3 Quenching the AOP reaction rate due to Fe(II)

The second-order hydroxyl rate constant for Fe(II) is  $3.3 \times 10^8 \text{ L/mol} \cdot \text{s}$ . For iron concentrations of 5.6 and 0.56 mg/L and a TCE concentration of 100  $\mu\text{g/L}$ , calculate the quenching of the reaction.

**Solution**

1. Determine  $Q_R$  using Eq. 18-8 for an iron concentration of 5.6 mg/L:

$$C_R = \frac{100 \mu\text{g/L}}{(131.39 \text{ g/mol})(10^6 \mu\text{g/g})} = 7.611 \times 10^{-7} \text{ mol/L}$$

$$C_{\text{Fe}} = \frac{5.6 \text{ mg/L}}{(55.84 \text{ g/mol})(1000 \text{ mg/g})} = 10^{-4} \text{ mol/L}$$

$$Q_R = \frac{(4.2 \times 10^9 \text{ L/mol} \cdot \text{s})(7.611 \times 10^{-7} \text{ mol/L})}{(3.3 \times 10^8 \text{ L/mol} \cdot \text{s})(10^{-4} \text{ mol/L}) + (4.2 \times 10^9 \text{ L/mol} \cdot \text{s})(7.611 \times 10^{-7} \text{ mol/L})}$$

$$= 0.088$$

2. Determine  $Q_R$  for an iron concentration of 0.56 mg/L:

$$C_R = 7.611 \times 10^{-7} \text{ mol/L}$$

$$C_{\text{Fe}} = \frac{(0.56 \text{ mg/L})}{(55.84 \text{ g/mol})(1000 \text{ mg/g})} = 10^{-5} \text{ mol/L}$$

$$Q_R = \frac{(4.2 \times 10^9 \text{ L/mol} \cdot \text{s})(7.611 \times 10^{-7} \text{ mol/L})}{(3.3 \times 10^8 \text{ L/mol} \cdot \text{s})(10^{-5} \text{ mol/L}) + (4.2 \times 10^9 \text{ L/mol} \cdot \text{s})(7.611 \times 10^{-7} \text{ mol/L})}$$

$$= 0.492$$

**Comment**

Although iron can also quench the hydroxyl radical reaction, NOM has a much greater impact, as shown in Example 18-2. The amount of quenching for TCE is about 33 (0.492/0.0147) times higher in tap water containing NOM as compared to water containing iron.

**REACTIVITY OF PARENT COMPONENT WITH HYDROXYL RADICAL**

Depending on the reactivity of the parent compound, the compound being oxidized can reduce the destruction rate of the parent compound significantly. For example, NOM can reduce the destruction rate of the parent compound by a factor of 100 for compounds with a second-order rate constant of  $10^9 \text{ L/mol} \cdot \text{s}$  or 1000 for compounds with a second-order rate constant of  $10^8 \text{ L/mol} \cdot \text{s}$  (Liao and Gurol, 1995; Westerhoff et al., 1999).

### Assessing Feasibility of AOPs

To assess the feasibility of AOPs, the following parameters should be measured: (1) alkalinity, (2) pH, (3) COD, (4) TOC, (5) Fe, (6) Mn, and (8) light transmission. Once these parameters are known, this information can be used to interpret and plan treatability studies for AOPs and investigate pretreatment options that may be needed. In addition, these parameters can be used in the simple models presented later in this chapter to assess the feasibility of AOPs.

## 18-2 Ozonation as an Advanced Oxidation Process

Approximately one-third of the water treatment plants in the United States use ozone for disinfection, taste and odor control, and target compound destruction. The production of ozone, ozone contactor design, and disinfection using ozone are presented in Chap. 13. In this section, the focus is on the destruction of organoleptic and other target compounds including MIB, geosmin, and atrazine. The fundamental question is whether water utilities have received the maximum benefit for target compound destruction using ozone alone or whether they can receive additional benefit by adding hydrogen peroxide after their disinfection requirements (*Ct*) are met. The addition of hydrogen peroxide, which reacts with ozone to produce hydroxyl radical, is discussed in Sec. 18-3. Target compound destruction using ozone is discussed in this section.

### Hydroxyl Radical Production from OH<sup>-</sup>

High pH values ( $\approx 11$ ) are thought to catalyze the formation of HO• radicals directly from O<sub>3</sub>. The complete set of reactions for HO• production from OH<sup>-</sup> is shown in Table 18-5 and listed in the following reaction sequence:

- where  $k_1$  = second-order rate constant between ozone and anion of hydrogen peroxide, L/mol · s ( $\text{M}^{-1} \text{s}^{-1}$ )  
 $k_2$  = second-order rate constant between ozone and hydroxyl ion, L/mol · s ( $\text{M}^{-1} \text{s}^{-1}$ )  
 $k_3$  = second-order rate constant between ozone and the ozonide ion radical, L/mol · s ( $\text{M}^{-1} \text{s}^{-1}$ )

$k_4$  = second-order rate constant between ozonide ion radical and hydrogen ion, L/mol · s ( $M^{-1} s^{-1}$ )

$k_5$  = first-order rate constant for ozonide radical,  $s^{-1}$

The overall stoichiometry of the reaction is given by the following reaction:

Consequently, the high-pH ozone process is inefficient and requires 1.5 mol of ozone to produce 1 mol of  $HO\cdot$ .

The first step in the reaction sequence, Eq. 18-9, is only fast at high pH. For example, the half-lives of ozone for the reaction in Eq. 18-9 at various pH values are (1) 1650 min at pH 7, (2) 165 min at pH 8, (3) 16.5 min at pH 9, (4) 1.65 min at pH 10, and (5) 0.165 min at pH 11. Consequently, the reaction does not proceed rapidly until the pH is 11.

Unfortunately, high pH values are detrimental to the production of  $HO\cdot$ , as shown in Eq. 18-15, and carbonate species quench the hydroxyl radicals that are formed from subsequent reactions. As shown in Table 18-4, the relative reaction rates for TCE (100  $\mu g/L$ ) at a total concentration of all carbonate species ( $C_{T,CO_3} = 2 \times 10^{-3}$  mol/L) decrease from a high of 5.78 percent at pH 7 to a low of 0.754 percent at pH 10. As a direct result of the low relative reaction rates at high pH, significant destruction rates of target compounds have not been observed with the high-pH  $O_3$  process (Hoigné and Bader, 1976).

When ozone reacts with NOM, it produces low levels of hydroxyl radical via the reaction

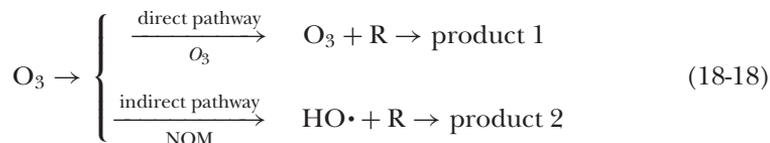

As discussed in Sec. 18-1, the hydroxyl radical that may be produced from Eq. 18-16 may also be quenched by the reaction with NOM, as shown in the reaction

where  $k_{13}$  = second-order rate constant between hydroxyl radical and NOM, L/(mol NOM C · s)

The quenching of hydroxyl radical with NOM is usually more important than quenching by bicarbonate and carbonate or metal species (see Sec. 18-1 for details, including rate constants).

Accordingly, when it comes to target compound destruction, ozonation can destroy organic compounds by either direct reactions with  $O_3$  or indirect reactions with  $HO\cdot$ , as shown in the following:

### Hydroxyl Radical Production from NOM

The rate of destruction of a target compound R is given by the equation

$$r_R = -k_{O_3} [O_3] [R] - k_{HO\cdot} [HO\cdot] [R] \quad (18-19)$$

where  $r_R$  = rate of disappearance of target compound R, mol/L · s  
 $[O_3]$  = concentration of ozone, mol/L  
 $[R]$  = concentration of target compound R, mol/L  
 $[HO\cdot]$  = concentration of hydroxyl radical, mol/L  
 $k_{HO\cdot}$  = second-order rate constants between hydroxyl radical and R, L/mol · s  
 $k_{O_3}$  = second-order rate constants between ozone and R, L/mol · s

The relative importance of the direct reaction with ozone and the indirect reaction with HO· can be assessed using the expression

$$\begin{aligned} f_{HO\cdot} &= \frac{k_{HO\cdot} [HO\cdot]}{k_{HO\cdot} [HO\cdot] + k_{O_3} [O_3]} = \frac{k_{HO\cdot} ([HO\cdot]/[O_3])}{k_{HO\cdot} ([HO\cdot]/[O_3]) + k_{O_3}} \\ &= \frac{k_{HO\cdot} C_{[HO\cdot]/[O_3]}}{k_{HO\cdot} C_{[HO\cdot]/[O_3]} + k_{O_3}} \end{aligned} \quad (18-20)$$

where  $f_{HO\cdot}$  = fraction of target compound destruction due to indirect reaction with HO·, dimensionless  
 $C_{[HO\cdot]/[O_3]}$  = ratio of hydroxyl radical concentration to ozone concentration, dimensionless

Second-order rate constants for ozone (listed in the electron Table E-2 at the website listed in App. E) are useful in assessing possible reactions and reaction kinetics. The rate constants for organics are highly dependent on the type of organic being oxidized. The indirect pathway reaction rate trend is from high for the hydroxyl radical with amine-substituted benzenes to low for aliphatics without nucleophilic sites. In contrast, many of the rate constants for the direct reaction with ozone appear to be low. It has been reported that the ratio of the concentration of the hydroxyl radical to the concentration of ozone ( $C_{[HO\cdot]/[O_3]}$ ) was relatively constant during the decomposition of ozone in the presence of NOM, with typical values ranging from  $10^{-7}$  to  $10^{-10}$  (Elovitz and von Gunten, 1999).

The reaction of ozone with NOM to produce HO· is the most important mechanism to destroy target compounds (Elovitz and von Gunten, 1999; Westerhoff et al., 1999). For example, it has been demonstrated that 83 percent of MIB and 90 percent of geosmin were degraded by the hydroxyl radical for an ozonated natural water (Bruce et al., 2002). This finding is important because, if ozone is able to remove taste- and odor-causing organics, it is probably due to HO· production from the reaction of ozone with NOM. The following example will demonstrate when the indirect or direct reaction of target compounds with HO· is an important pathway for target compound destruction.

### Example 18-4 Fraction of target compound destruction by direct and indirect reaction pathways

Determine the fraction of the reaction that is carried out by the indirect reaction with HO• for second-order HO• rate constants of  $10^7$ ,  $10^8$ , and  $10^9$  L/mol · s. For the calculation, use  $C_{[\text{HO}\cdot]}/[\text{O}_3]$  values of  $10^{-7}$ ,  $10^{-8}$ ,  $10^{-9}$ , and  $10^{-10}$  and a rate constant for the direct reaction with ozone of 10 L/mol · s.

#### Solution

1. Calculate the fraction of target compound destruction due to the indirect reaction with HO• for  $k_{\text{O}_3}$  of 10 L/mol · s using Eq. 18-20: For  $k_{\text{HO}\cdot} = 10^7$  L/mol · s and  $C_{[\text{HO}\cdot]}/[\text{O}_3] = 10^{-7}$ ,

$$f_{\text{HO}\cdot} = \frac{(10^7 \text{ L/mol} \cdot \text{s}) \times 10^{-7}}{(10^7 \text{ L/mol} \cdot \text{s})10^{-7} + (10 \text{ L/mol} \cdot \text{s})} = 0.0909$$

2. Tabulate the results—fraction of target compound destruction due to indirect reaction with HO• for  $k_{\text{O}_3}$  of 10 L/mol · s:

$C_{[\text{HO}\cdot]}/[\text{O}_3]$	$f_{\text{HO}\cdot}$		
	$k_{\text{HO}\cdot} = 10^7 \text{ M}^{-1} \text{ s}^{-1}$	$k_{\text{HO}\cdot} = 10^8 \text{ M}^{-1} \text{ s}^{-1}$	$k_{\text{HO}\cdot} = 10^9 \text{ M}^{-1} \text{ s}^{-1}$
$10^{-7}$	$9.09 \times 10^{-2}$	$5.00 \times 10^{-1}$	$9.09 \times 10^{-1}$
$10^{-8}$	$9.90 \times 10^{-3}$	$9.09 \times 10^{-2}$	$5.00 \times 10^{-1}$
$10^{-9}$	$9.99 \times 10^{-4}$	$9.90 \times 10^{-3}$	$9.09 \times 10^{-2}$
$10^{-10}$	$1.00 \times 10^{-4}$	$9.99 \times 10^{-4}$	$9.90 \times 10^{-3}$

#### Comment

The direct ozonation reaction is more important than the indirect reaction with HO• for  $k_{\text{HO}\cdot} = 10^7 \text{ M}^{-1} \text{ s}^{-1}$ . For  $k_{\text{HO}\cdot} = 10^8 \text{ M}^{-1} \text{ s}^{-1}$ , the direct ozonation reaction is less important than the indirect reaction with HO• for  $C_{[\text{HO}\cdot]}/[\text{O}_3]$  greater than  $10^{-7}$ . For  $k_{\text{HO}\cdot} = 10^9 \text{ M}^{-1} \text{ s}^{-1}$ , the direct ozonation reaction is less important than the indirect reaction with HO• for  $C_{[\text{HO}\cdot]}/[\text{O}_3]$  greater than  $10^{-8}$ .

A simple model may be developed using Eq. 18-20. The loss of ozone and target compound may be described by the following pseudo-first-order reaction:

$$r_{\text{O}_3} = -k [\text{O}_3] \quad (18-21)$$

$$r_{\text{R}} = -(k_{\text{O}_3} + k_{\text{HO}\cdot} C_{[\text{HO}\cdot]}/[\text{O}_3]) [\text{O}_3] [\text{R}] \quad (18-22)$$

where  $r_{O_3}$  = rate of loss of ozone, mol/L · s  
 $k$  = pseudo-first-order decay rate constant for ozone, s<sup>-1</sup>

For a PFR with detention time  $\tau$  or a completely mixed batch reactor with an elapsed time  $t$  Eqs. 18-21 and 18-22 may be written and solved as shown below:

$$\frac{d[O_3]}{dt} = -k [O_3] \quad (18-23)$$

$$[O_3] = [O_3]_0 e^{-kt} \quad (18-24)$$

$$\frac{d[R]}{dt} = - (k_{HO\cdot} C_{[HO\cdot]/[O_3]} [R] + k_{O_3} [R]) [O_3]_0 e^{-kt} \quad (18-25)$$

$$[R] = [R]_0 \exp \left[ \frac{[O_3]_0}{k} (k_{HO\cdot} C_{[HO\cdot]/[O_3]} + k_{O_3}) (e^{-kt} - 1) \right] \quad (18-26)$$

where  $[O_3]_0$  = initial concentration of ozone, mol/L  
 $[R]_0$  = initial concentration of target compound R, mol/L

The following example is presented to illustrate how Eq. 18-26 can be used to predict the destruction of target compounds.

### Example 18-5 Time required for destruction of target compound

Calculate the half-life and the time required for 95 percent destruction of geosmin and MIB in a batch reactor. The second-order rate constants with HO· for geosmin and MIB are  $(1.4 \pm 0.3) \times 10^{10}$  and  $(8.2 \pm 0.4) \times 10^9$ , respectively. For the calculation, use  $C_{[HO\cdot]/[O_3]}$  ranging from  $10^{-9}$  to  $10^{-7}$  and an initial ozone concentration of 3 mg/L. The rate constant for the direct reaction with ozone is  $10 \text{ M}^{-1} \text{ s}^{-1}$ . Use a typical ozone pseudo-first-order decay rate constant of  $0.1 \text{ min}^{-1}$ .

#### Solution

1. Calculate the half-life for destruction of a target compound. Rearrange Eq. 18-26 to obtain an expression for  $t_{1/2}$ :

$$t_{1/2} = - \frac{\ln \left\{ 1 + \left[ \ln \left( \frac{1}{2} \right) \right] (k) / \left[ [O_3]_0 (k_{HO\cdot} C_{[HO\cdot]/[O_3]} + k_{O_3}) \right] \right\}}{k}$$

- a. Convert initial ozone concentration from mg/L to mol/L:

$$[O_3]_0 = \frac{3 \text{ mg/L}}{(48 \text{ g/mol}) (10^3 \text{ mg/g})} = 6.25 \times 10^{-5} \text{ mol/L}$$

- b. Calculate  $t_{1/2}$  for MIB and geosmin when  $C_{[HO\cdot]/[O_3]} = 10^{-7}$ :

i. For MIB,

$$k_{\text{HO}} \cdot C_{[\text{HO}\cdot]/[\text{O}_3]} + k_{\text{O}_3} = \{[(8.2 \times 10^9)(10^{-7}) + 10] \text{ L/mol} \cdot \text{s}\} (60 \text{ s/min})$$

$$= 49,800 \text{ L/mol} \cdot \text{min}$$

$$t_{1/2} = - \frac{\ln \{1 + [\ln(\frac{1}{2})](0.1/\text{min}) / [(6.25 \times 10^{-5} \text{ mol/L})(49,800 \text{ L/mol} \cdot \text{min})]\}}{0.1/\text{min}}$$

$$= 0.23 \text{ min}$$

ii. For geosmin,

$$k_{\text{HO}} \cdot C_{[\text{HO}\cdot]/[\text{O}_3]} + k_{\text{O}_3} = \{[(1.4 \times 10^{10})(10^{-7}) + 10] \text{ L/mol} \cdot \text{s}\} (60 \text{ s/min})$$

$$= 84,600 \text{ L/mol} \cdot \text{min}$$

$$t_{1/2} = - \frac{\ln \{1 + [\ln(\frac{1}{2})](0.1/\text{min}) / [(6.25 \times 10^{-5} \text{ mol/L})(84,600 \text{ L/mol} \cdot \text{min})]\}}{0.1/\text{min}}$$

$$= 0.13 \text{ min}$$

c. Tabulate the  $t_{1/2}$  results for  $10^{-9} \leq C_{[\text{HO}\cdot]/[\text{O}_3]} \leq 10^{-7}$ :

$C_{[\text{HO}\cdot]/[\text{O}_3]}$	$t_{1/2}, \text{ min}$	
	MIB	Geosmin
$1.00 \times 10^{-7}$	0.23	0.13
$5.00 \times 10^{-8}$	0.45	0.26
$1.00 \times 10^{-8}$	2.24	1.32
$5.00 \times 10^{-9}$	4.50	2.63
$3.00 \times 10^{-9}$	7.64	4.39
$1.50 \times 10^{-9}$	17.65	9.07
$1.05 \times 10^{-9}$	49.95	13.80
$1.00 \times 10^{-9}$	$\infty$	14.70

2. Calculate the time required for 95 percent destruction of a target compound:

$$t = - \frac{\ln \{1 + [\ln(1 - 0.95)](k) / [[\text{O}_3]_0 (k_{\text{HO}} \cdot C_{[\text{HO}\cdot]/[\text{O}_3]} + k_{\text{O}_3})]\}}{k}$$

$$= - \frac{\ln \{1 + [\ln(1 - 0.95)](k) / [[\text{O}_3]_0 (k_{\text{HO}} \cdot C_{[\text{HO}\cdot]/[\text{O}_3]} + k_{\text{O}_3})]\}}{k}$$

a. Calculate  $t$  for MIB and geosmin when  $C_{[\text{HO}\cdot]/[\text{O}_3]} = 10^{-7}$ :

i. For MIB,

$$t = \frac{\ln \left\{ 1 + [\ln(0.05)] (0.1/\text{min}) / [(6.25 \times 10^{-5} \text{ mol/L})(49,800 \text{ L/mol} \cdot \text{min})] \right\}}{0.1/\text{min}}$$

$$= 1.01 \text{ min}$$

ii. For geosmin,

$$t = \frac{\ln \left\{ 1 + [\ln(0.05)] (0.1/\text{min}) / [(6.25 \times 10^{-5} \text{ mol/L})(84,600 \text{ L/mol} \cdot \text{min})] \right\}}{0.1/\text{min}}$$

$$= 0.58 \text{ min}$$

b. Tabulate the  $t$  results for  $10^{-9} \leq C_{[\text{HO}\cdot]/[\text{O}_3]} \leq 10^{-7}$ :

$C_{[\text{HO}\cdot]/[\text{O}_3]}$	$t, \text{ min}$	
	MIB	Geosmin
$1.00 \times 10^{-7}$	1.01	0.58
$5.00 \times 10^{-8}$	2.11	1.19
$1.00 \times 10^{-8}$	20.27	7.61
$8.55 \times 10^{-9}$	58.8	9.57
$8.50 \times 10^{-9}$	$\infty$	9.66
$5.00 \times 10^{-9}$	$\infty$	65.55
$4.95 \times 10^{-9}$	$\infty$	$\infty$

### Comment

The destruction of geosmin and MIB is possible if  $C_{[\text{HO}\cdot]/[\text{O}_3]}$  is greater than  $5.00 \times 10^{-8}$ . Many unsaturated compounds have a second-order rate constant for  $\text{HO}\cdot$  less than  $10^9 \text{ M}^{-1} \text{ s}^{-1}$  and ozone alone would not be effective in destroying such compounds.

### Determination of Destruction of Target Compounds from Bench-Scale Tests

While Eq. 18-26 can be used to describe the destruction rate of target compounds, there is no way to predict the value of  $C_{[\text{HO}\cdot]/[\text{O}_3]}$  or the pseudo-first-order rate constant for ozone,  $k$ . Consequently, batch tests are required to determine  $C_{[\text{HO}\cdot]/[\text{O}_3]}$  and  $k$ . The basics of the batch-testing method include the following steps:

1. Ozonate the water and measure the initial ozone concentration and the concentration of ozone as a function of time.
2. Determine the pseudo-first-order rate constant for ozone by fitting Eq. 18-24 to the ozone-versus-time data using commercially available software with a graphing function.

3. Measure the concentration of one or more target compounds as a function of time.
4. Determine the best-fit  $C_{[\text{HO}\cdot]/[\text{O}_3]}$  value by fitting the target compound data using Eq. 18-26 and commercially available software with a graphing function. The suggested method is to define an objective function as shown below and to minimize an objective function by using a spreadsheet and making  $C_{[\text{HO}\cdot]/[\text{O}_3]}$  the target cell, which is adjusted to find the minimum objective function or best fit:

$$\text{OF} = \sqrt{\frac{1}{n-1} \sum_{i=1}^n \left( \frac{C_{\text{data},i} - C_{\text{model},i}}{C_{\text{data},i}} \right)^2} \quad (18-27)$$

where OF = objective function, dimensionless

$n$  = number of data points, unitless

$C_{\text{data},i}$  = measured concentration of data point  $i$ , mg/L

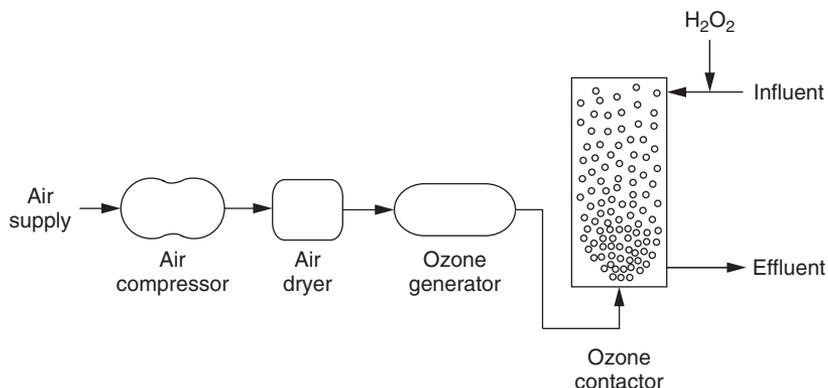

$C_{\text{model},i}$  = predicted concentration of data point  $i$ , mg/L

The values for  $k_{\text{O}_3}$  and  $k_{\text{HO}\cdot}$  must be known to determine  $C_{[\text{HO}\cdot]/[\text{O}_3]}$ , and in most instances the contribution of  $k_{\text{O}_3}$  can be ignored. If the  $k_{\text{HO}\cdot}$  is known for the destruction of the target compound, then the destruction of other target compounds can be predicted using the appropriate  $k_{\text{HO}\cdot}$  and the fitted  $C_{[\text{HO}\cdot]/[\text{O}_3]}$ . If  $k_{\text{HO}\cdot}$  is not known, then a fitted parameter ( $k_{\text{HO}\cdot} C_{[\text{HO}\cdot]/[\text{O}_3]} + k_{\text{O}_3}$ ) can be determined. In either situation, the target compound destruction for different influent concentrations and ozone dosages can be predicted using the fitted parameter ( $k_{\text{HO}\cdot} C_{[\text{HO}\cdot]/[\text{O}_3]} + k_{\text{O}_3}$ ) or  $C_{[\text{HO}\cdot]/[\text{O}_3]}$ . If acceptable destruction rates are not achieved by ozonation alone, then the addition of hydrogen peroxide should be considered. The  $\text{O}_3/\text{H}_2\text{O}_2$  process is discussed in Sec. 18-3.

## 18-3 Hydrogen Peroxide/Ozone Process for Potable Water

---

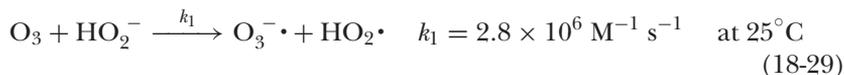

The material in this section covers the benefits of adding hydrogen peroxide in conjunction with ozone and the basic reactions involved in the hydrogen peroxide/ozone process. The activation of NOM with ozone is ignored because it is insignificant when hydrogen peroxide is added. However, the quenching of hydroxyl radical by NOM is considered. At the end of the section, bench-scale testing that is used to determine process feasibility is discussed. The basic components of the hydrogen peroxide/ozone process with a single injection point for ozone is shown on Fig. 18-1. As discussed earlier, ozone can form bromate when bromide is present, and one way to reduce bromate formation is to reduce the ozone concentration. As discussed above, the use of a reactor with multiple injection points, lowering the pH, chlorine addition, and ammonia addition are methods that have been proposed to reduce bromate production.

hydrogen peroxide–ozone  
process. (Courtesy of Applied  
Process Technology.)

## Reaction Mechanisms

The elementary reactions that are involved in the production of  $\text{HO}\cdot$  from  $\text{H}_2\text{O}_2/\text{O}_3$  are listed in Table 18-5. The following discussion of the reaction mechanisms will cover the  $\text{H}_2\text{O}_2/\text{O}_3$  process at neutral pH (values near 7). The  $\text{H}_2\text{O}_2/\text{O}_3$  reaction sequence begins by forming the ozonide ion radical,  $\text{O}_3^{\cdot-}$ , and the superoxide radical,  $\text{HO}_2\cdot$ , which is the rate-limiting step (Buhler et al., 1984; Forni et al., 1982; Sehested et al., 1982):

where  $K_a$  = equilibrium constant, dimensionless

$k_1$  = second-order rate constant between ozone and anion of hydrogen peroxide,  $\text{L/mol}\cdot\text{s}$

The rate-limiting step in the formation of  $\text{HO}\cdot$  is the formation of  $\text{O}_3^{\cdot-}$  and  $\text{HO}_2\cdot$ , which is slow, especially at low pH. Consequently, low reaction rates have been observed at pH values of 5 or less and the  $\text{H}_2\text{O}_2/\text{O}_3$  AOP may not be a viable option for the destruction of organics if the pH is 5 or less. Once the superoxide radical,  $\text{HO}_2\cdot$ , has been formed, it can form the ozonide ion radical,  $\text{O}_3^{\cdot-}$ , as follows:

where  $k_3$  = second-order rate constant between ozonide ion radical and ozone,  $\text{L/mol}\cdot\text{s}$  ( $\text{M}^{-1} \text{ s}^{-1}$ )

The ozonide ion radical forms  $\text{HO}\cdot$  according to the following reactions:

where  $k_4$  = second-order rate constant between ozonide ion radical and hydrogen ion, L/mol · s ( $M^{-1} s^{-1}$ )

$k_5$  = first-order rate constant for ozonide radical,  $s^{-1}$

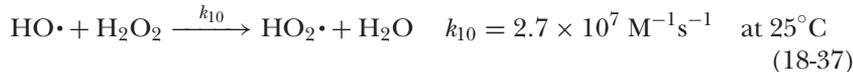

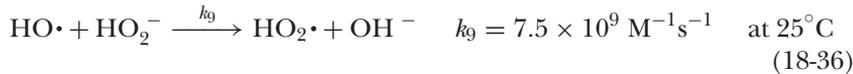

The overall reaction for HO• radical formation is

According to Eq. 18-34, 0.5 mol  $H_2O_2$  is needed for every mole of  $O_3$  or a mass ratio of 0.354 kg  $H_2O_2$  is needed for every kilogram of  $O_3$ . However, there are several issues that impact the proper dosages of  $H_2O_2$  and  $O_3$ . First,  $O_3$  tends to be more reactive with background organic matter and inorganic species than  $H_2O_2$ . ( $O_3$  mass transfer efficiency is usually greater than 95 percent.) As a result, the applied  $O_3$  dosage will have to be higher than estimated from stoichiometry to achieve the optimum ratio. However, an excess  $O_3$  dosage has the potential of wasting  $O_3$  and scavenging HO• radicals via the reaction

The  $HO_2\cdot$  radical, formed as shown in Eq. 18-35, may produce more HO• via reactions through Eqs. 18-30 to 18-33 assuming there is adequate ozone remaining in solution. Excess  $H_2O_2$  is also detrimental to the  $H_2O_2/O_3$  AOP because it may scavenge HO• via the following reactions:

where  $k_9$  = second-order rate constant between hydroxyl radical and anion of hydrogen peroxide, L/mol · s

$k_{10}$  = second-order rate constant between hydroxyl radical and hydrogen peroxide, L/mol · s

Further, the  $H_2O_2$  residual can be more problematic than ozone because hydrogen peroxide is more stable than ozone. As pointed out previously, some vendors have attempted to overcome the problem of  $H_2O_2$  quenching of HO• by adding  $H_2O_2$  at multiple points in a single reactor or by using multiple reactors in series.

The elementary reactions for the  $O_3/H_2O_2$  process are listed in Table 18-5. The elementary reactions include the initiation (reactions 1, 3, 4, and 5 or Eqs. 18-29 and 18-31 to 18-33), propagation (reactions 9 and 10 or Eqs. 18-36 and 18-37), and termination reactions of the radical chain reaction. Termination reactions involve recombination of radical species and are not shown because they have a low probability of occurrence

Reactions  
for  $H_2O_2/O_3$   
Process**

(e.g.,  $\text{HO}\cdot + \text{HO}\cdot \rightarrow \text{H}_2\text{O}_2$ ). The elementary reactions also include the oxidation of the target organic compound (R) and the scavenging of the hydroxyl radical by bicarbonate, carbonate, and NOM, as discussed in Sec. 18-1.

The net rates of formation of various radicals are given by the expressions

$$\eta_{\text{HO}\cdot} = k_5 [\text{HO}_3\cdot] - k_9 [\text{HO}\cdot] [\text{HO}_2^-] - k_{10} [\text{HO}\cdot] [\text{H}_2\text{O}_2] \quad (18-38)$$

$$- k_{11} [\text{HO}\cdot] [\text{HCO}_3^-] - k_{12} [\text{HO}\cdot] [\text{R}] - k_{13} [\text{HO}\cdot] [\text{NOM}]$$

$$\eta_{\text{HO}_3\cdot} = k_4 [\text{O}_3^-\cdot] [\text{H}^+] - k_5 [\text{HO}_3\cdot] \quad (18-39)$$

$$r_{\text{O}_3^-\cdot} = k_1 [\text{O}_3] [\text{HO}_2^-] + k_3 [\text{O}_2^-\cdot] [\text{O}_3] - k_4 [\text{O}_3^-\cdot] [\text{H}^+] \quad (18-40)$$

$$r_{\text{HO}_2\cdot/\text{O}_2^-\cdot} = k_1 [\text{HO}_2^-] [\text{O}_3] + k_9 [\text{HO}\cdot] [\text{HO}_2^-] + k_{10} [\text{HO}\cdot] [\text{H}_2\text{O}_2]$$

$$- k_3 [\text{O}_3] [\text{O}_2^-\cdot] \quad (18-41)$$

- where
- $\eta_{\text{HO}\cdot}$  = rate of hydroxyl radical formation, mol/L · s
  - $\eta_{\text{HO}_3\cdot}$  = rate of ozonide radical formation, mol/L · s
  - $r_{\text{O}_3^-\cdot}$  = rate of ozonide ion radical formation, mol/L · s
  - $r_{\text{HO}_2\cdot/\text{O}_2^-\cdot}$  = total rate of superoxide radical formation, mol/L · s
  - $k_{11}$  = second-order rate constant between hydroxyl radical and bicarbonate, L/mol · s
  - $k_{12}$  = second-order rate constant between hydroxyl radical and target organic compound R, L/mol · s
  - $k_{13}$  = second-order rate constant between hydroxyl radical and NOM, L/mol · s
  - $[\text{HO}_3\cdot]$  = concentration of ozonide radical, mol/L
  - $[\text{HO}\cdot]$  = concentration of hydroxyl radical, mol/L
  - $[\text{HO}_2^-]$  = concentration of conjugate base or anion of hydrogen peroxide, mol/L
  - $[\text{H}_2\text{O}_2]$  = concentration of hydrogen peroxide, mol/L
  - $[\text{HCO}_3^-]$  = concentration of bicarbonate, mol/L
  - $[\text{R}]$  = concentration of target organic compound R, mol/L
  - $[\text{NOM}]$  = concentration of NOM, mol/L
  - $[\text{O}_3^-\cdot]$  = concentration of ozonide ion radical, mol/L
  - $[\text{H}^+]$  = concentration of hydrogen ion, mol/L
  - $[\text{O}_2^-\cdot]$  = concentration of superoxide anion radical, mol/L
  - $[\text{O}_3]$  = concentration of ozone, mol/L

The net rate of formation of all radical species can be set to zero because their concentrations are small and change rapidly in response to changing solution conditions. This rapid response is known as the pseudo-steady-state approximation. Invoking the pseudo-steady-state approximation for the various radical intermediates, four algebraic equations are obtained and radical species other than  $\text{HO}\cdot$  can be eliminated from Eq. 18-38.

Equation 18-38 can be rearranged to obtain the following expression for HO•:

$$[\text{HO}\cdot]_{\text{ss}} = \frac{2k_1 [\text{HO}_2^-] [\text{O}_3]}{k_{11} [\text{HCO}_3^-] + k_{12} [\text{R}] + k_{13} [\text{NOM}]} \quad (18-42)$$

where  $[\text{HO}\cdot]_{\text{ss}}$  = pseudo-steady-state concentration of HO•, mol/L

When the H<sub>2</sub>O<sub>2</sub>/ozone ratio is close to the stoichiometric optimum, the liquid-phase reaction occurs so fast that the ozone transfer is the limiting factor in the reaction rate. The O<sub>3</sub> concentration can be assumed to be constant and is much lower than the saturation concentration, as follows:

$$[\text{O}_3]_s = \frac{P_{\text{O}_3}}{H_{\text{O}_3}} \quad (18-43)$$

where  $[\text{O}_3]_s$  = saturation concentration of ozone, mol/L

$P_{\text{O}_3}$  = partial pressure of ozone in inlet gas, atm

$H_{\text{O}_3}$  = Henry's law constant for ozone, atm · L/mol

The reaction of O<sub>3</sub> with hydroxyl ion and the target compounds can be ignored because of the low O<sub>3</sub> concentration and the relatively low rate constant for the reaction between O<sub>3</sub> and the target compound. The resulting rate expression for O<sub>3</sub> formation is given by

$$r_{\text{O}_3} = (K_L a)_{\text{O}_3} \left( \frac{P_{\text{O}_3}}{H_{\text{O}_3}} - [\text{O}_3] \right) - k_1 [\text{HO}_2^-] [\text{O}_3] - k_3 [\text{O}_2^- \cdot] [\text{O}_3] \quad (18-44)$$

where  $(K_L a)_{\text{O}_3}$  = overall mass transfer coefficient for ozone, s<sup>-1</sup>

The pseudo-steady-state expression for the rate of formation of ozone is invoked and Eq. 18-44 may be rearranged to the form

$$(K_L a)_{\text{O}_3} \left( \frac{P_{\text{O}_3}}{H_{\text{O}_3}} - [\text{O}_3] \right) = k_1 [\text{HO}_2^-] [\text{O}_3] + k_3 [\text{O}_2^- \cdot] [\text{O}_3] \quad (18-45)$$

The pseudo-steady state for the rate of formation of HO<sub>2</sub>•/O<sub>2</sub>• shown in Eq. 18-41 may be rearranged to the form

$$k_3 [\text{O}_2^- \cdot] [\text{O}_3] = k_1 [\text{HO}_2^-] [\text{O}_3] + k_9 [\text{HO}_2^-] [\text{HO}\cdot] + k_{10} [\text{H}_2\text{O}_2] [\text{HO}\cdot] \quad (18-46)$$

Substituting Eq. 18-41 into Eq. 18-46 yields

$$2k_1 [\text{HO}_2^-] [\text{O}_3] = (K_L a)_{\text{O}_3} \left( \frac{P_{\text{O}_3}}{H_{\text{O}_3}} - [\text{O}_3] \right) - k_9 [\text{HO}_2^-] [\text{HO}\cdot] - k_{10} [\text{H}_2\text{O}_2] [\text{HO}\cdot] \quad (18-47)$$

The following expression is obtained after substituting Eq. 18-47 into Eq. 18-42 and rearranging:

$$[\text{HO}\cdot]_{\text{ss}} = \frac{(K_L a)_{\text{O}_3} (P_{\text{O}_3}/H_{\text{O}_3} - [\text{O}_3])}{k_9 [\text{HO}_2^-] + k_{10} [\text{H}_2\text{O}_2] + k_{11} [\text{HCO}_3^-] + k_{12} [\text{R}] + k_{13} [\text{NOM}]} \quad (18-48)$$

The initial pseudo-steady-state concentration of HO• is obtained by neglecting [O<sub>3</sub>] as compared to  $P_{\text{O}_3}/H_{\text{O}_3}$  and the reaction between O<sub>3</sub> and HO• (ignoring this reaction is reasonable because the concentrations of both O<sub>3</sub> and the hydroxyl radical are low), as shown in the expression

$$[\text{HO}\cdot]_{\text{ss},0} = \frac{(K_L a)_{\text{O}_3} (P_{\text{O}_3}/H_{\text{O}_3})}{k_9 [\text{HO}_2^-]_0 + k_{10} [\text{H}_2\text{O}_2]_0 + k_{11} [\text{HCO}_3^-]_0 + k_{12} [\text{R}]_0 + k_{13} [\text{NOM}]_0} \quad (18-49)$$

where  $[\text{HO}\cdot]_{\text{ss},0}$  = initial steady-state concentration of HO•, mol/L  
 $[\text{HO}_2^-]_0$  = initial concentration of anion of hydrogen peroxide, mol/L  
 $[\text{H}_2\text{O}_2]_0$  = initial concentration of hydrogen peroxide, mol/L  
 $[\text{HCO}_3^-]_0$  = initial concentration of bicarbonate, mol/L  
 $[\text{R}]_0$  = initial concentration of target organic compound R, mol/L  
 $[\text{NOM}]_0$  = initial concentration of NOM, mol/L

The initial steady-state O<sub>3</sub> concentration can be estimated from Eq. 18-44:

$$[\text{O}_3]_{\text{ss},0} = \frac{K_L a (P_{\text{O}_3}/H_{\text{O}_3}) - k_9 [\text{HO}\cdot]_{\text{ss},0} [\text{H}_2\text{O}_2]_0 \times 10^{(\text{pH} - \text{p}K_{\text{H}_2\text{O}_2})} - k_{10} [\text{HO}\cdot]_{\text{ss},0} [\text{H}_2\text{O}_2]_0}{(K_L a)_{\text{O}_3} + 2k_1 [\text{H}_2\text{O}_2]_0 \times 10^{(\text{pH} - \text{p}K_{\text{H}_2\text{O}_2})}} \quad (18-50)$$

where  $\text{p}K_{\text{H}_2\text{O}_2}$  = acid dissociation constant for hydrogen peroxide ( $\text{p}K_{a5}$  in Table 18-5)

The rate laws for the parent compound R and H<sub>2</sub>O<sub>2</sub> are given by the equations

$$r_{\text{R}} = -k_6 [\text{R}] [\text{O}_3] - k_{12} [\text{R}] [\text{HO}\cdot] \quad (18-51)$$

$$r_{\text{H}_2\text{O}_2} = -k_1 [\text{HO}_2^-] [\text{O}_3] - k_9 [\text{HO}_2^-] [\text{HO}\cdot] - k_{10} [\text{H}_2\text{O}_2] [\text{HO}\cdot] \quad (18-52)$$

where  $r_{\text{R}}$  = rate of target compound R destruction, mol/L · s  
 $r_{\text{H}_2\text{O}_2}$  = rate of hydrogen peroxide loss, mol/L · s  
 $k_6$  = second-order rate constant between target compound R and ozone, L/mol · s

For the situation where the direct ozonation rate of a target compound is much lower than the reaction rate with hydroxyl radicals (the most common situation), that is,  $k_6 [\text{O}_3] \ll k_{12} [\text{HO}\cdot]$ , the first term in Eq. (18-51) can be ignored.

A simplified model of the  $\text{H}_2\text{O}_2/\text{O}_3$  process can be developed for various cases to provide an estimate of the destruction rates of the parent compound and hydrogen peroxide. The following two cases are considered: (1)  $\text{H}_2\text{O}_2$  and  $\text{O}_3$  are added together and (2)  $\text{H}_2\text{O}_2$  is added to water containing  $\text{O}_3$ .

### Simplified Model for $\text{H}_2\text{O}_2/\text{O}_3$ Process

#### $\text{H}_2\text{O}_2$ AND $\text{O}_3$ ARE ADDED SIMULTANEOUSLY

A simplified analysis for the  $\text{H}_2\text{O}_2/\text{O}_3$  process can be obtained by assuming that the hydroxyl radical concentration does not change with time and is equal to the initial steady-state hydroxyl radical concentration. This assumption yields a pseudo-first-order rate law, which results in the prediction of reaction rates that are faster than would be observed. The pseudo-first-order rate law and coefficient are given by the expressions

$$k_R = k_{12} [\text{HO}\cdot]_{\text{ss},0} \quad (18-53)$$

$$r_R = -k_R [R] \quad (18-54)$$

where  $k_R$  = pseudo-first-order rate constant for target compound R,  $\text{s}^{-1}$

Other terms as defined previously.

The residual of the hydrogen peroxide concentration is of interest, and the following pseudo-first-order rate law and coefficient can be obtained by assuming that the hydroxyl radical and ozone concentrations do not change with time and are equal to their initial steady-state concentration, which are given by the following expressions, respectively:

$$k_{\text{H}_2\text{O}_2} = k_1[\text{O}_3]_{\text{ss},0} \left( 10^{\text{pH} - \text{p}K_{\text{H}_2\text{O}_2}} \right) + k_9[\text{HO}\cdot]_{\text{ss},0} \left( 10^{\text{pH} - \text{p}K_{\text{H}_2\text{O}_2}} \right) + k_{10}[\text{HO}\cdot]_{\text{ss},0} \quad (18-55)$$

$$r_{\text{H}_2\text{O}_2} = -k_{\text{H}_2\text{O}_2} [\text{H}_2\text{O}_2] \quad (18-56)$$

where  $k_{\text{H}_2\text{O}_2}$  = pseudo-first-order rate constant for hydrogen peroxide,  $\text{s}^{-1}$

The above model, termed the *simplified pseudo-steady-state model*, overestimates the destruction rates of the parent compound and hydrogen peroxide. Consequently, when these expressions are used to assess the feasibility of destroying organic compounds and to provide an estimate of the effluent concentration of hydrogen peroxide, the computed value will be lower than the observed value.

#### $\text{H}_2\text{O}_2$ IS ADDED TO A WATER CONTAINING $\text{O}_3$

Some utilities add ozone for disinfection, and, when  $Ct$  disinfection credit is obtained, it may be useful to estimate the potential benefit of adding hydrogen peroxide for the destruction of target micropollutants such as atrazine. In this situation, the residual ozone concentration  $[\text{O}_3]_{\text{res}}$  is known, and hydrogen peroxide is added to produce the hydroxyl radical. The rate law for  $\text{O}_3$  is given by the equation

$$r_{\text{O}_3} = -k_1 [\text{HO}_2^-] [\text{O}_3] - k_3 [\text{O}_2^{\cdot-}] [\text{O}_3] \quad (18-57)$$

Substituting Eq. 18-46 into Eq. 18-57 yields

$$r_{O_3} = - (2k_1 [HO_2^-] [O_3] + k_9 [HO\cdot] [HO_2^-] + k_{10} [HO\cdot] [H_2O_2]) \quad (18-58)$$

According to Eq. 18-58, the initial pseudo-steady-state concentration of  $HO\cdot$  is given by the equation

$$[HO\cdot]_{ss,0} = \frac{2k_1 [H_2O_2]_0 \left(10^{pH-pK_{H_2O_2}}\right) [O_3]_{res}}{k_{11} [HCO_3^-]_0 + k_{12} [R]_0 + k_{13} [NOM]_0} \quad (18-59)$$

The rate laws for the parent compound R and  $H_2O_2$  are given by Eqs. 18-51 and 18-52. In most cases, because  $k_6 [O_3] \ll k_{12} [HO\cdot]$ , the first term in Eq. 18-51 can be ignored. A simplified model can be obtained by assuming that the hydroxyl radical does not change with time and is equal to the initial steady-state hydroxyl radical concentration, which is given by Eq. 18-59. The pseudo-first-order rate law and coefficient are given by the expressions

$$k_R = k_{12} [HO\cdot]_{ss,0} \quad (18-60)$$

$$r_R = -k_R [R] \quad (18-61)$$

The pseudo-first-order rate law and coefficient for hydrogen peroxide can be obtained by assuming that the hydroxyl radical and ozone concentrations do not change with time and are equal to their initial steady-state concentration. The initial concentration of ozone is equal to  $[O_3]_{res}$ :

$$k_{H_2O_2} = k_1 [O_3]_{res} \left(10^{pH-pK_{H_2O_2}}\right) + k_9 [HO\cdot]_{ss,0} \left(10^{pH-pK_{H_2O_2}}\right) + k_{10} [HO\cdot]_{ss,0} \quad (18-62)$$

$$r_{H_2O_2} = -k_{H_2O_2} [H_2O_2] \quad (18-63)$$

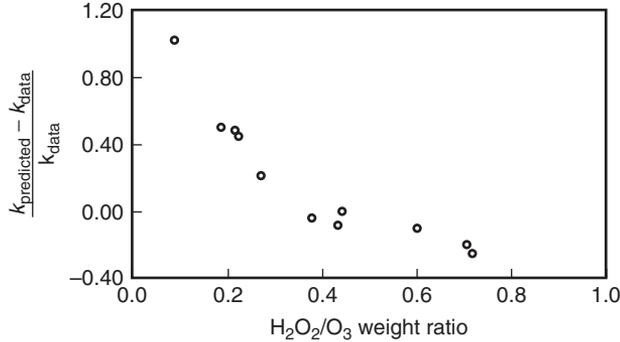

Because the initial concentrations are used, the above model predicts reaction rates that are faster than would be observed.

#### MASS BALANCES USING SIMPLIFIED RATE LAWS

The steady-state mass balances for a CMFR, tanks in series (TIS), a PFR, and dispersed-flow reactor for a pseudo-first-order reaction are provided in Sec. 8-4. Another model for nonideal mixing, the segregated-flow model, is provided in Chap 6.

#### Comparison of Simplified Model to Data and Its Limitations

The simple pseudo-steady-state (Sim-PSS) model was compared to the data that were provided by Glaze and Kang (1989). A comparison of the model predicted pseudo-first-order rate constants to the experimentally determined values is displayed on Fig. 18-2. The measured data are predicted well with the Sim-PSS model when the  $H_2O_2/O_3$  mass ratio is from 0.3 to about 0.6, which is around the stoichiometric optimum of 0.35. For a mass ratio less than 0.3, the predicted rate constants are higher than the

**Figure 18-2**

Comparison of model-predicted pseudo-first-order rate constants to experimental values.

measured values, and when the ratio exceeds 0.6, the predicted values are less than the measured values. The observed variations are due to the complexity of the H<sub>2</sub>O<sub>2</sub>/O<sub>3</sub> reaction system; in particular, different mechanisms control the overall reaction rate from O<sub>3</sub> control to H<sub>2</sub>O<sub>2</sub> control as the H<sub>2</sub>O<sub>2</sub>/O<sub>3</sub> ratio changes. Consequently, to predict process performance more accurately, a sophisticated model is required. However, the Sim-PSS model is precise enough to examine the feasibility of the process. Moreover, pilot testing is necessary to evaluate the technology in the field once process feasibility has been assessed using the Sim-PSS model.

Numerous studies have been reported in the literature on the efficacy of the H<sub>2</sub>O<sub>2</sub>/O<sub>3</sub> process. When compared with the results of these studies, the simple model does a reasonable job of predicting process performance. The electrical efficiency per log order reduction (EE/O) (see Eq. 8-130 in Chap. 8) for the H<sub>2</sub>O<sub>2</sub>/O<sub>3</sub> process can also be calculated using the energy required to produce ozone and the observed first-order rate constants. These EE/O values are much lower than the values that are typically reported for the UV/hydrogen peroxide process for the destruction of TCE and PCE (0.53 to 2.64 kWh/m<sup>3</sup> per log order reduction for UV/hydrogen peroxide process vs. 0.11 kWh/m<sup>3</sup> per log order reduction for the H<sub>2</sub>O<sub>2</sub>/O<sub>3</sub> process). Thus, the H<sub>2</sub>O<sub>2</sub>/O<sub>3</sub> process appears to be a more energy-efficient method for producing hydroxyl radicals than the UV/hydrogen peroxide process.

Several problems are associated with the hydrogen peroxide/ozone process. One problem is the stripping of volatile species into the off-gas from the ozone contactor. The stripping phenomenon is not important for the more reactive volatile species but can be for species that are less reactive with hydroxyl radical, such as carbon tetrachloride. Another problem with the use of the hydrogen peroxide/ozone process is the production of bromate when the water being treated contains significant amounts of bromide ion. The formation of bromate can occur with any advanced oxidation process, but the presence of ozone in the H<sub>2</sub>O<sub>2</sub>/O<sub>3</sub> process adds a second route of formation, namely direct oxidation by O<sub>3</sub> itself (see Chap. 8).

### Disadvantages of H<sub>2</sub>O<sub>2</sub>/O<sub>3</sub> Process

For California State Project water and Colorado River water (CRW), each containing about 90  $\mu\text{g/L}$  bromide, it was found that the  $\text{H}_2\text{O}_2/\text{O}_3$  process produced bromate concentrations in excess of the MCL of 10  $\mu\text{g/L}$  (Liang et al., 1999). A number of researchers have investigated the mechanism of bromide oxidation by ozone alone (Buxton and Greenstock, 1988; Haag and Hoigné, 1983; Hoigné and Bader, 1976; Hoigné et al., 1985; Taube, 1942).

Models of bromate formation from bromide reactions with ozone alone, discussed under ozone reactions (see Chap. 19), have been developed (von Gunten and Hoigné, 1994; Westerhoff et al., 1994, 1998). A study of bromate formation in advanced oxidation processes in which the influence of  $\text{H}_2\text{O}_2$  on the bromide oxidation by  $\text{O}_3$  is considered is available in the literature (von Gunten and Hoigné, 1994). A model of the pathways of bromide oxidation reaction, which includes almost all of the known mechanisms, has been developed and tested (Westerhoff et al., 1998).

It has been observed that lower bromate concentrations were produced when a hydrogen peroxide–ozone weight ratio of 1.0 was used as compared to ozone alone (Liang et al., 2001). It appears that bromate formation could be controlled effectively with higher hydrogen peroxide–ozone ratios because excess hydrogen peroxide accelerates ozone decay. However, a high hydrogen peroxide–ozone ratio might not be optimal for contaminant removal. As a result, removal efficiency and bromate formation have to be considered when using the hydrogen peroxide/ozone process. Other strategies, such as pH depression and ammonia addition (see Chap. 19), can also be used to control bromate formation.

In spite of the success of the bromate formation models and what is known about bromate formation, pilot studies are recommended for treatability assessment and process optimization. The simple models of the process presented in this section are only useful for preliminary process assessment and planning the scope of pilot investigations.

### **Example 18-6 Contaminant Effluent Concentration Using the Hydrogen peroxide–ozone process**

A small city has recently discovered that one of its wells is contaminated with 200  $\mu\text{g/L}$  (1.52  $\mu\text{mol/L}$ ) TCE. To continue using the well as a drinking water source, the TCE needs to be destroyed and the effluent concentration must be less than 5  $\mu\text{g/L}$ . During normal pumping operations, the well produces water at about 0.025  $\text{m}^3/\text{s}$  (400 gal/min). The  $\text{HCO}_3^-$ , pH, and DOC concentrations are 488 mg/L, 7.5, and 0.7 mg/L, respectively. The physicochemical properties of TCE and NOM are as follows:

Compound	MW, g/mol	HO• Rate Constant, $k_{HO\bullet}$ , L/mol · s
TCE	131.389	$4.20 \times 10^9$
NOM <sup>a</sup>	NA	$3.90 \times 10^8$

<sup>a</sup>For NOM, the unit of  $k_{HO\bullet}$  is L/mol NOM C · s.

For simplicity, a proprietary reactor will be used. It has been determined by conducting tracer studies on the reactor that its hydraulic performance can be described using four completely mixed flow reactors in series. Given the following information: (1) the  $H_2O_2$  dosage is 0.8 mg/L, (2)  $O_3$  is generated onsite and the ozone flow rate is 1 mg/L · min, (3) the partial pressure of ozone in the inlet gas is 0.07 atm, (4) the Henry's law constant for  $O_3$  at 23°C is 83.9 atm · L/mol, (5) the overall mass transfer coefficient for  $O_3$ ,  $K_L a$ , was measured to be  $7 \times 10^{-4} s^{-1}$ , and (6) the reactor volume is 5500 L ( $5.5 m^3$ ). Determine the expected effluent concentration for TCE and the  $H_2O_2$  residual concentration.

### Solution

1. Calculate the hydraulic detention time ( $\tau$ ):

$$\tau = \frac{V}{Q} = \frac{5.5 m^3}{(0.025 m^3/s)(60 s/min)} = 3.7 \text{ min}$$

2. Calculate the initial steady-state concentration of hydroxyl radical using Eq. 18-49:

$$[HO\bullet]_{ss,0} = \frac{K_L a(P_{O_3}/H_{O_3})}{k_9[HO_2^-]_0 + k_{10}[H_2O_2]_0 + k_{11}[HCO_3^-]_0 + k_{12}[R]_0 + k_{13}[NOM]_0}$$

- a. Obtain the reaction rate constants and acid dissociation constants from Table 18-5:

$$\begin{aligned} k_9 &= 7.5 \times 10^9 \text{ L/mol} \cdot \text{s} \\ k_{10} &= 2.7 \times 10^7 \text{ L/mol} \cdot \text{s} \\ k_{11} &= 805 \times 10^6 \text{ L/mol} \cdot \text{s} \\ k_{12} &= 4.2 \times 10^9 \text{ L/mol} \cdot \text{s} \\ k_{13} &= 3.9 \times 10^8 \text{ L/mol NOM C} \cdot \text{s} \\ pK_{H_2O_2} &= 11.75 \end{aligned}$$

- b. Calculate the concentration of each component:

$$[H_2O_2]_0 = \frac{0.8 \text{ mg/L}}{(34 \text{ g/mol})(1000 \text{ mg/g})} = 2.35 \times 10^{-5} \text{ mol/L}$$

$$\begin{aligned} [\text{HO}_2^-]_0 &= [\text{H}_2\text{O}_2]_0 (10^{\text{pH} - \text{p}K_{\text{H}_2\text{O}_2}}) = (2.35 \times 10^{-5} \text{ mol/L}) (10^{7.5 - 11.75}) \\ &= 1.32 \times 10^{-9} \text{ mol/L} \end{aligned}$$

$$[\text{HCO}_3^-]_0 = \frac{488 \text{ mg/L}}{(61 \text{ g/mol}) (1000 \text{ mg/g})} = 0.008 \text{ mol/L}$$

$$[\text{R}]_0 = [\text{TCE}]_0 = \frac{1.52 \text{ } \mu\text{mol/L}}{10^6 \text{ } \mu\text{mol/mol}} = 1.52 \times 10^{-6} \text{ mol/L}$$

$$\begin{aligned} [\text{NOM}]_0 &= \frac{0.7 \text{ mg/L}}{(12 \text{ g C/mol NOM C}) (1000 \text{ mg/g})} \\ &= 5.83 \times 10^{-5} \text{ mol NOM C/L} \end{aligned}$$

c. Calculate the product of the rate constant and initial concentration of each component needed in Eq. 18-49:

$$k_9 [\text{HO}_2^-]_0 = (7.5 \times 10^9 \text{ L/mol} \cdot \text{s}) (1.32 \times 10^{-9} \text{ mol/L}) = 9.9 \text{ s}^{-1}$$

$$k_{10} [\text{H}_2\text{O}_2]_0 = (2.7 \times 10^7 \text{ L/mol} \cdot \text{s}) (2.35 \times 10^{-5} \text{ mol/L}) = 634.5 \text{ s}^{-1}$$

$$k_{11} [\text{HCO}_3^-]_0 = (8.5 \times 10^6 \text{ L/mol} \cdot \text{s}) (0.008 \text{ mol/L}) = 68,000 \text{ s}^{-1}$$

$$\begin{aligned} k_{12} [\text{R}]_0 &= k_{12} [\text{TCE}]_0 = (4.2 \times 10^9 \text{ L/mol} \cdot \text{s}) (1.52 \times 10^{-6} \text{ mol/L}) \\ &= 6384 \text{ s}^{-1} \end{aligned}$$

$$\begin{aligned} k_{13} [\text{NOM}]_0 &= (3.9 \times 10^8 \text{ L/mol NOM C} \cdot \text{s}) (5.83 \times 10^{-5} \text{ mol NOM C/L}) \\ &= 22737 \text{ s}^{-1} \end{aligned}$$

d. Calculate the initial steady-state concentration of the hydroxyl radical using Eq. 18-49:

$$\begin{aligned} [\text{HO}\cdot]_{\text{ss},0} &= \frac{(7 \times 10^{-4} \text{ s}^{-1}) [(0.07 \text{ atm}) / (83.9 \text{ L} \cdot \text{atm/mol})]}{(9.9 + 634.5 + 68000 + 6384 + 22737) \text{ s}^{-1}} \\ &= 5.97 \times 10^{-12} \text{ mol/L} \end{aligned}$$

3. Calculate the TCE effluent concentration:

- a. Determine  $k_{TCE}$  using the pseudo-first-order rate law presented in Eq. 18-49:

$$k_R = k_{TCE} = k_{12} [\text{HO}\cdot]_{ss,0} = (4.2 \times 10^9 \text{ L/mol}\cdot\text{s}) (5.97 \times 10^{-12} \text{ mol/L}) \\ = 0.025 \text{ s}^{-1}$$

- b. Determine the effluent TCE concentration using the TIS model presented in Sec. 8-4:

$$[\text{TCE}] = [R] = \frac{[R]_0}{(1 + k_{TCE}\tau/n)^n} = \frac{200 \mu\text{g/L}}{[1 + (0.025 \text{ s}^{-1})(3.7 \text{ min})(60 \text{ s/min})/4]^4} \\ = 6.2 \mu\text{g/L}$$

4. Estimate the initial steady-state concentration of  $\text{O}_3$  using Eq. 18-50:

$$[\text{O}_3]_{ss,0} = \frac{K_L a (P_{\text{O}_3}/H_{\text{O}_3}) - k_9 [\text{HO}\cdot]_{ss,0} [\text{H}_2\text{O}_2]_0 (10^{\text{pH}-\text{p}K_{\text{H}_2\text{O}_2}}) - k_{10} [\text{HO}\cdot]_{ss,0} [\text{H}_2\text{O}_2]_0}{K_L a + 2k_1 [\text{H}_2\text{O}_2]_0 (10^{\text{pH}-\text{p}K_{\text{H}_2\text{O}_2}})}$$

- a. From Table 18-5,

$$k_1 = 2.8 \times 10^6 \text{ L/mol}\cdot\text{s}$$

- b. From steps 2a, 2b, and 2c,

$$k_9 [\text{H}_2\text{O}_2]_0 (10^{\text{pH}-\text{p}K_{\text{H}_2\text{O}_2}}) = k_9 [\text{HO}_2^-]_0 = 9.9 \text{ s}^{-1}$$

$$k_{10} [\text{H}_2\text{O}_2]_0 = 634.5 \text{ s}^{-1}$$

$$[\text{H}_2\text{O}_2]_0 (10^{\text{pH}-\text{p}K_{\text{H}_2\text{O}_2}}) = [\text{HO}_2^-]_0 = 1.32 \times 10^{-9} \text{ mol/L}$$

- c. Solve for  $K_L a (P_{\text{O}_3}/H_{\text{O}_3})$ :

$$K_L a \frac{P_{\text{O}_3}}{H_{\text{O}_3}} = (7 \times 10^{-4} \text{ s}^{-1}) \left( \frac{0.07 \text{ atm}}{83.9 \text{ L}\cdot\text{atm/mol}} \right) = 5.84 \times 10^{-7} \text{ mol/L}\cdot\text{s}$$

- d. Combine results of 4b with result of 2d:

$$k_9 [\text{H}_2\text{O}_2]_0 (10^{\text{pH}-\text{p}K_{\text{H}_2\text{O}_2}}) \times [\text{HO}\cdot]_{ss,0} = (9.9 \text{ s}^{-1}) (5.97 \times 10^{-12} \text{ mol/L}) \\ = 5.9 \times 10^{-11} \text{ mol/L}\cdot\text{s}$$

$$k_{10} [\text{H}_2\text{O}_2]_0 [\text{HO}\cdot]_{ss,0} = (634.5 \text{ s}^{-1}) (5.97 \times 10^{-12} \text{ mol/L}) \\ = 3.79 \times 10^{-9} \text{ mol/L}\cdot\text{s}$$

e. Solve for  $[O_3]_{ss,0}$ :

$$[O_3]_{ss,0} = \frac{[(5.84 \times 10^{-7}) - (5.9 \times 10^{-11}) - (3.79 \times 10^{-9})] \text{ mol/L} \cdot \text{s}}{(7 \times 10^{-4} \text{ s}^{-1}) + [2(2.8 \times 10^6 \text{ L/mol} \cdot \text{s})(1.32 \times 10^{-9} \text{ mol/L})]}$$

$$= 7.17 \times 10^{-5} \text{ mol/L (3.44 mg/L)}$$

5. Estimate  $H_2O_2$  residual:

a. Estimate the pseudo-first-order rate constant for hydrogen peroxide using Eq. 18-55:

$$k_{H_2O_2} = k_1 [O_3]_{ss,0} (10^{pH-pK_{H_2O_2}}) + k_9 [HO\cdot]_{ss,0} (10^{pH-pK_{H_2O_2}}) + k_{10} [HO\cdot]_{ss,0}$$

i. Determine the values of the rate constant times concentration needed in Eq. 18-55:

$$k_1 [O_3]_{ss,0} (10^{pH-pK_{H_2O_2}}) = (2.8 \times 10^6 \text{ L/mol} \cdot \text{s})(7.17 \times 10^{-5} \text{ mol/L}) \times 10^{(7.5-11.75)}$$

$$= 0.0112 \text{ s}^{-1}$$

$$k_9 [HO\cdot]_{ss,0} (10^{pH-pK_{H_2O_2}}) = (7.5 \times 10^9 \text{ L/mol} \cdot \text{s})(5.97 \times 10^{-12} \text{ mol/L}) \times 10^{(7.5-11.75)}$$

$$= 2.52 \times 10^{-6} \text{ s}^{-1}$$

$$k_{10} [HO\cdot]_{ss,0} = (2.7 \times 10^7 \text{ L/mol} \cdot \text{s})(5.97 \times 10^{-12} \text{ mol/L})$$

$$= 1.61 \times 10^{-4} \text{ s}^{-1}$$

ii. Determine  $k_{H_2O_2}$ :

$$k_{H_2O_2} = (0.0112 \text{ s}^{-1}) + (2.52 \times 10^{-6} \text{ s}^{-1}) + (1.61 \times 10^{-4} \text{ s}^{-1})$$

$$= 0.0114 \text{ s}^{-1}$$

b. Estimate the  $H_2O_2$  residual using the TIS model (see Sec. 8-4):

$$[H_2O_2] = \frac{[H_2O_2]_0}{(1 + k_{H_2O_2} \tau)^n} = \frac{0.8 \text{ mg/L}}{[1 + (0.0114 \text{ s}^{-1})(3.7 \text{ min})(60 \text{ s/min})/4]^4}$$

$$= 0.11 \text{ mg/L}$$

### Comment

The initial ozone concentration is only an approximate estimate because it was assumed that the reactor contents are mixed completely and the gas-phase ozone concentration does not change. The effluent hydrogen peroxide concentration is only an estimate, and, based on the reactions that were

considered, it is the lowest expected effluent concentration. Measurements will have to be taken to ensure that this residual does not interfere with disinfection (e.g., consume chlorine) and is not transmitted to the distribution system.

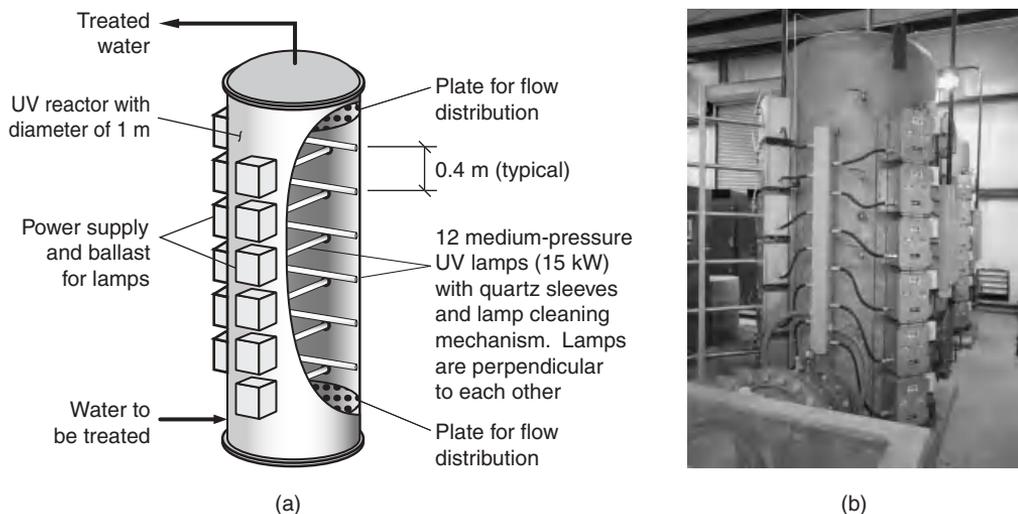

## 18-4 Hydrogen Peroxide/UV Light Process

The UV/ hydrogen peroxide process includes hydrogen peroxide injection and mixing followed by a reactor that is equipped with UV lights. As shown on Fig. 18-3, a typical UV reactor is a stainless steel column that contains UV lights in a crisscrossing pattern. The details of the reactor are discussed in Secs. 8-4 and 13-9. The UV/H<sub>2</sub>O<sub>2</sub> process cannot be used for potable water treatment because it has high effluent H<sub>2</sub>O<sub>2</sub> concentrations. High effluent H<sub>2</sub>O<sub>2</sub> concentrations are unavoidable, because high initial dosages of H<sub>2</sub>O<sub>2</sub> are required in order to efficiently utilize the UV light and produce hydroxyl radical. Aside from the health issues associated with high effluent H<sub>2</sub>O<sub>2</sub> concentrations in the finished water, the residual H<sub>2</sub>O<sub>2</sub> will consume chlorine and interfere with disinfection. This challenge will have to be overcome before the UV/ H<sub>2</sub>O<sub>2</sub> process is used in drinking water treatment.

The complex elementary radical reactions that are involved with the H<sub>2</sub>O<sub>2</sub>/UV process have been discovered. It is now possible to predict the destruction of the target compound using these reactions and gain insight into the factors that impact the H<sub>2</sub>O<sub>2</sub>/UV process (Glaze et al., 1990; Liao and Gurol, 1995; Crittenden et al., 1999). The mechanisms that may be considered are (1) photolysis of H<sub>2</sub>O<sub>2</sub> with a multichromatic light source, (2) UV absorption by the background components in the water matrix, (3) scavenging of hydroxyl radical by NOM and carbonate species, and (4) direct photolysis of NOM and the target compound. A rigorous AOP model was developed to predict the destruction of target compounds and the effluent H<sub>2</sub>O<sub>2</sub> concentration using the complete radical reaction pathway presented by Crittenden et al. (1999).

However, reasonable predictions of target compound destruction and residual H<sub>2</sub>O<sub>2</sub> can be obtained by using a simplified pseudo-steady-state model as shown below, although some accuracy will be lost (Crittenden et al., 1999). The most important elementary reactions in the H<sub>2</sub>O<sub>2</sub>/UV process at neutral pH are shown in Table 18-5. The reaction pathway is extremely simplified and ignores radical-radical reactions, the reactions between HO<sub>2</sub><sup>-</sup> and CO<sub>3</sub><sup>2-</sup> and other species (due to the large *pK<sub>a</sub>* values) and unimportant radical species (CO<sub>3</sub><sup>-•</sup>; etc.).

### Elementary Reactions for the Hydrogen Peroxide/UV Process

**Figure 18-3**  
UV reactor used for advanced oxidation: (a) schematic and (b) photograph.

The elementary reactions that are involved in the  $\text{H}_2\text{O}_2/\text{UV}$  process include initiation (reaction 7), propagation (reactions 9, 10), and termination reactions of the radical chain reactions. (Termination reactions involve recombination of radical species and are not shown because they have a low probability of occurrence, e.g.,  $\text{HO}\cdot + \text{HO}\cdot \rightarrow \text{H}_2\text{O}_2$ ) The elementary reactions also include the oxidation of the target organic compound (R) and the scavenging of hydroxyl radical by bicarbonate, carbonate, and NOM.

#### PRODUCTION OF HYDROXYL RADICAL

Early investigations of hydrogen peroxide photolysis (Heidt, 1932; Volman, 1949; Volman and Chen, 1959; Hunt and Taube, 1952; Baxendale and Wilson, 1957) as well as more recent studies (Sehested et al., 1968; Bielski and Richter, 1977; Bielski et al., 1985) indicate that the following radical chain reactions occur in a hydrogen peroxide solution with UV light irradiation. As shown in Table 18-5, the production of hydroxyl radical is initiated via the following reaction:

#### QUANTUM YIELD

The primary quantum yield for  $\text{H}_2\text{O}_2$  is 0.5 for wavelengths in the UV region (Volman and Chen, 1959; Zellner et al., 1990), but the primary quantum yield of  $\text{H}_2\text{O}_2$  depends slightly on temperature. For example, the quantum yield is 0.41 at  $5^\circ\text{C}$ . However, this is not important because the temperature in a UV reactor generally achieves room temperature due to heat produced during lamp illumination.

**SIMPLIFIED PSEUDO-STEADY-STATE MODEL**

Based on the reactions that are presented in Table 18-5, the rate expression for HO• is given by this expression.

$$\begin{aligned} r_{\text{HO}\cdot} = & 2\phi_{\text{H}_2\text{O}_2}P_{\text{u-v}}f_{\text{H}_2\text{O}_2}(1 - e^{-A}) - k_{10}[\text{HO}\cdot][\text{H}_2\text{O}_2] - k_{11}[\text{HO}\cdot][\text{HCO}_3^-] \\ & - k_{12}[\text{HO}\cdot][\text{R}] - k_{13}[\text{HO}\cdot][\text{NOM}] \end{aligned} \quad (18-65)$$

where

- $r_{\text{HO}\cdot}$  = rate of hydroxyl radical formation, mol/L · s
- $\phi_{\text{H}_2\text{O}_2}$  = quantum yield of hydrogen peroxide, mol/einstein
- $P_{\text{U-V}}$  = photonic intensity per unit volume, einsteins/cm<sup>3</sup> · s
- $f_{\text{H}_2\text{O}_2}$  = fraction of light absorbed by hydrogen peroxide, dimensionless
- $A$  = absorbance, dimensionless
- $k_{10}$  = second-order rate constant between hydroxyl radical and hydrogen peroxide, L/mol · s (M<sup>-1</sup>s<sup>-1</sup>)
- $k_{11}$  = second-order rate constant between hydroxyl radical and carbonate, L/mol · s (M<sup>-1</sup>s<sup>-1</sup>)
- $k_{12}$  = second-order rate constant between hydroxyl radical and target organic compound R, L/mol · s (M<sup>-1</sup>s<sup>-1</sup>)
- $k_{13}$  = second-order rate constant between hydroxyl radical and NOM, L/mol · s (M<sup>-1</sup>s<sup>-1</sup>)
- $[\text{HO}\cdot]$  = concentration of hydroxyl radical, mol/L
- $[\text{H}_2\text{O}_2]$  = concentration of hydrogen peroxide, mol/L
- $[\text{HCO}_3^-]$  = concentration of carbonate, mol/L
- $[\text{R}]$  = concentration of target compound R, mol/L
- $[\text{NOM}]$  = concentration of NOM, mol carbon/L

The photonic intensity per unit volume of reactor,  $P_{\text{U-V}}$ , can be calculated using the the following expression:

$$P_{\text{U-V}} = \frac{P\eta}{N_{\text{av}}Vh\nu} \quad (18-66)$$

where

- $\eta$  = efficiency of the UV lamp, dimensionless
- $V$  = volume of reactor solution, L

According to the pseudo-steady-state assumption, the change of hydroxyl radical concentration with time is negligible because the rate of reactions involving HO• are very fast and HO• concentration is very small as compared to other compounds. Consequently, the formation rate of hydroxyl radical can be set equal to zero. By setting the formation rate of HO• equal to zero, the pseudo-steady-state concentration of hydroxyl radical can be determined.

$$[\text{HO}\cdot]_{\text{ss}} = \frac{2\phi_{\text{H}_2\text{O}_2}P_{\text{u-v}}f_{\text{H}_2\text{O}_2}(1 - e^{-A})}{k_{10}[\text{H}_2\text{O}_2] + k_{11}[\text{HCO}_3^-] + k_{12}[\text{R}] + k_{13}[\text{NOM}]} \quad (18-67)$$

where  $[\text{HO}\cdot]_{\text{ss}}$  = pseudo-steady-state concentration of hydroxyl radical, mol/L

A further simplification of the UV/ $\text{H}_2\text{O}_2$  process model that can be used to show trends and estimate process feasibility is obtained by assuming that the NOM, R, and  $\text{H}_2\text{O}_2$  concentrations are constant and equal to their initial concentration, when calculating the pseudo-steady-state concentration of hydroxyl radical. This version of the model is called the simple pseudo-steady-state (Sim-PSS) model and the hydroxyl radical concentration becomes the following expression:

$$[\text{HO}\cdot]_{\text{ss},0} = \frac{2\phi_{\text{H}_2\text{O}_2} P_{\text{u-v}/\text{H}_2\text{O}_2} (1 - e^{-A})}{k_{10}[\text{H}_2\text{O}_2]_0 + k_{11}[\text{HCO}_3^-]_0 + k_{12}[\text{R}]_0 + k_{13}[\text{NOM}]_0} \quad (18-68)$$

where  $[\text{HO}\cdot]_{\text{ss},0}$  = initial pseudo-steady-state concentration of hydroxyl radical, mol/L  
 $[\text{H}_2\text{O}_2]_0$  = initial concentration of hydrogen peroxide, mol/L  
 $[\text{HCO}_3^-]_0$  = initial concentration of carbonate, mol/L  
 $[\text{R}]_0$  = initial concentration of target compound R, mol/L  
 $[\text{NOM}]_0$  = initial concentration of NOM, mol/L

Accordingly, the rate law for the disappearance of the target compound and hydrogen peroxide are given by the following expressions:

$$r_{\text{R}} = -k_{12}[\text{R}][\text{HO}\cdot]_{\text{ss},0} - \phi_{\text{R}} P_{\text{u-v}/\text{R}} (1 - e^{-A}) \quad (18-69)$$

$$r_{\text{H}_2\text{O}_2} = -\phi_{\text{H}_2\text{O}_2} P_{\text{u-v}/\text{H}_2\text{O}_2} (1 - e^{-A}) - k_{10}[\text{HO}\cdot]_{\text{ss},0}[\text{H}_2\text{O}_2] \quad (18-70)$$

In many cases, the photolysis rate of the target compound is small and the second term in Eq. 18-69 can be neglected; and photoreactors are designed so all the light is absorbed. For this situation, Eqs. 18-69 and 18-70 simplify to the following equations:

$$r_{\text{R}} = -k'_{12}[\text{R}] \quad (18-71)$$

$$r_{\text{H}_2\text{O}_2} = -\phi_{\text{H}_2\text{O}_2} P_{\text{u-v}/\text{H}_2\text{O}_2} - k_{10}[\text{HO}\cdot]_{\text{ss},0}[\text{H}_2\text{O}_2] \quad (18-72)$$

where  $k'_{12} = k_{12}[\text{HO}\cdot]_{\text{ss},0}$  = pseudo-first-order rate constant,  $\text{s}^{-1}$

Equation 18-71 may be further simplified by assuming that  $f_{\text{H}_2\text{O}_2}$  does not change with time and may be calculated from the following expression:

$$\phi_{\text{H}_2\text{O}_2} P_{\text{u-v}/\text{H}_2\text{O}_2} = \frac{0.5 P_{\text{u-v}} \epsilon_{\text{H}_2\text{O}_2} [\text{H}_2\text{O}_2]}{\sum \epsilon_i C_i} \quad (18-73)$$

where  $\epsilon_{\text{H}_2\text{O}_2}$  = extinction coefficient for hydrogen peroxide,  
 L/mol · cm  
 $\epsilon_i$  = extinction coefficient for component  $i$ , L/mol · cm  
 $C_i$  = concentration of component  $i$ , mol/L

If the major background chromophores are Fe(II) and NOM, and their concentrations are assumed to be constant and equal to their initial concentration, Eq. 18-74 simplifies to the following expression:

$$\phi_{\text{H}_2\text{O}_2} P_{\text{u-v}}/f_{\text{H}_2\text{O}_2} = \frac{0.5P_{\text{u-v}}\epsilon_{\text{H}_2\text{O}_2} [\text{H}_2\text{O}_2]}{\epsilon_{\text{H}_2\text{O}_2} [\text{H}_2\text{O}_2]_0 + \epsilon_{\text{NOM}} [\text{NOM}]_0 + \epsilon_{\text{Fe(II)}} [\text{Fe(II)}]_0} \quad (18-74)$$

where  $[\text{Fe(II)}]_0$  = initial concentration of ferrous ion, mol/L

The key assumption for Eq. 18-74 is that  $\epsilon_{\text{H}_2\text{O}_2} [\text{H}_2\text{O}_2]$  is a constant, which is equal to  $\epsilon_{\text{H}_2\text{O}_2} [\text{H}_2\text{O}_2]_0$ , and this assumption will predict a lower photolysis rate. However, the effluent concentration that is predicted using the Sim-PSS is lower than that will be actually observed because the pseudo-steady-state concentration of hydroxyl radical is taken to be the initial value in the simplified pseudo-steady-state model. Accordingly, if the predicted concentration is too high, then the process may be considered infeasible.

The final rate expression for loss of  $\text{H}_2\text{O}_2$  using the Sim-PSS model is given by the following expressions:

$$r_{\text{H}_2\text{O}_2} = -k'_{10} [\text{H}_2\text{O}_2] \quad (18-75)$$

$$k'_{10} = \frac{0.5P_{\text{u-v}}\epsilon_{\text{H}_2\text{O}_2}}{\epsilon_{\text{H}_2\text{O}_2} [\text{H}_2\text{O}_2]_0 + \epsilon_{\text{NOM}} [\text{NOM}]_0 + \epsilon_{\text{Fe(II)}} [\text{Fe(II)}]_0} + k_{10} [\text{HO}\cdot]_{\text{ss},0} \quad (18-76)$$

where  $k'_{10}$  = pseudo-first-order rate constant for the destruction of hydrogen peroxide,  $\text{s}^{-1}$

The steady-state mass balances for a completely mixed flow reactor (CMFR), CMFRs in series, a plug flow reactor (PFR), and a dispersed flow reactor for a pseudo-first-order reaction is provided in Sec. 8-4. The identical equations may be used. Another model for nonideal mixing, the segregated-flow model, is provided in Chap. 6.

#### UV LIGHT TRANSMISSION

The ability of  $\text{H}_2\text{O}_2$  to absorb UV light and produce  $\text{HO}\cdot$  via reaction shown in Eq. 18-76 is dependent upon the wavelength and quantum yield and the UV light absorbance of the background components in the water, as discussed in Sec. 8-4.

AOPs that utilize UV light for the production of  $\text{HO}\cdot$  radicals must have reasonable light transmission in the UV region of the light because any light that is not absorbed by the oxidant is wasted, and the generation

of UV light represents a significant operational cost. Accordingly, it is important to evaluate the influence of pretreatment effectiveness and cost (e.g., particle removal and the removal of certain UV absorbing species) on UV light transmission. For example, when considering the UV/H<sub>2</sub>O<sub>2</sub> process, a preliminary evaluation would include an estimate of the fraction of UV light that would be available to activate the H<sub>2</sub>O<sub>2</sub> and the influence that pretreatment would have on the available light transmission. In a highly contaminated groundwater, an absorbance of 0.385 for a 1 cm depth at 254 nm was measured. The light absorption coefficient for H<sub>2</sub>O<sub>2</sub> is about 19 M<sup>-1</sup>cm<sup>-1</sup> at 254 nm and the quantity of light and the fraction of light that produces hydroxyl radical may be estimated from the following equation:

$$f_{\text{oxidant}} = \frac{\epsilon_{\text{H}_2\text{O}_2} C_{\text{H}_2\text{O}_2} L}{\epsilon_{\text{H}_2\text{O}_2} C_{\text{H}_2\text{O}_2} L + \epsilon_{\text{bac}} C_{\text{bac}} L} = \frac{\epsilon_{\text{H}_2\text{O}_2} C_{\text{H}_2\text{O}_2}}{\epsilon_{\text{H}_2\text{O}_2} C_{\text{H}_2\text{O}_2} + \epsilon_{\text{bac}} C_{\text{bac}}} \quad (18-77)$$

where  $f_{\text{oxidant}}$  = light absorbed by the oxidant, dimensionless  
 $C_{\text{H}_2\text{O}_2}$  = concentration of hydrogen peroxide, mol/L  
 $L$  = reactor depth, cm  
 $\epsilon_{\text{H}_2\text{O}_2}$  = extinction coefficients for hydrogen peroxide,  
 L/mol · cm  
 $\epsilon_{\text{bac}}$  = extinction coefficients for background, L/mol · cm

For example, fraction of light absorbed by an H<sub>2</sub>O<sub>2</sub> concentration of 80 mg/L is only 10.7 percent, or 90 percent of the light is wasted.

When considering pretreatment options, it is useful to know the light absorption of certain dissolved species in water because this can form the basis for pretreatment.

### Example 18-7 Fraction of light absorbed by hydrogen peroxide for various Fe(II) solutions

Calculate the fraction of light absorbed by 1 mM H<sub>2</sub>O<sub>2</sub> in solutions of 0.5 and 5 mg/L of Fe(II) at 254 nm. At 254 nm, the molar extinction coefficients of H<sub>2</sub>O<sub>2</sub> and ferrous ion are 19 and 448 L/mol · cm, respectively.

#### Solution

1. Calculate the absorbance of H<sub>2</sub>O<sub>2</sub>:  
 From the Beer–Lambert law presented in Sec. 8-4:

$$A = \epsilon C X$$

The absorbance of  $\text{H}_2\text{O}_2$  at 1 mM is

$$\begin{aligned} A_{\text{H}_2\text{O}_2} &= \varepsilon_{\text{H}_2\text{O}_2} C_{\text{H}_2\text{O}_2} x = (19 \text{ L/mol} \cdot \text{cm})(1 \times 10^{-3} \text{ mol/L})x \\ &= 0.019x \text{ cm}^{-1} \end{aligned}$$

2. Calculate the absorbance of Fe(II).

a. Calculate the absorbance of Fe(II) at 0.5 mg/L:

$$\begin{aligned} A_{\text{Fe(II)}} &= \varepsilon_{\text{Fe(II)}} C_{\text{Fe(II)}} x = (448 \text{ L/mol} \cdot \text{cm}) \left[ \frac{0.5 \text{ mg/L}}{(55.85 \text{ g/mol})(1000 \text{ mg/g})} \right] x \\ &= (4.01 \times 10^{-3})x \text{ cm}^{-1} \end{aligned}$$

b. Calculate the absorbance of Fe(II) at 5 mg/L:

$$\begin{aligned} A_{\text{Fe(II)}} &= \varepsilon_{\text{Fe(II)}} C_{\text{Fe(II)}} x = (448 \text{ L/mol} \cdot \text{cm}) \left[ \frac{5 \text{ mg/L}}{(55.85 \text{ g/mol})(1000 \text{ mg/g})} \right] x \\ &= (4.01 \times 10^{-2})x \text{ cm}^{-1} \end{aligned}$$

3. Calculate the fraction of light absorbed by  $\text{H}_2\text{O}_2$ .

The total absorbance of the solution is

$$A_t = A_{\text{H}_2\text{O}_2} + A_{\text{Fe(II)}} = x(\varepsilon_{\text{H}_2\text{O}_2} C_{\text{H}_2\text{O}_2} + \varepsilon_{\text{Fe(II)}} C_{\text{Fe(II)}})$$

The fraction of light absorbed by  $\text{H}_2\text{O}_2$  can be calculated using Eq. 18-77:

$$f_{\text{H}_2\text{O}_2} = \frac{A_{\text{H}_2\text{O}_2}}{A_t} \times 100\% = \frac{\varepsilon_{\text{H}_2\text{O}_2} C_{\text{H}_2\text{O}_2}}{\varepsilon_{\text{H}_2\text{O}_2} C_{\text{H}_2\text{O}_2} + \varepsilon_{\text{Fe(II)}} C_{\text{Fe(II)}}} \times 100\%$$

a. For Fe(II) concentration of 0.5 mg/L:

$$f_{\text{H}_2\text{O}_2} = \frac{0.019x}{[0.019x + (4.01 \times 10^{-3})x]} \times 100\% = 82.6\%$$

b. For Fe(II) concentration of 5 mg/L:

$$f_{\text{H}_2\text{O}_2} = \frac{0.019x}{0.019x + (4.01 \times 10^{-2})x} \times 100\% = 32.1\%$$

### Comment

Iron can absorb a significant amount of UV light and scavenges hydroxyl radical. Consequently, it may be worthwhile to remove iron from groundwaters that contain high concentrations, if the hydrogen peroxide/UV process is considered for organics destruction.

### Example 18-8 Fraction of light adsorbed by hydrogen peroxide for various NOM concentrations

Calculate the fraction of light absorbed by 1 mM  $\text{H}_2\text{O}_2$  for 0.5, 1, 2, 5, and 10 mg/L of NOM at 254 nm. At 254 nm, the extinction coefficient of NOM is 0.0196 L/mg NOM  $\cdot$  cm. From Example 18-7 at 254 nm, the absorbance of  $\text{H}_2\text{O}_2$  at 1 mM is 0.0196  $\text{cm}^{-1}$ .

#### Solution

- Calculate the fraction of light absorbed by  $\text{H}_2\text{O}_2$  for 0.5 mg/L of NOM.
  - Calculate the absorbance of NOM at a concentration of 0.5 mg/L:

$$A_{\text{NOM}} = \epsilon_{\text{NOM}} C_{\text{NOM}} x = (0.0196 \text{ L/mg} \cdot \text{cm}) (0.5 \text{ mg/L}) x = 0.01x \text{ cm}^{-1}$$

- Calculate the fraction of light absorbed by  $\text{H}_2\text{O}_2$ :  
In a similar manner compared to the solution of Example 18-7, the fraction of light absorbed by  $\text{H}_2\text{O}_2$  may be calculated from the following equation:

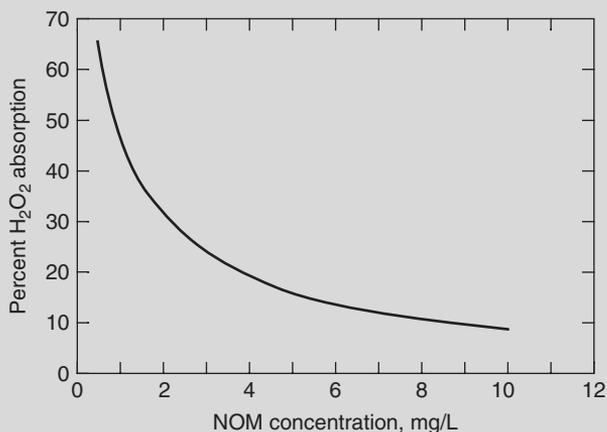

$$f_{\text{H}_2\text{O}_2} = \frac{\epsilon_{\text{H}_2\text{O}_2} C_{\text{H}_2\text{O}_2}}{\epsilon_{\text{H}_2\text{O}_2} C_{\text{H}_2\text{O}_2} + \epsilon_{\text{NOM}} C_{\text{NOM}}}$$

The fraction of light absorbed by  $\text{H}_2\text{O}_2$  at 0.5 mg NOM/L is

$$f_{\text{H}_2\text{O}_2} = \left( \frac{0.019x}{0.019x + 0.01x} \right) \times 100\% = 65.5\%$$

- Plot the fraction of UV light absorbed by  $\text{H}_2\text{O}_2$  versus NOM concentrations (0.5, 1, 2, 5, and 10 mg/L).

The following figure gives the fraction of UV light absorbed by  $\text{H}_2\text{O}_2$  at different NOM concentrations:

**Comment**

NOM can absorb a significant amount of UV light, and very high concentrations of hydrogen peroxide may be needed in such cases to increase the UV light absorption of hydrogen peroxide and hydroxyl radical concentration.

Through numerous experiments with 1,2-dibromo-3-chloropropane (DBCP) it has been found that the data follows a pseudo-first-order reaction (Glaze et al., 1995). Consequently, the ability of the Sim-PSS and rigorous AOP models to predict process performance can be demonstrated by comparing the pseudo-first-order rate constants that were calculated with the various models to the rate constants that were determined from the data. The pseudo-first-order rate constants that are predicted from the various models are compared to the data in Table 18-6. The pseudo-steady-state model assumes that the concentration of hydrogen peroxide changes with time and Eqs. 18-67, 18-69, and 18-70 can be solved using MatLab or Mathcad, once they are used in appropriate reactor mass balances. The simplified pseudo-steady-state model assumes that the hydrogen peroxide concentration does not change and is equal to the initial concentration of hydrogen peroxide as shown in Eq. 18-68. Pseudo-first-order rate constants of  $2.5 \times 10^{-4}$  to  $2.5 \times 10^{-3} \text{ s}^{-1}$ , which are reported in Table 18-6, would have a pseudo-steady-state hydroxyl concentrations that range from  $5.95 \times 10^{-14}$  and  $5.95 \times 10^{-13} \text{ M}$ , respectively. This is 3 orders of magnitude lower than observed in full-scale processes because this was a small laboratory reactor. It appears that the pseudo-steady-state model and the simplified pseudo-steady-state model predict the DBCP destruction very well and follows most of the trends of the rigorous AOP model, which is termed AdOx (Li et al., 1999; Crittenden et al., 1999). Given the simplicity and accuracy of the simple pseudo-steady-state model, it can be used for preliminary design calculations. However, the rigorous model that solves all the equations is a much better design tool for detailed calculations because it can simulate pH change, and multiple wavelengths, and multiple components, and it has databases for physicochemical properties with graphical user interface (Li et al. 1999, Crittenden et al., 1999). And importantly as shown on Fig. 18-4, it predicts the experimental data more accurately (Crittenden et al., 1999).

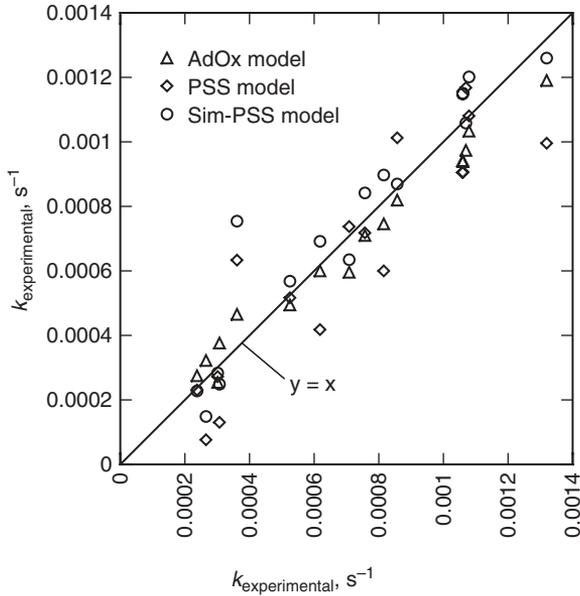

Additional calculations that are not reported here show that the simplified PSS model can be used to evaluate the impact of pH and alkalinity on the TCE destruction. The simplified pseudo-steady-state model predicted similar results as AdOx (Li et al., 1999; Crittenden et al., 1999) except at high pH because the rate of photolysis of the hydrogen peroxide anion is much higher than the neutral species.

**Comparison  
of the Simplified  
Model to Data  
and Its  
Limitations**

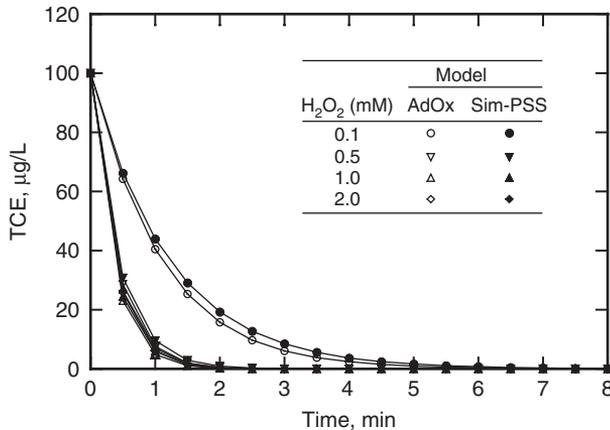

**Table 18-6**

A comparison of pseudo-first-order rate constants that are predicted from the various models and experimental data

[DBCP] <sub>0</sub> μM	[H <sub>2</sub> O <sub>2</sub> ] <sub>0</sub> mM	P <sub>u-v</sub> eins./Ls	[TIC] mM	pH	k <sub>0</sub> , s <sup>-1</sup>

**Figure 18-4**

Comparison of pseudo-first-order rate constants of DBCP degradation from experimental data, the AdOx model, the pseudo-steady-state (PSS) model and the simplified pseudo-steady-state (Sim-PSS) model.  $[\text{DBCP}]_0 = 1.42\text{--}1.83 \mu\text{M}$ ,  $[\text{H}_2\text{O}_2]_0 = 0.054\text{--}4.4 \text{ mM}$ ,  $I_0 = 1.04 \times 10^{-6} \text{ einsteins/L} \cdot \text{s}$ ,  $\text{pH} = 8.3\text{--}8.4$ , total inorganic concentration = 4 mM.

**Figure 18-5**

Comparison of predicted trichloroethylene concentration versus time for hydrogen peroxide dosages of 0.1, 0.5, 1.0, and 2.0 mM, alkalinity of 100 mg/L as  $\text{CaCO}_3$ , and a pH of 7 using AdOx and the simplified pseudo-steady-state model.

#### SELECTION OF HYDROGEN PEROXIDE DOSAGE

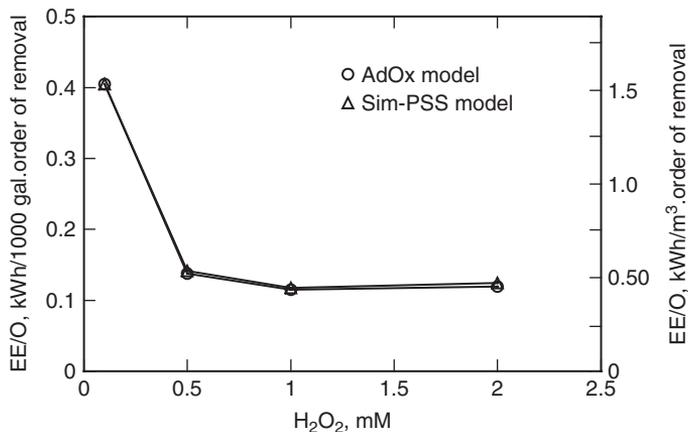

One of the most important design issues for the UV/ $\text{H}_2\text{O}_2$  process is proper selection of the appropriate dosage of  $\text{H}_2\text{O}_2$ . The predicted trichloroethylene concentration versus time for hydrogen peroxide dosages of 0.1, 0.5, 1.0, and 2.0 mM, alkalinity of 100 mg/L as  $\text{CaCO}_3$ , and a pH of 7 using AdOx, and the simplified pseudo-steady-state model is shown on Fig. 18-5. The initial TCE concentration is 100  $\mu\text{g/L}$ . The rate of destruction increases until the hydrogen peroxide concentration increases to 1 mM, and then it decreases slightly because of increased scavenging of hydroxyl radical by hydrogen peroxide. It appears that the optimum hydrogen peroxide dosage

is in the range of 0.5 to 2 mM. The predicted results using simplified pseudo-steady-state model were very close to the fully dynamic model that does not invoke the pseudo-steady-state assumption (AdOx; Li et al., 1999); consequently, it could also be used to examine the impact of hydrogen peroxide dosage.

#### ELECTRICAL EFFICIENCY PER ORDER OF TARGET COMPOUND DESTRUCTION

Most photoreactors are designed to absorb all the UV light. For these reactors (see Sec. 8-4), the destruction of the target compound will only depend on the total radiant energy that is received by the reactor. Consequently, the EE/O is a very effective metric in evaluating the electrical efficiency of the UV/H<sub>2</sub>O<sub>2</sub> process. The EE/O versus hydrogen peroxide concentration is plotted on Fig. 18-6, and the optimum hydrogen peroxide concentration can be determined. Predictions using the simplified pseudo-steady-state model and AdOx are identical. Accordingly, the optimum peroxide dosage is between 0.5 and 2 mM and about 0.50 kWh/m<sup>3</sup> of water treated (0.1 kWh/1000 gal) for an order of magnitude reduction in TCE concentration. This is a very low value but the influence of NOM has not been included.

Generally, EE/O values less than 0.265 kWh/m<sup>3</sup> (1.0 kWh/1000 gal) of water treated are considered favorable, but the process has been used in cases where much higher values have been observed when there are no other treatment options (Bolton and Carter, 1994). A value of 0.265 would correspond to electrical energy costs of 0.1325 dollars per cubic meter of water treated (50 cents per thousand gallons) for an order of magnitude reduction in concentration, assuming that electric power costs are 10 cents per kW h and the lamps have an electrical efficiency of 20 percent. Given the price of hydrogen peroxide versus the cost of electricity, EE/O is the most important design parameter, and the optimum hydrogen peroxide dosage must be selected on the basis of EE/O.

**Figure 18-6**

Impact of H<sub>2</sub>O<sub>2</sub> dosage on EE/O for trichloroethylene (TCE) destruction using H<sub>2</sub>O<sub>2</sub>/UV process (operating conditions: [TCE]<sub>0</sub> = 100 μg/L, alkalinity = 100 mg/L CaCO<sub>3</sub>, [NOM] = 0 mg/L, UV light intensity = 1.04 × 10<sup>-6</sup> einstein L<sup>-1</sup> s<sup>-1</sup> at 254 nm, reactor size = 70 L with 15.8 cm of the effective path length, and the total lamp power is 160 W (assuming 20 % efficiency).

### Example 18-9 Lamp power requirement

Calculate the lamp wattage for a flow rate  $0.03 \text{ m}^3/\text{s}$  (500 gal/min), 1 order of magnitude of destruction, and an EE/O of  $0.25 \text{ kWh}/\text{m}^3$  ( $0.95 \text{ kWh}/1000 \text{ gal}$ ). The lamp efficiency is 30 percent.

#### Solution

1. Derive the equation for lamp power output based on the definition of EE/O (see Eq. 8-130 in Chap.8):

$$\text{EE/O} = \frac{P}{Q \log \left( \frac{C_i}{C_f} \right)}$$

$$P = (\text{EE/O})(Q) \log \left( \frac{C_i}{C_f} \right)$$

2. Calculate lamp power output:

$$P = (\text{EE/O})(Q) \log \left( \frac{C}{C_0} \right)$$

$$= (0.25 \text{ kW} \cdot \text{h}/\text{m}^3) (0.03 \text{ m}^3/\text{s}) (3600 \text{ s}/\text{h}) \times \log(10)$$

$$= 27 \text{ kW}$$

3. Calculate the lamp power requirement:

$$\text{Power requirement} = \frac{\text{power output}}{\text{efficiency}} = \frac{27 \text{ kW}}{0.30} = 90 \text{ kW}$$

#### Comment

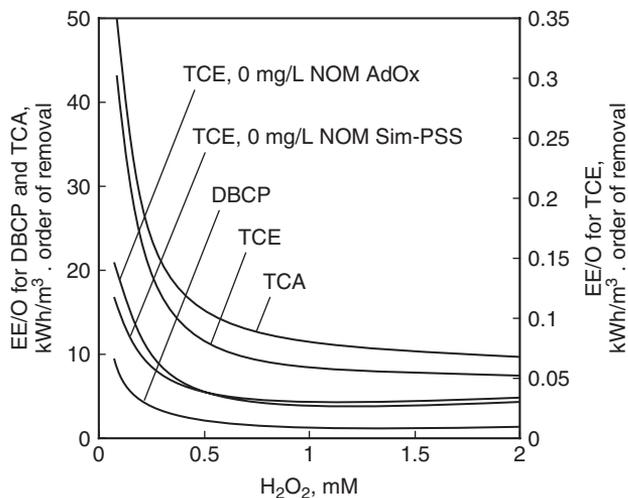

High-output low-pressure lamps are more efficient than medium-pressure lamps. The high-output lamps are about 400 W and the medium-pressure lamps can be 15-kW. If 15-kW lamps are used, only 6 such lamps would be required. A reactor that uses 400-W lamps would need about 225 lamps.

Another important factor in the  $\text{H}_2\text{O}_2/\text{UV}$  AOP process is the reactivity of the compounds. Compounds with double bonds tend to react more quickly than saturated compounds because saturated compounds must undergo hydrogen abstraction, whereas double bonds only undergo addition. Consequently, more energy and hydrogen peroxide are required to destroy saturated compounds than compounds with double bonds. The EE/O for 1,1,1-trichloroethane (TCA), dibromochloropropane (DBCP), and trichloroethylene (TCE) are shown on Fig. 18-7 for the conditions of

#### Impact of NOM and Compound Type on Target Compound Destruction

**Figure 18-7**

Comparison of EE/O values for 1,1,1-trichloroethane (TCA), dibromochloropropane (DBCP), and trichloroethylene (TCE) (initial concentrations = 100  $\mu\text{g/L}$ , pH of 7, and alkalinity = 100 mg/L as  $\text{CaCO}_3$ ). NOM = 1 mg/L except where noted. Results are both AdOX and Sim-PSS models except where noted.

initial concentrations of 100  $\mu\text{g/L}$ , pH of 7, alkalinity of 100 mg/L  $\text{CaCO}_3$ , and 1 mg/L NOM unless noted otherwise. The optimum EE/O for TCE, DBCP, and TCA are 0.052, 2.4, and 10.2  $\text{kWh/m}^3$  order, respectively. The EE/O for DBCP is lower than TCA because there are more hydrogen atoms on the molecule for attack by hydrogen abstraction. As expected, TCA requires a great deal more radiant energy and hydrogen peroxide than does TCE. Further, the simplified pseudo-steady-state model can describe most situations at one wavelength and is useful to assess the feasibility of the process.

Of all of the factors, NOM has the greatest impact, and this is because it not only scavenges hydroxyl radical but it also absorbs UV that may otherwise be absorbed by the hydrogen peroxide and create hydroxyl radicals. Figure 18-7 shows the impact of NOM on the EE/O for TCE. As shown, the EE/O for TCE increases from 0.025 to 0.052 when 1 mg/L NOM is present.

### Example 18-10 Using the simplified pseudo-steady-state model to estimate the effluent concentration

The city of Eagle River recently discovered that one of its wells was contaminated with 200  $\mu\text{g/L}$  (1.52  $\mu\text{mol/L}$ ) TCE. Calculate the effluent concentration of TCE for  $\text{H}_2\text{O}_2$  dosage of 2.5 mM (85 mg/L) and estimate the residual of  $\text{H}_2\text{O}_2$  in the effluent. The treatment objective for TCE is 5.0  $\mu\text{g/L}$ . During normal pumping of the well field, the flow rate is 0.20  $\text{m}^3/\text{s}$

(3200 gpm). The pH, alkalinity, and DOC concentrations are 6.8, 400 mg/L as  $\text{CaCO}_3$ , and 0.7 mg/L, respectively. The following table shows some important physicochemical properties of  $\text{H}_2\text{O}_2$ , TCE, and NOM.

Compound	MW (g/mol)	OH Radical Rate Constant, $k_{\text{OH}}$ , (L/mol · s)	Extinction Coefficient, $\epsilon$ , (L/mol · cm)	Quantum Yield, $\phi$ (mol/einstein)
Trichloroethylene	131.389	$4.20 \times 10^9$	Ignored	0
NOM <sup>a</sup>	NA	$3.90 \times 10^8$	0.0196	0
$\text{H}_2\text{O}_2$	34.015	—	19.6	0.5

<sup>a</sup>For NOM, the units of  $k_{\text{OH}}$  is L/mol NOM carbon-s and the unit of  $\epsilon$  is L/mg NOM · cm.

For simplicity, a proprietary reactor will be used. A dye study on the reactor has shown that four completely mixed flow reactors in series describes mixing that occurs in the reactor. The reactor size is 1 m in diameter by 3 m in height and the volume is approximately 2300 L with  $12 \times 15$  kW medium-pressure lamp, as shown on Fig. 18-8. To simplify the calculations, it can be assumed that the UV light intensity is monochromatic at 254 nm and that the lamps are 20 percent efficient. Assume that all the UV light is absorbed and  $[\text{HO}_2^-]$  and  $[\text{CO}_3^{2-}]$  can be neglected at pH 6.8.

### Solution

1. Calculate the hydraulic detention time ( $\tau$ ):

$$\tau = \frac{\text{Total reactor volume}}{Q} = \left( \frac{2300 \text{ L}}{(0.20 \text{ m}^3/\text{s})(1000 \text{ L/m}^3)(60\text{s}/\text{min})} \right)$$

$$= 0.19 \text{ min}$$

2. Calculate the fraction of light absorbed by  $\text{H}_2\text{O}_2$  according to Eq. 18-77:

To simplify the calculation, it will be assumed that all the light is absorbed by the water matrix (the walls of the vessel reflect all light back into the water and absorb no light).

$$f_{\text{H}_2\text{O}_2} = \frac{\epsilon_{\text{H}_2\text{O}_2} C_{\text{H}_2\text{O}_2}}{(\epsilon_{\text{H}_2\text{O}_2} C_{\text{H}_2\text{O}_2} + \epsilon_{\text{NOM}} C_{\text{NOM}})}$$

$$= \frac{(19.6 \text{ L/mol} \cdot \text{cm})(2.5 \times 10^{-3} \text{ mol/L})}{(19.6 \text{ L/mol} \cdot \text{cm})(2.5 \times 10^{-3} \text{ mol/L}) + (0.0196 \text{ L/mg} \cdot \text{cm})(0.7 \text{ mg/L})}$$

$$= 0.78$$

## 3. Determine the UV light intensity:

The light power is related to the UV intensity by Eq. 18-66:

$$P_{UV} = \frac{P_{\eta}}{N_{av}Vh\nu}$$

## a. Calculate the frequency of light using Eq. 8-94:

$$\nu = \frac{c}{\lambda} = \frac{(3 \times 10^8 \text{ m/s}) (10^9 \text{ nm/m})}{254 \text{ nm}} = 1.18 \times 10^{15} \text{ s}^{-1}$$

## b. Calculate UV intensity:

Assume 20 percent efficiency and 12 lamps turned on. The UV intensity can be calculated:

$$P_{UV} = \frac{(180 \text{ kW}) (1000 \text{ W/kW}) [(1 \text{ J/s}) / \text{W}] (0.2) (1 \text{ einstein/mol})}{(6.023 \times 10^{23} \text{ photons/mol})(2300 \text{ L})(6.62 \times 10^{-34} \text{ J} \cdot \text{s})(1.18 \times 10^{15} \text{ s}^{-1})}$$

$$= 3.3 \times 10^{-5} \text{ einsteins/L} \cdot \text{s}$$

## 4. Calculate the effluent concentration of TCE.

## a. Convert the concentration of each component from mg/L to mol/L:

$$[\text{HCO}_3^-]_0 = \frac{400 \text{ mg/L}}{(50 \text{ g/mol}) (1000 \text{ mg/g})} = 0.008 \text{ mol/L}$$

$$[\text{NOM}]_0 = \frac{0.7 \text{ mg/L}}{(12 \text{ g C/mol NOM C}) (1000 \text{ mg/g})} = 5.83 \times 10^{-5} \text{ mol NOM C/L}$$

## b. From Table 18-5 and the problem statement:

$$k_{10} = 2.7 \times 10^7 \text{ L/mol} \cdot \text{s}$$

$$k_{11} = 8.5 \times 10^6 \text{ L/mol} \cdot \text{s}$$

$$k_{12} = 4.2 \times 10^9 \text{ L/mol} \cdot \text{s} \text{ (see Table 18-2)}$$

$$k_{13} = 3.9 \times 10^8 \text{ L/mol NOM carbon} \cdot \text{s}$$

## c. Determine values of the product of rate constant and concentration:

$$k_{10}[\text{H}_2\text{O}_2]_0 = (2.7 \times 10^7 \text{ L/mol} \cdot \text{s}) (2.5 \times 10^{-3} \text{ mol/L}) = 67,500 \text{ s}^{-1}$$

$$k_{11}[\text{HCO}_3^-]_0 = (8.5 \times 10^6 \text{ L/mol} \cdot \text{s}) (0.008 \text{ mol/L}) = 68,000 \text{ s}^{-1}$$

$$k_{12}[\text{R}]_0 = k_{12}[\text{TCE}]_0 = (4.2 \times 10^9 \text{ L/mol} \cdot \text{s}) (1.52 \times 10^{-6} \text{ mol/L}) = 6384 \text{ s}^{-1}$$

$$k_{13}[\text{NOM}]_0 = (3.9 \times 10^8 \text{ L/mol NOM C} \cdot \text{s}) (5.83 \times 10^{-5} \text{ mol NOM C/L})$$

$$= 22737 \text{ s}^{-1}$$

- d. Calculate  $[\text{HO}\cdot]_{\text{ss},0}$  using Eq. 18-68:

Assuming that all the light was absorbed and  $[\text{HO}_2^-]$  and  $[\text{CO}_3^{2-}]$  can be neglected at pH 6.8, the pseudo-steady-state concentration of hydroxyl radical is given by Eq. 18-68

$$[\text{HO}\cdot]_{\text{ss},0} = \frac{2\phi_{\text{H}_2\text{O}_2} I_0 f_{\text{H}_2\text{O}_2} (1 - e^{-A})}{k_{10}[\text{H}_2\text{O}_2]_0 + k_{11}[\text{HCO}_3^-] + k_{12}[\text{TCE}]_0 + k_{13}[\text{NOM}]_0}$$

$$= \frac{2(0.5 \text{ mol/einstein}) (3.3 \times 10^{-5} \text{ einstein/L} \cdot \text{s}) 0.78}{(67,500 + 68,000 + 6384 + 22,737) \text{ s}^{-1}}$$

$$= 1.58 \times 10^{-10} \text{ mol/L}$$

- e. Calculate pseudo-first-order rate constant for TCE:

$$k'_{12} = k_{12}[\text{HO}\cdot]_{\text{ss},0}$$

$$= (4.2 \times 10^9 \text{ L/mol} \cdot \text{s}) (1.58 \times 10^{-10} \text{ mol/L})$$

$$= 0.66 \text{ s}^{-1}$$

- f. Calculate TCE effluent concentration using the tanks in series model (see Sec. 8-4):

$$[\text{TCE}] = \frac{[\text{TCE}]_0}{(1 + k'_{12}\tau/n)^n} = \frac{200 \text{ } \mu\text{g/L}}{\left[1 + \frac{(0.66 \text{ 1/s})(0.19 \text{ min})(60 \text{ s/min})}{4}\right]^4}$$

$$= 2.9 \text{ } \mu\text{g/L}$$

5. Calculate the residual hydrogen peroxide concentration.

- a. Estimate pseudo-first-order rate constant for hydrogen peroxide assuming that NOM is the major background chromophore, using Eq. 18-76:

$$k'_{10} = \frac{0.5 I_0 \rho_{\text{u-v}} \epsilon_{\text{H}_2\text{O}_2}}{\epsilon_{\text{H}_2\text{O}_2} [\text{H}_2\text{O}_2]_0 + \epsilon_{\text{NOM}} [\text{NOM}]_0} + k_{10} [\text{HO}\cdot]_{\text{ss},0}$$

- i. Determine  $0.5 I_0 \epsilon_{\text{H}_2\text{O}_2}$ ,  $\epsilon_{\text{H}_2\text{O}_2} [\text{H}_2\text{O}_2]_0$ ,  $\epsilon_{\text{NOM}} [\text{NOM}]_0$ , and  $k_{10} [\text{HO}\cdot]_{\text{ss},0}$ :

$$0.5 I_0 \epsilon_{\text{H}_2\text{O}_2} = (0.5 \text{ mol/einstein})(19.6 \text{ L/mol} \cdot \text{s})(3.3 \times 10^{-5} \text{ einstein/L} \cdot \text{s})$$

$$= 3.23 \times 10^{-4} \text{ s}^{-2}$$

$$\varepsilon_{\text{H}_2\text{O}_2}[\text{H}_2\text{O}_2]_0 = (19.6 \text{ L/mol} \cdot \text{s})(2.5 \times 10^{-3} \text{ mol/L}) = 0.049 \text{ s}^{-1}$$

$$\varepsilon_{\text{NOM}}[\text{NOM}]_0 = (0.7 \text{ mg/L})(0.0196 \text{ L/mg} \cdot \text{s}) = 0.01372 \text{ s}^{-1}$$

$$k_{10}[\text{HO}\cdot]_{\text{ss},0} = (2.7 \times 10^7 \text{ L/mol} \cdot \text{s})(1.58 \times 10^{-10} \text{ mol/L}) = 0.004266 \text{ s}^{-1}$$

ii. Determine  $k'_{10}$ :

$$k'_{10} = \frac{3.23 \times 10^{-4} \text{ s}^{-2}}{(0.049 + 0.01372) \text{ s}^{-1}} + (0.004266 \text{ s}^{-1})$$

$$= 9.42 \times 10^{-3} \text{ s}^{-1}$$

b. Estimate  $\text{H}_2\text{O}_2$  residual using the tanks in series model:

$$[\text{H}_2\text{O}_2] = \frac{[\text{H}_2\text{O}_2]_0}{[1 + k'_{10}\tau/n]^n} = \frac{2.5 \times 10^{-3} \text{ mol/L}}{\left[1 + \frac{(9.42 \times 10^{-3} \text{ s}^{-1})(0.19 \text{ min})(60 \text{ s/min})}{4}\right]^4}$$

$$= 2.25 \times 10^{-3} \text{ mol/L (76.5 mg/L)}$$

### Comment

While the treatment objective for TCE can be met, the residual hydrogen peroxide concentration is too high to use the process for water treatment. The residual hydrogen peroxide concentration is the lowest possible value because the pseudo-steady-state concentration of hydroxyl radical is taken to be the initial value in the simplified pseudo-steady-state model. However, this approach is still useful because it can be used to calculate the lowest expected residual hydrogen peroxide concentration, and, if the residual is unacceptable, then process is not a viable option. The effluent concentration of hydrogen peroxide predicted by the rigorous AOP model is  $2.39 \times 10^{-3}$  mol/L.

## 18-5 Other Advanced Oxidation Processes

The AOPs discussed in this section are not commonly used for water treatment or are only tested at a laboratory scale for feasibility. The AOPs considered are (1) the ozone/ UV light process, (2) the photocatalysis with titanium dioxide process, (3) the hydrogen peroxide/iron (Fenton's reaction) process, and (4) the sonolysis process.

The first step of the O<sub>3</sub>/UV process is the formation of H<sub>2</sub>O<sub>2</sub> by photolysis of ozone:

The reactions between H<sub>2</sub>O<sub>2</sub> and O<sub>3</sub> species produce hydroxyl radical, as discussed in Sec. 18-3. It is also possible for UV light to split H<sub>2</sub>O<sub>2</sub> into HO•; however, the extinction coefficient for O<sub>3</sub> is about 199 times greater than that for H<sub>2</sub>O<sub>2</sub> at 254 nm. Using ozone to produce H<sub>2</sub>O<sub>2</sub>, which in turn reacts with O<sub>3</sub> to produce HO•, is a very inefficient way to produce HO• radicals because it takes a lot of energy to form ozone onsite. Although H<sub>2</sub>O<sub>2</sub> is a relatively cheap and stable chemical that may be purchased in bulk, the net overall hydroxyl radical yield for the O<sub>3</sub>/UV process approaches 1 mol HO•/mol O<sub>3</sub> (Peyton and Glaze, 1986). Due to the energy that is required to produce ozone and UV light, the O<sub>3</sub>/UV process is most applicable where direct photolysis of the contaminants is significant (e.g., PCE and some aromatic halides) because the radical chain reactions can be initiated from reactions between photolytic by-products and ozone.

An additional complication for the reaction to proceed in the most efficient manner is the ratio of H<sub>2</sub>O<sub>2</sub> to O<sub>3</sub>. The proper ratio of H<sub>2</sub>O<sub>2</sub> to O<sub>3</sub> must be maintained for compounds that do not undergo direct photolysis, and this ratio will be impossible to meet because of complexity of the competing reactions. Further discussion on the ratio that is required is provided in Sec 18-3. The one potential advantage is that one would not have to be concerned about how ozone mass transfer and mixing would affect the reactor performance.

When a photon with sufficient light energy is absorbed by titanium dioxide, an electron in the outer orbital of the valance band (VB) moves up to the conduction band (CB), as shown on Fig. 18-8. The difference in potential between the VB and the CB is called the band gap and the band gap of TiO<sub>2</sub> is 3.2 eV. The movement of an electron from the VB to the CB produces a hole in the valence band and an electron that can move freely in the conduction band, as shown in the expression

where  $h^+$  = hole in valence band, electronic charge  $1.6 \times 10^{-19}$  C

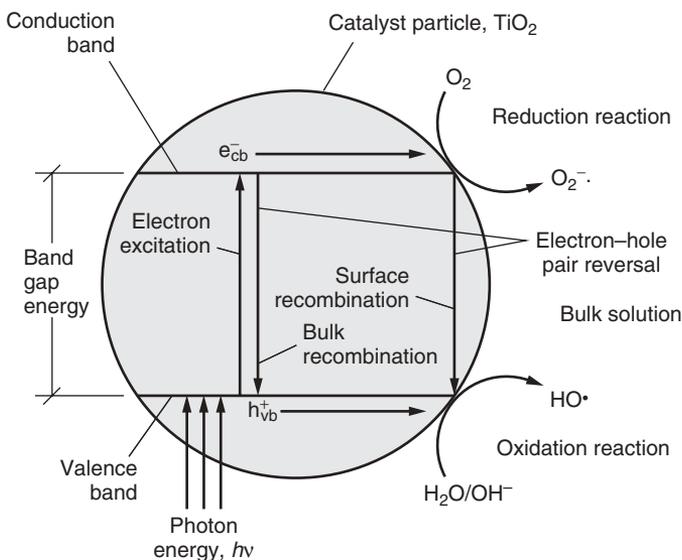

$e_{\text{cb}}$  = electron in conduction band, electronic charge  $1.6 \times 10^{-19}$  C

Unfortunately, most of the holes and conduction band electrons recombine before they undergo any chemical reactions on the surface and the light energy is simply wasted:

## Ozone/UV Light

## Photocatalysis with Titanium Dioxide

**Figure 18-8**

Schematic diagram of mechanisms of photocatalytic oxidation and reduction.

The electrochemical energy for the photocatalytic AOP comes from subsequent reactions with the hole and conduction band electron. At a pH value of 7, the hole has a reduction potential  $E_H^\circ$  of approximately 2.9 V and the conduction band electron has a reduction potential  $E_H^\circ$  of approximately  $-0.3$  V (Hashimoto et al., 1984). Consequently, a hydroxyl radical is produced when the hole in the valence band reacts with water, as shown in the following reaction because the standard electrode potential for the formation of hydroxyl radical is 2.59 or 2.177 V at pH 7:

A conduction band electron can reduce the hydrogen ion and oxygen depending on the pH and oxygen concentration as follows:

The addition of hydrogen peroxide has been shown to improve the reaction rate, which may occur because hydrogen peroxide has a higher reduction potential than oxygen. In addition, hydrogen peroxide photolysis can generate additional hydroxyl radicals.

The mechanisms of propagation and termination of the radical chain are the same as the UV/H<sub>2</sub>O<sub>2</sub> process except that photolysis of hydrogen peroxide does not occur unless it is added. One advantage of the UV/TiO<sub>2</sub> process is that good light transmission is not as much of a factor because, if the TiO<sub>2</sub> is added as a slurry, then fluid mixing can transport the TiO<sub>2</sub> to the light and back into bulk solution. This will allow the chemical reactions to occur throughout the reactor depending on the level of fluid mixing.

As with the other AOPs, the primary reaction for oxidation of electron-rich organic pollutants begins with the attack of the organic pollutant by hydroxyl radicals that are produced on the surface. Subsequent organic radical chain reactions with oxygen and other species eventually will completely mineralize the parent compound, as discussed in Sec. 18-1.

### Example 18-11 Titanium dioxide: band gap and wavelength for lowest energy

When an electron in the valence band absorbs a photon with energy greater than 3.2 eV, it can move up into the conduction band. Calculate the wavelength of light required to create a hole and conduction band electron in  $\text{TiO}_2$  and prove that the hole can oxidize water to produce  $\text{HO}\cdot$ . What band gap and wavelength corresponds to lowest energy input that can create  $\text{HO}\cdot$ ?

#### Solution

1. Calculate the frequency of light.

The frequency of light can be calculated from the band gap energy for electron excitation that is required and Planck's constant as presented in Eq. 8.94 in Chap 8.

$$\nu = \frac{E}{h} = \frac{(3.2 \text{ J/C}) (1.60 \times 10^{-19} \text{ C})}{(6.62 \times 10^{-34} \text{ J} \cdot \text{s})} = 7.73 \times 10^{14} \text{ s}^{-1}$$

2. Calculate the wavelength of light required.

The wavelength of light can be calculated from the speed and frequency of light as presented in Eq. 8-95 in Chap.8

$$\lambda = \frac{c}{\nu} = \frac{(3.00 \times 10^8 \text{ m/s})}{(7.73 \times 10^{14} \text{ s}^{-1})} = 3.88 \times 10^{-7} \text{ m (388 nm)}$$

3. Prove that the hole can oxidize water to produce  $\text{HO}\cdot$ .

The hole in the valence band can power the oxidation of water to form hydroxyl radical because the hole has a reduction potential of 2.9 V and the oxidation reaction requires 2.177 V.

4. Determine band gap corresponding to the lowest energy input that can create  $\text{HO}\cdot$ .

The electrode potential for the formation of hydroxyl radical is 2.177 at pH of 7. Therefore, the lowest reduction potential in the valence band

is 2.177 V. The conduction band electron has a reduction potential of approximately  $-0.3$  V. The band gap corresponding to the lowest energy input that can create  $\text{HO}\cdot$  is 2.477 eV.

5. Determine wavelength corresponding to the lowest energy input that can create  $\text{HO}\cdot$  :
  - a. Calculate the frequency of light:

$$\nu = \frac{E}{h} = \frac{(2.477 \text{ J/C}) (1.60 \times 10^{-19} \text{ C})}{6.62 \times 10^{-34} \text{ J} \cdot \text{s}} = 5.99 \times 10^{14} \text{ s}^{-1}$$

- b. Calculate the wavelength of light required.

$$\lambda = \frac{c}{\nu} = \frac{3.00 \times 10^8 \text{ m/s}}{5.99 \times 10^{14} \text{ s}^{-1}} = 5.01 \times 10^{-7} \text{ m (501 nm)}$$

### Comment

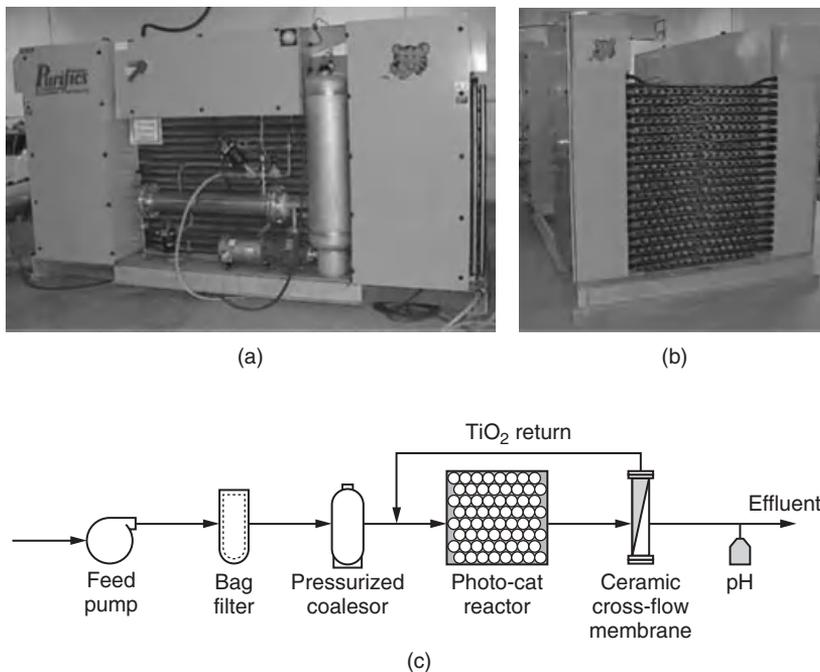

The band gap of  $\text{TiO}_2$  has sufficient power to create hydroxyl radical from water. Further, the wavelength that is required to produce hydroxyl radical is fairly large, and it may be possible to harness sunlight to create an oxidizing environment for toxic organics destruction.

### QUANTUM YIELD

The apparent quantum yield (moles of parent compound reacted per mole of photons illuminating the reactor) for most photocatalytic reactions is in the range of 0.1 to 3 percent depending on the reactant and its concentration, light intensity, and the constituents in the water matrix. There are strategies for increasing the quantum yield and this is an area of ongoing research. For example, it has been demonstrated that the catalyst recombination reaction is reduced by impregnating the catalyst with a small amount of platinum (1 percent) and platinum impregnation significantly increased the rate of reaction (Suri et al., 1993).

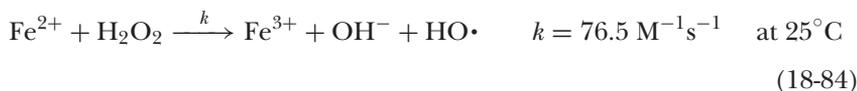

### COMMERCIALLY AVAILABLE REACTORS

There are several vendors that provide  $\text{TiO}_2$  treatment systems, and one of the most successful units is provided by Purifics, as shown in the photographs on Fig. 18-9a and b. A schematic of its system is displayed on Fig. 18-9c. The ceramic cross-flow membrane, which is shown on Fig. 18-9c, is used to recover the  $\text{TiO}_2$ . The quantity of  $\text{TiO}_2$  is very small ( $\sim 10$  kg) and it can last several years before it has to be replaced. An interesting feature of their technology is that wipers are not required for their lamps because they do not develop fouling deposits when  $\text{TiO}_2$  is present. They have many installations that are able to treat many kinds of organic contaminants and are resistant to alkalinity, pH, and turbidity and temperature changes.

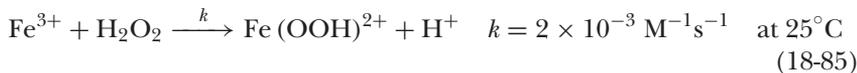

**Figure 18-9**  
Panfics Photo-Cat System.

(b) Photograph of side view,  
and (c) Schematic of the  
Process.

Reductive metal ions can catalyze the hydrolysis of H<sub>2</sub>O<sub>2</sub> to form hydroxyl radicals. Fenton's reagent, a mixture of ferrous ion and hydrogen peroxide, has been known as a powerful oxidant for organic contaminants. The principal mechanism for Fenton's reagent is as follows:

The ferric ions produced can then produce HO<sub>2</sub>• through the following reactions (Barb et al., 1951):

Reaction 18-86 is much slower than reaction 18-85. As a result, the overall oxidation process slows down after the conversion of ferrous to ferric ion (Venkatadri and Peters, 1993), even though small concentrations of iron can generate hydroxyl radicals (as low as 0.05 mM). Reaction 18-85 is also the initial mechanism of the Fe(III) Fenton-like system.

The optimum pH for Fenton's reagent processes ranges from 2 to 4, which prevents its use for in situ treatment or in water treatment applications because pH adjustment before and after treatment is needed. This would

### Reactions with Iron (Fenton's Reactions)

not only be expensive but also would raise the TDS above the secondary standard.

### Sonolysis

Ultrasonic irradiation, or sonolysis, is an effective method for the destruction of many environmentally important and refractory contaminants, such as chlorinated hydrocarbons, pesticides, fuel additives, atrazine, parathion, aromatic compounds, or even humic acids (Cheung et al., 1991; Gondrexon et al., 1999; Nagata et al., 1996; Olson and Barbier, 1994; Schramm and Hua, 2001). Ultrasound destroys organics by creating small bubbles by cavitation, which occurs during the low-pressure portion of a wave cycle. Extremely high temperatures and high pressures occur during bubble collapse. This causes pyrolysis of organics and produces highly reactive chemical radicals. The estimated transient temperature is in the range of about 4000 to 10,000 K and the pressure is in the range of 300 to 975 bar (Hoffmann et al., 1996). This localized extreme condition is able to provide enough energy for the pyrolysis of most, if not all, contaminants, including water, to form radicals. As a result, two main mechanisms are responsible for the destruction of contaminants during the sonolysis process: (1) pyrolysis reactions at the cavitation bubble and (2) radical reactions by HO• and H• formed through the sonolysis of H<sub>2</sub>O. The two mechanisms are as follows:

The concentration of HO• at a bubble interface can be as high as  $4 \times 10^{-3}$  M, which is  $10^8$  or  $10^9$  times higher than that in the other advanced oxidation process (Gutierrez et al., 1991).

The pyrolysis of contaminants can also form radicals and initiate chain reactions, such as the degradation of carbon tetrachloride (Fogler and Crittenden, 1970):

Although the technology has been shown to be feasible on a small scale, the commercialization of sonolysis is still a challenge, due to the high energy requirement of the process. Based on the observed destruction rates, the EE/O of sonolysis of organic compounds is on the order of 2600 kWh/m<sup>3</sup> per order of destruction.

The combination of sonolysis and other advanced oxidation options, such as ozone and elemental iron, can further improve the destruction of

contaminants and process intermediates (Schramm and Hua, 2001). The enhancement has been attributed to the improvement of HO• and/or H• radical production.

## Problems and Discussion Topics

---

- 18-1 The second-order rate constant of HO• for methyl ethyl ketone (MEK) is  $9.0 \times 10^9$  L/mol·s. Calculate the half-life of MEK for a HO• concentration of  $10^{-12}$  mol/L.
- 18-2 Calculate the quenching of the reaction for TCE and hydroxyl radical in a natural water with alkalinity of 75 mg/L as CaCO<sub>3</sub> assuming that all alkalinity is due to bicarbonate. The rate constant  $k_{\text{TCE}}$  is  $4.2 \times 10^9$  L/mol·s and TCE concentration is 100 μg/L.
- 18-3 Examine the difference in the rate of oxidation of TCE and chloroacetic acid (CAA) in double-distilled water versus the rate in a typical natural water. Here,  $k_{\text{NOM}}$  is  $3 \times 10^8$  L/mol C·s,  $k_{\text{TCE}}$  is  $4.2 \times 10^9$  L/mol·s, and  $k_{\text{CAA}}$  is  $4.3 \times 10^7$  L/mol·s. The NOM concentrations in distilled water and natural water are 0.05 and 1.4 mg/L, respectively. The initial concentrations of TCE and CAA are 100 and 60 μg/L. Estimate  $Q_R$  for each compound in distilled water and in the natural water.
- 18-4 The second-order hydroxyl rate constants for Fe(II) and Mn(II) are  $2.3 \times 10^8$  and  $1.4 \times 10^8$  L/mol·s, respectively. For iron concentration of 5.6 mg/L, manganese concentration of 5 mg/L, and TCE concentration of 100 μg/L, calculate the quenching of the reaction for TCE. Assume  $k_{\text{TCE}}$  is  $4.2 \times 10^9$  L/mol·s.
- 18-5 Determine the fraction of the reaction that is carried out by the indirect reaction with HO• versus the direct reaction with O<sub>3</sub> for the oxidation of geosmin and MIB. The second-order rate constants for HO• for geosmin and MIB are  $1.4 \times 10^{10}$  and  $8.2 \times 10^9$  L/mol·s respectively. For the calculation, use  $C_{[\text{HO}\cdot]/[\text{O}_3]}$  values of  $10^{-7}$ ,  $10^{-8}$ ,  $10^{-9}$ , and  $10^{-10}$  and a rate constant for the direct reaction with ozone of 10 L/mol·s.
- 18-6 Calculate the time required for 99 percent destruction of MIB in a batch reactor. The second-order rate constant with HO• is  $8.2 \times 10^9$  L/mol·s. For the calculation, use  $C_{[\text{HO}\cdot]/[\text{O}_3]}$  ranging from  $10^{-9}$  to  $10^{-7}$  and an initial ozone concentration of 3 mg/L. The rate constant for the direct reaction with ozone is 10 L/mol·s. Use a typical ozone pseudo-first-order rate constant of  $0.1 \text{ min}^{-1}$ .
- 18-7 Derive the simple pseudo-steady-state model for the hydrogen peroxide/ozone processes.

- 18-8 A municipality recently discovered that one of its wells was contaminated with the compounds listed in the following:

Compound	Influent Concentration, $C_0$ , $\mu\text{g/L}$	Treatment Objective, $C_{T0}$ , $\mu\text{g/L}$
Trichloroethylene (TCE)	130	5.0
Tetrachloroethylene (PCE)	75	5.0
Vinyl chloride	15	2.0
Benzene	80	5.0

To continue using the well as a drinking water resource, the compounds need to be removed to meet the treatment objectives shown in the table. During normal pumping operations, the well produces about 400 gpm, and further expansion of the well field may be considered depending on the efficacy of the ozone/hydrogen peroxide process. The pH, alkalinity, and DOC concentrations are 7.5, 400 mg/L as  $\text{CaCO}_3$ , and 1.2 mg/L, respectively. Important physicochemical properties for the compounds that need to be removed are as follows:

Compound	MW g/mol	HO $\cdot$ Rate Constant, $k_{\text{HO}\cdot}$ , L/mol $\cdot$ s
Trichloroethylene	131.4	$4.20 \times 10^9$
Tetrachloroethylene	165.8	$2.60 \times 10^9$
Vinyl chloride	62.5	$1.20 \times 10^{10}$
Benzene <sup>a</sup>	78.1	$7.80 \times 10^9$
NOM <sup>b</sup>	NA	17,666

<sup>a</sup> Molar extinction coefficient is high but quantum yield is very low; consequently, photolysis can be ignored.

<sup>b</sup> For NOM, the unit of  $k_{\text{HO}\cdot}$  is L/mg  $\cdot$  s.

For simplicity, a proprietary reactor will be used. Based on dye studies, it has been found that the reactor can be modeled as four completely mixed reactors in series. The reactor is 1 m in diameter and 3 m in height, and the volume is approximately 2300 L. For the given conditions, determine the optimum  $\text{H}_2\text{O}_2$  dosage to achieve the treatment objectives based on the simplified model (Sim-PSS) for 0.025 m<sup>3</sup>/s (400 gpm). Consider ozone dosages of 1, 3, and 5 mg/L.

- 18-9 Use the information given in Problem 18-8 with an  $\text{H}_2\text{O}_2$  dosage of 0.8 mg/L. Ozone ( $\text{O}_3$ ) is generated onsite and the ozone flow rate is 1 mg/L  $\cdot$  min. The partial pressure of  $\text{O}_3$  in the inlet gas is 0.07 atm. Henry's law constant for  $\text{O}_3$  at 23°C is 83.9 atm  $\cdot$  L/mol, and the overall mass transfer coefficient for  $\text{O}_3$ ,  $k_L a$ , was measured to

- be  $7 \times 10^{-4} \text{ s}^{-1}$ . Determine the expected effluent concentrations of all contaminants and  $\text{H}_2\text{O}_2$  residual concentration.
- 18-10 Discuss the advantages and disadvantages of advanced oxidation processes that are not commonly used for water treatment.

## Terminology for Disinfection/Oxidation By-Products

---

<b>Term</b>	<b>Definition</b>
Assimilable organic carbon (AOC)	Measure of the biodegradability of the natural organic matter in a water sample, significant in that ozonation increases the AOC, which can lead to regrowth problems in distribution systems.
Biodegradable dissolved organic carbon (BDOC)	Measure of the biodegradability of the natural organic matter in a water sample.
Bromate	By-product of ozonation.
Disinfection by-product (DBP)	Product of a disinfection reaction other than the desired product. By-products are significant in disinfection because many are suspected to have negative human health consequences.
Formation potential	Test of the ability of DBPs to form in water. The test is conducted with predefined conditions that are expected to produce the maximum amount of the target DBP.
Haloacetic acid (HAA)	Class of DBPs caused by chlorination of water containing natural organic matter.
N-nitrosodimethylamine (NDMA)	By-product of chloramination.
Locational running annual average (LRAA)	Method of determining concentrations for compliance with DBP regulations in which running annual averages are calculated for every sample location.
Running annual average (RAA)	Method of determining concentrations for compliance with DBP regulations in which a year of data is averaged. For each sampling period, the new data is added and the oldest data is dropped, but the average always contains a year's worth of data.
Trihalomethane (THM)	Class of DBPs caused by chlorination of water containing natural organic matter.

---

Chemical disinfection became an integral part of municipal drinking water treatment over 100 years ago as a vital tool in achieving its principal objective: protection of public health. Oxidation, while not as vital to achieving public health objectives as disinfection, has also been accepted as an important part of drinking water treatment. Typically, oxidation is used to address aesthetic concerns such as color, taste, and odor, which

impact consumer perception and acceptance of a water as fit for human consumption. Disinfection is discussed at length in Chap. 13 of this book and oxidation is presented in Chaps. 8 and 18. Unfortunately, disinfection and oxidation produce a variety of by-products, which is the focus of this chapter. The discussion of disinfection and oxidation by-products is presented in five sections. Following an introduction to the subject, separate sections are devoted to the by-products formed by chlorine, chloramines, chlorine dioxide, and ozone. For each disinfectant/oxidant, the chemistry of formation, means of controlling (i.e., reducing) their formation, and means of removing these by-products, if possible, after they form are presented and discussed in this chapter.

## 19-1 Introduction

---

The use of chemicals for disinfection and oxidation is common, occurring at nearly every drinking water treatment plant in the industrialized world. Familiarity with the by-products of the chemicals used for disinfection and oxidation is important because these by-products can impact consumer health. Some health effects are not fully understood, and some health effects have been identified only recently, making disinfection/oxidation by-products an ever-changing part of the drinking water treatment situation. An overview of disinfection by-products, including a historical perspective, some known by-products, regulatory requirements, and practical considerations regarding the balance between the need to prevent microbial contamination and minimizing exposure to by-products is presented in this section.

Since the introduction of chlorine as a disinfectant in drinking water treatment at the turn of the twentieth century, chemical disinfection has been an integral part of municipal drinking water treatment. In addition to use as a microbial disinfectant, chlorine—as well as other chemical disinfectants such as ozone and chlorine dioxide—had other benefits, including the ability to eliminate color and destroy many naturally occurring chemicals that cause objectionable taste and odor in the water. Consequently, water treatment plant operators commonly added as much disinfectant as necessary to achieve the desired aesthetic and microbial water quality.

In the early 1970s, researchers in the Netherlands and the United States were able to identify and quantify the formation of chloroform ( $\text{CHCl}_3$ ) and other trihalomethanes (THMs) in drinking water and relate this formation to the use of chlorine during treatment (Rook, 1971, 1974; Bellar and Lichtenberg, 1974). These early findings led to a large number of studies in the United States on the formation of these “by-products” of chlorination. The studies included several monitoring surveys to assess the magnitude of the problem in drinking water treatment plants across

### Historical Perspective

the United States (i.e., occurrence studies), as well as studies to investigate how chlorination by-products were formed and what water quality and/or treatment conditions affected their formation.

It was also discovered that chloroform was not the only chemical formed as a result of the reaction of chlorine with natural organic matter (NOM) present in water and that in the presence of bromide ion ( $\text{Br}^-$ ), the reaction between chlorine, bromide, and NOM resulted in the formation of a mix of chlorinated and brominated chemical by-products. Using mass balance calculations it has been shown that the known chlorination by-products constitute between 30 and 60 percent of the total organic halides (TOX) formed upon the reaction of chlorine with NOM and bromide (Singer and Chang, 1989). Additional work is needed to identify and characterize the unknown by-products of chlorination.

The formation of disinfection by-products (DBPs) is not limited to chlorine disinfection. Haag and Hoigné (1983) reported the formation of bromate ion ( $\text{BrO}_3^-$ ) when ozone was added to waters containing bromide. Bromate was later identified as a suspected carcinogen (Kurokawa et al., 1990). Ozone addition to natural water was also implicated in the formation of numerous organic by-products, such as aldehydes (NAS, 1980). Bromate is now regulated, but thus far the presence of organic ozone by-products in drinking water has not been determined to be a public health concern at the typical levels at which they are formed.

Another disinfectant used in water treatment is chloramines (combined chlorine). In the 1970s, the U.S. EPA identified combined chlorine as an alternative to free chlorine because it was believed not to form THMs. Later research showed that while monochloramine, the principle component of combined chlorine, is less reactive than free chlorine, it does react to form DBPs but at much lower concentrations than are formed with free chlorine (Carlson and Hardy, 1998). The prominent category of DBPs formed during chloramination of potable water is haloacetic acids (HAAs), mostly the dihalogenated species (Cowman and Singer, 1996). The presence of bromide ion will both increase the production of HAAs and shift the speciation to the more brominated species, which are thought to present a greater carcinogen risk (Bull and Kopfler, 1991). In addition, Krasner et al. (1989) reported the results of a 35-utility study in which they identified several new by-products, including cyanogen halides (e.g.,  $\text{CNCl}$ ), as by-products of chloramination.

However, no chloramine by-product was believed to be a significant public health concern until Najm and Trussell (2001) reported that *N*-nitrosodimethylamine (NDMA) was a by-product of chloramination of drinking water and wastewater.

Chlorine dioxide forms by-products such as chlorite ( $\text{ClO}_2^-$ ) and chlorate ( $\text{ClO}_3^-$ ) ions, both of which have been suspected to cause health effects (Bull, 1982). While the health effects of chlorate and chlorite continue to be

a topic of debate, there was sufficient concern that a maximum contaminant limit (MCL) for chlorite was adopted by the U.S. EPA (1998).

As described above, it has been well established over the last 35 years that all chemical disinfectants and oxidants currently used in water treatment form chemical by-products. Even among the known DBPs, the health effects of many are still uncertain. Some of the known DBPs that form from the use of disinfectants during drinking water treatment are summarized in Table 19-1. While many of the DBPs listed in this table have been detected in some treated waters, they are typically present at very low concentrations.

### **Some Known By-products**

After the discovery that THMs can form during chlorination of drinking water and because of concerns about the health effects of chloroform (NCl, 1976), the U.S. EPA issued the THM Rule in 1979. The four regulated THMs were chloroform ( $\text{CHCl}_3$ ), bromodichloromethane ( $\text{CHBrCl}_2$ ), dibromochloromethane ( $\text{CHBr}_2\text{Cl}$ ), and bromoform ( $\text{CHBr}_3$ ). The THM Rule set an MCL of 0.10 mg/L (100  $\mu\text{g/L}$ ) for the total sum of these four THMs (on a mass basis) in the distribution system. The THM Rule required water systems to monitor a minimum of four locations throughout the distribution system on a quarterly basis. Three monitoring sites were to be located at average hydraulic travel time through the system and one site was to be located at the far reaches of the system, representing maximum THM formation due to long travel time. The running annual average (RAA) of all distribution system samples collected every quarter was not to exceed the MCL. The rationale for using the RAA for compliance instead of individual THM concentrations was that the adverse health effects of exposure to THMs were caused by long-term exposure not short-term effects.

### **Regulatory Requirements**

In 1998, the U.S. EPA expanded the number of regulated DBPs by issuing Stage 1 of the Disinfectants/Disinfection By-products (D/DBP) Rule (U.S. EPA, 1998). This rule reduced the MCL for total THMs from 0.10 to 0.080 mg/L and added MCLs for additional DBPs, as listed in Table 19-2. Of nine HAAs formed with chlorine and bromine, only five were included in the D/DBP Rule because analysis of the remaining four HAAs was not practical at the time the regulation was promulgated. Compliance with the new MCLs began in January 2002. The Stage 1 D/DBP Rule also included a requirement to use chemical coagulation and filtration to maximize the removal of NOM through a conventional water treatment plant (i.e., enhanced coagulation, as discussed in Chap. 9). This requirement was based on the concept that minimizing the concentration of NOM would reduce the amount of DBPs formed with subsequent chlorination.

In January 2006, the U.S. EPA promulgated the Stage 2 D/DBP Rule (U.S. EPA, 2006). The Stage 2 rule was designed to further reduce exposure to DBPs without undermining the control of microbial pathogens. A concern that led to passage of the rule was that some portions of distribution systems may have DBP concentrations considerably higher than the average

**Table 19-1**

Some known by-products of chlorine, combined chlorine (chloramines), chlorine dioxide, and ozone application during drinking water treatment

Class of Compound	By-product Name	Chemical Formula	By-product of
Trihalomethanes	Chloroform	$\text{CHCl}_3$	Chlorine
	Bromodichloromethane	$\text{CHBrCl}_2$	Chlorine
	Dibromochloromethane	$\text{CHBr}_2\text{Cl}$	Chlorine
	Bromoform	$\text{CHBr}_3$	Chlorine, ozone
	Dichloriodomethane	$\text{CHCl}_2\text{I}$	Chlorine
	Chlorodiiodomethane	$\text{CHI}_2\text{Cl}$	Chlorine
	Bromochloriodomethane	$\text{CHBrClI}$	Chlorine
	Dibromiodomethane	$\text{CHBr}_2\text{I}$	Chlorine
	Bromodiiodomethane	$\text{CHBrI}_2$	Chlorine
	Triiodomethane	$\text{CHI}_3$	Chlorine
Haloacetic acids	Monochloroacetic acid	$\text{CH}_2\text{ClCOOH}$	Chlorine
	Dichloroacetic acid	$\text{CHCl}_2\text{COOH}$	Chlorine
	Trichloroacetic acid	$\text{CCl}_3\text{COOH}$	Chlorine
	Bromochloroacetic acid	$\text{CHBrClCOOH}$	Chlorine
	Bromodichloroacetic acid	$\text{CBrCl}_2\text{COOH}$	Chlorine
	Dibromochloroacetic acid	$\text{CBr}_2\text{ClCOOH}$	Chlorine
	Monobromoacetic acid	$\text{CH}_2\text{BrCOOH}$	Chlorine
	Dibromoacetic acid	$\text{CHBr}_2\text{COOH}$	Chlorine
	Tribromoacetic acid	$\text{CBr}_3\text{COOH}$	Chlorine
Haloacetonitriles	Trichloroacetonitrile	$\text{CCl}_3\text{C} \equiv \text{N}$	Chlorine
	Dichloroacetonitrile	$\text{CHCl}_2\text{C} \equiv \text{N}$	Chlorine
	Bromochloroacetonitrile	$\text{CHBrClC} \equiv \text{N}$	Chlorine
	Dibromoacetonitrile	$\text{CHBr}_2\text{C} \equiv \text{N}$	Chlorine
Haloketones	1,1-Dichloroacetone	$\text{CHCl}_2\text{COCH}_3$	Chlorine
	1,1,1-Trichloroacetone	$\text{CCl}_3\text{COCH}_3$	Chlorine
Aldehydes	Formaldehyde	$\text{HCHO}$	Ozone, chlorine
	Acetaldehyde	$\text{CH}_3\text{CHO}$	Ozone, chlorine
	Glyoxal	$\text{OHCCHO}$	Ozone, chlorine
	Methyl glyoxal	$\text{CH}_3\text{COCHO}$	Ozone, chlorine
Carboxylic acids	Formate	$\text{HCOO}^-$	Ozone
	Acetate	$\text{CH}_3\text{COO}^-$	Ozone
	Oxalate	$\text{OOC}^-\text{COO}^{2-}$	Ozone
Ketoacids	Glyoxylic acid	$\text{OHCCOOH}$	Ozone
	Pyruvic acid	$\text{CH}_3\text{COCOOH}$	Ozone
	Ketomalonic acid	$\text{HOCCOCOOH}$	Ozone
Oxyhalides	Chlorite	$\text{ClO}_2^-$	Chlorine dioxide
	Chlorate	$\text{ClO}_3^-$	Chlorine dioxide
	Bromate	$\text{BrO}_3^-$	Ozone

**Table 19-1** (Continued)

Class of Compound	By-product Name	Chemical Formula	By-product of
Nitrosamines	N-Nitrosodimethylamine	$(\text{CH}_3)_2\text{NNO}$	Chloramines
Cyanogen halides	Cyanogen chloride	CICN	Chloramines
	Cyanogen bromide	BrCN	Chloramines
Miscellaneous	Chloral hydrate	$\text{CCl}_3\text{CH}(\text{OH})_2$	Chlorine
Trihalonitromethanes	Trichloronitromethane (Chloropicrin)	$\text{CCl}_3\text{NO}_2$	Chlorine
	Bromodichloronitromethane	$\text{CBrCl}_2\text{NO}_2$	Chlorine
	Dibromochloronitromethane	$\text{CBr}_2\text{ClNO}_2$	Chlorine
	Tribromonitromethane	$\text{CBr}_3\text{NO}_2$	Chlorine

**Table 19-2**

Disinfection by-products regulated under D/DBP Rule

By-product	Regulatory Limit, mg/L	By-product of
Total THMs <sup>a</sup>	0.080	Chlorine
Five Haloacetic Acids (HAA5) <sup>b</sup>	0.060	Chlorine
Bromate ( $\text{BrO}_3^-$ )	0.010	Ozone
Chlorite ( $\text{ClO}_2^-$ )	1.0	Chlorine dioxide

<sup>a</sup>Sum of four THMs: chloroform, bromodichloromethane, dibromochloromethane, and bromoform.

<sup>b</sup>Sum of five HAAs: monochloroacetic acid, dichloroacetic acid, trichloroacetic acid, monobromoacetic acid, and dibromoacetic acid.

and that some customers might be exposed to DBP concentrations above the MCLs on a consistent basis. The Stage 2 D/DBP Rule required water utilities to conduct an initial distribution system evaluation (IDSE) to identify the locations in the system with the highest DBP concentrations. Once suitable sampling locations were identified, compliance was evaluated via a locational running annual average (LRAA). The LRAA requires a running annual average at each sampling site, whereas the former RAA required only a running annual average over all sampling sites in the entire system. The IDSE and the LRAA provide increased assurance that customers are receiving more consistent protection against exposure to DBPs, even in areas of a distribution system that had typically had higher DBP concentrations. Furthermore, if a utility makes changes to treatment to reduce DBP concentrations in portions of the distribution system, concentrations may be reduced throughout the rest of the distribution system as well. Calculation of the RAA and LRAA are demonstrated in Example 19-1.

### Example 19-1 Calculating compliance under the Stage 1 and Stage 2 D/DBP rules

Two years of quarterly THM data from sampling sites in a distribution system are listed in the following table, in  $\mu\text{g/L}$ . Calculate the RAA and the LRAA for THMs from this data, and determine if this distribution system would meet both the Stage 1 D/DBP Rule and the Stage 2 D/DBP Rule. Note that the THM data shows both spatial and temporal trends; THMs tend to be the highest in July in all locations, and the THMs at locations Distr-3 and Distr-4 are higher than at Distr-1 and Distr-2.

Sample	Location			
	Distr-1	Distr-2	Distr-3	Distr-4
Jan, 2009	31	35	55	42
Apr, 2009	35	41	57	51
Jul, 2009	62	78	110	91
Oct, 2009	45	55	90	78
Jan, 2010	27	23	45	37
Apr, 2010	39	41	72	72
Jul, 2010	78	94	131	105
Oct, 2010	51	65	104	73

#### Solution

1. Calculate the RAA for the distribution system data.

The RAA is calculated by averaging the data from all locations for one sampling event, and then averaging the results from four consecutive sampling events (i.e., one year of data). As each new quarter of data is generated, the data from the quarter one year previous is dropped off and the new quarter is added.

The RAA data are summarized in the following table:

Sample	RAA
Oct, 2009	60
Jan, 2010	58
Apr, 2010	60
Jul, 2010	65
Oct, 2010	66

2. Calculate the LRAA for the distribution system data.

The LRAA is calculated by averaging the results from four consecutive sampling events (i.e., one year of data) at each sample location. As each new quarter of data is generated, the data from the quarter one year previous is dropped and the new quarter is added.

The LRAA data are summarized in the following table:

Sample	Location			
	Distr-1	Distr-2	Distr-3	Distr-4
Oct, 2009	43	52	78	66
Jan, 2010	42	49	76	64
Apr, 2010	43	49	79	70
Jul, 2010	47	53	85	73
Oct, 2010	49	56	88	72

- Evaluate compliance with the Stage 1 and Stage 2 D/DBP rules. The MCL for THMs is 80  $\mu\text{g/L}$ . Several individual samples, particularly in July each year and particularly at sample location Distr-3, are above the MCL. However, the MCL does not apply to individual samples. Under the Stage 1 D/DBP Rule, compliance was calculated on the basis of the RAA. The calculated RAA values range from 58 to 66  $\mu\text{g/L}$ . The system meets the Stage 1 D/DBP Rule for THMs every quarter. Under the Stage 2 D/DBP Rule, compliance is calculated on the basis of the LRAA. The LRAA values are below the MCL at locations Distr-1, Distr-2, and Distr-4, but the calculated LRAA values at Distr-3 are 85  $\mu\text{g/L}$  in July 2010 and 88  $\mu\text{g/L}$  in Oct 2010. The system is not in compliance with the Stage 2 D/DBP Rule.

### Comment

Some water systems may require modifications to meet the Stage 2 D/DBP Rule. Operational changes may include (1) process modifications to reduce by-product precursor material, (2) removal of by-products after formation, (3) changes in the type of secondary disinfectants that are used, and (4) distribution system operation changes to minimize stagnant flow areas and reduce travel time to far reaches of the system to limit the time by-products may form in the distribution system.

The only ozone by-product currently regulated in the D/DBP Rule is bromate ( $\text{BrO}_3^-$ ), with an MCL of 0.010 mg/L (10  $\mu\text{g/L}$ ). Some health effects data has indicated that the  $10^{-6}$  cancer risk level for bromate may be as low as 0.05  $\mu\text{g/L}$  (Bull et al., 2001). The U.S. EPA typically sets MCLs for carcinogens at a level between their  $10^{-6}$  and  $10^{-4}$  cancer risk levels, which suggests that the bromate MCL may be lowered to a level

between 0.05 and 5  $\mu\text{g/L}$  at some time in the future. (The current practical quantification limit for bromate is 10  $\mu\text{g/L}$ .) However, the bromate MCL was not identified as a candidate for revision in the most recent 6-year review of drinking water standards (U.S. EPA, 2010a), so action toward a revision to this MCL will probably not occur before the year 2016 when the next 6-year review will take place. A lower MCL for bromate will make it difficult to use ozone as a disinfectant when treating water containing measurable concentrations of bromide.

### Practical Considerations

Minimizing DBP formation needs to be balanced with the need to maximize disinfection. Since DBPs are formed via the reaction of various water constituents with disinfectants, one way of reducing DBP formation is to reduce the concentration of the disinfectant in the water and/or the time it is present in that water. Reducing the disinfectant concentration and/or contact time will directly reduce disinfection efficiency, and thus reduce public protection against exposure to disease-causing microorganisms. Therefore, any effort to reduce the formation of DBPs through minimizing disinfectant concentration and/or contact time during water treatment must be balanced against the need to lower the microbial risk through adequate disinfection.

## 19-2 Free-Chlorine By-products

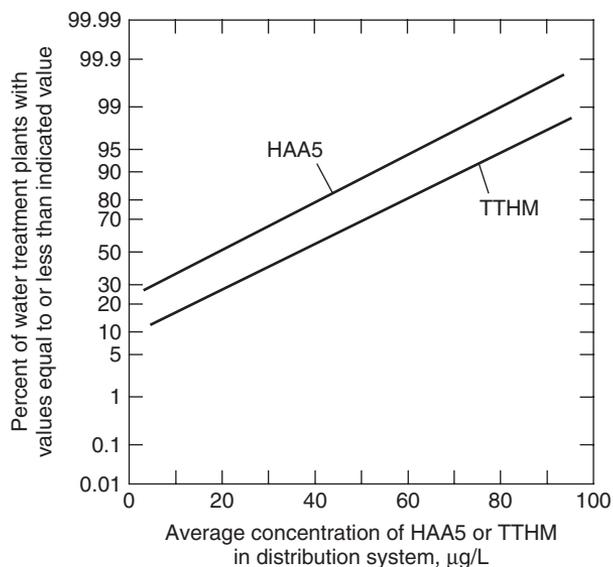

---

Chlorine is by far the most widely used disinfectant in drinking water treatment in the United States. It is also the disinfectant that forms the greatest variety of known by-products, many of which are listed in Table 19-1. Of the known chlorination by-products, the primary by-products of concern in drinking water treatment are THMs and HAAs. A cumulative distribution profile of average concentrations of total THMs (TTHM) and five HAAs (HAA5) in the distribution systems of approximately 360 U.S. water treatment plants (McGuire, 1999) is shown on Fig. 19-1. This information was collected over a 9-month period spanning summer 1997 through winter 1998. As shown on Fig. 19-1, on average, 10 percent of U.S. distribution systems contained greater than 51  $\mu\text{g/L}$  of HAA5 and greater than 73  $\mu\text{g/L}$  of TTHM. Based on the data shown on Fig. 19-1, the majority of distribution systems in the United States contain HAAs and THMs, and slightly less than 10 percent of distribution systems may not be meeting the Stage 1 D/DBP Rule.

### Chemistry of Formation

At an elementary level, chlorine reacts with NOM and bromide ions to form halogenated by-products, as shown in the following reaction:

**Figure 19-1**

Cumulative distribution profile of average TTHMs and HAA5 in approximately 360 U.S. distribution systems monitored over a 9-month period beginning in summer 1997 and ending winter 1998 (adapted from McGuire, 1999).

According to Fuson and Bull (1934), the reaction between certain organic chemicals and chlorine to produce “haloforms” has been known since 1822. However, it was only after the discovery of chloroform formation upon chlorination of drinking water in the early 1970s that the occurrence of haloform reactions in drinking water treatment was recognized. Many researchers have explored the mechanisms of THM and other by-product formation upon chlorination of natural waters (Christman et al., 1978; Norwood et al., 1980, 1987; Reckhow and Singer, 1985; Rook, 1974, 1977). Because NOM in natural waters is complex and has unidentifiable structures, it has not been possible to identify and verify every specific reaction mechanism between NOM and chlorine. Regardless of the exact mechanisms involved in the formation of chlorination by-products, higher concentrations of chlorination by-products are formed with higher concentrations of organic precursor material, bromide ions (inorganic precursor), or chlorine, as shown in Eq. 19-1.

THMs and HAAs form simultaneously when chlorine reacts with NOM, but the ideal conditions for THM formation are different from the ideal conditions for HAA formation. It is generally believed that the reaction mechanism leading to the formation of THMs is base catalyzed, meaning the reaction is catalyzed by hydroxide ions ( $\text{OH}^-$ ) present in the water, and therefore proceeds faster at more alkaline pH (Rook, 1977). Conversely, HAAs formation is enhanced under acidic conditions. Therefore, pH will directly influence whether THM formation is favored or HAA formation is favored.

The presence of bromide increases the mass concentration of THMs formed when chlorine reacts with NOM. Bromide ions ( $\text{Br}^-$ ) participate in the reaction between NOM and chlorine to form various by-products that have a mix of chlorine and bromine substitutions (e.g., bromodichloromethane, bromochloroacetic acid). Brominated THMs form after hypochlorous acid oxidizes bromide ions to form hypobromous acid (HOBr) as follows:

Hypobromous acid is a weak acid that dissociates depending on pH:

HOBr and  $\text{OBr}^-$  are both capable of reacting with NOM during chlorination to form a mixture of chlorinated and brominated by-products. The increase in THM formation when bromide is present occurs because bromine has a molecular weight of 79 g/mol compared to 35.5 g/mol for chlorine. Thus, an equal molar concentration of a highly brominated DBP (e.g., bromoform) compared to a purely chlorinated DBP (e.g., chloroform) will result in a significantly higher mass-based concentration of THMs, as demonstrated in Example 19-2.

### Example 19-2 Comparison of mass and molar concentrations of THMs chloroform and bromoform

Determine the mass concentrations of 0.5  $\mu\text{M}$  solutions of (a) chloroform ( $\text{CHCl}_3$ ) and (b) bromoform ( $\text{CHBr}_3$ ) and compare the results.

#### Solution

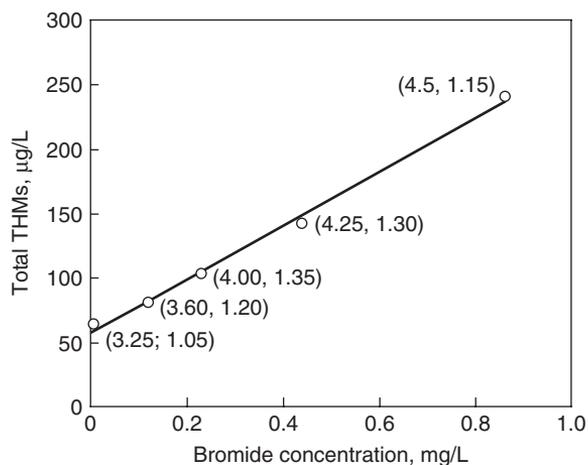

- Calculate the molecular weight of chloroform and bromoform:
  - $\text{CHCl}_3 = [12 + 1 + 3(35.5)] = 119.5 \text{ g/mol}$  or  $119.5 \mu\text{g}/\mu\text{mol}$ .
  - $\text{CHBr}_3 = [12 + 1 + 3(79.9)] = 252.7 \text{ g/mol}$  or  $252.7 \mu\text{g}/\mu\text{mol}$ .
- Multiply the molar concentration ( $\mu\text{M} = \mu\text{mol/L}$ ) by the molecular weight of each compound:
  - Mass concentration of  $\text{CHCl}_3 = (0.5 \mu\text{mol/L})(119.5 \mu\text{g}/\mu\text{mol}) = 59.8 \mu\text{g/L} = 0.0598 \text{ mg/L}$ .
  - Mass concentration  $\text{CHBr}_3 = (0.5 \mu\text{mol/L})(252.7 \mu\text{g}/\mu\text{mol}) = 126 \mu\text{g/L} = 0.126 \text{ mg/L}$ .
- Compare the mass concentrations. The mass concentration of  $\text{CHBr}_3$  is nearly double that of  $\text{CHCl}_3$ . If drinking water contained 0.5  $\mu\text{M}$  of THMs, it would meet the MCL of 0.080 mg/L if only chloroform was present but would not if only bromoform was present.

### Comment

Regulatory requirements for DBPs are based on mass. Therefore, waters with moderate organic carbon concentrations and high bromide ion concentrations produce higher levels of chlorination by-products on a mass concentration basis. There is some rationale for this approach, because brominated by-products are more toxic.

The effect of bromide increasing the mass concentration of by-products formed is demonstrated on Fig. 19-2. As shown on Fig. 19-2, the increase in bromide ion concentration from 0.12 to 0.44 mg/L increased the total THM levels formed in 3 h of free-chlorine contact time from 80 to 142  $\mu\text{g/L}$ , a 70 percent increase. Increasing the bromide concentration resulted in a slight increase in the chlorine dose required to achieve the same 3-h residual (see values in parentheses on Fig. 19-2). Therefore, the increase in THM formation was caused by both the higher bromide concentration and the higher chlorine dose added. The linear relationship between bromide concentration and TTHMs shown on Fig. 19-2 is not universal, as other work has shown a more logarithmic relationship between bromide concentration and THM formation in natural waters (Trussell and Umphres, 1978).

The type of NOM present also influences the amount of DBP formation. Researchers have been able to fractionate NOM present in different waters according to its molecular size and/or chemical characteristics (Aiken et al., 1992; Croué et al., 1993; Leenheer and Croué, 2003; Reckhow et al., 1990). In natural waters, NOM consists of humic (hydrophobic) and nonhumic (hydrophilic/polar) fractions. In most, but not all, natural waters, hydrophobic NOM contributes more to THM and HAA formation

**Figure 19-2**

Impact of bromide on THM formation (adapted from Krasner et al., 1994) (Conditions: Temperature = 25°C, pH = 8.2, contact time = 3 h, TOC = 3.25 mg/L. Values in parentheses represent the chlorine dose and the 3-h chlorine residual for each data point.)

than hydrophilic NOM (Kavanaugh, 1978; Croué et al., 2000). An example where the hydrophilic fraction has a higher THM and HAA yield compared to its hydrophobic fraction is Colorado River water (Hwang et al., 2000). Many conventional and advanced treatment processes preferentially remove hydrophobic NOM over hydrophilic NOM, so it may be important to characterize the source water NOM to assist in selecting the appropriate treatment process for the source water (see enhanced coagulation in Chap. 9). The specific UV absorbance (SUVA) is an important water quality indicator that correlates well with the amount of hydrophobic NOM in water; high SUVA values can be an indicator that a source water is predisposed to higher THM or HAA formation.

### Estimating By-product Formation

THMs and HAAs formation has been studied extensively in the past 30 years. Formation data can be correlated to water quality conditions such as pH, alkalinity, and TOC concentration and operating parameters such as chlorine dose, chlorine residual, and time using multivariate regression analyses to determine the effect of each parameter on DBP formation. In an extensive review, Sadiq and Rodriguez (2004) identified 25 publications in peer-reviewed literature that presented correlations between THM and HAA concentrations and water quality and operating conditions. More recently, Obolensky and Singer (2008) used extensive field data from the Information Collection Rule to develop a similar correlation. The Obolensky and Singer regression considers temperature, alkalinity, TOC, UV absorbance, chlorine dose, chlorine residual, pH, and time as factors that affect THM formation. The THM formation model is

$$\begin{aligned} \log [\text{THM}_4] = & -1.371 + 0.015 (T) - 0.0005 (\text{ALK}) \\ & + 0.188 [\log (\text{TOC})] + 0.326 [\log (\text{UV})] \\ & + 0.291 [\log (\text{Cl}_2)] + 0.119 [\log (t)] \\ & + 0.087 (\text{pH}) + 0.167 [\log (\text{Cl}_{\text{res}})] \end{aligned} \quad (19-4)$$

where  $\text{THM}_4$  = THM concentration,  $\mu\text{mol/L}$

$T$  = plant influent temperature,  $^{\circ}\text{C}$

ALK = plant influent alkalinity,  $\text{mg/L}$  as  $\text{CaCO}_3$

TOC = total organic carbon conc. at point of  $\text{Cl}_2$  addition,  $\text{mg/L}$

UV =  $\text{UV}_{254}$  absorbance at point of  $\text{Cl}_2$  addition,  $\text{cm}^{-1}$

$\text{Cl}_2$  = chlorine consumed (dose minus residual),  $\text{mg/L}$  as  $\text{Cl}_2$

$t$  =  $\text{Cl}_2$  contact time in treatment plant, h

$\text{Cl}_{\text{res}}$  = chlorine residual in finished water,  $\text{mg/L}$  as  $\text{Cl}_2$

Obolensky and Singer (2008) also presented model parameters for calculation of three individual THMs (excluding bromoform because low concentrations in the data set led to unacceptable model results) and five HAAs. Since the equations estimate DBPs in units of  $\mu\text{mol/L}$ , it is necessary

to calculate each THM individually, multiply by the molecular weight, and sum the results to determine the THM concentration in  $\mu\text{g/L}$ .

Simplier models have been developed by Chen and Westerhoff (2010) that predict THM and HAA formation potentials. Formation potential tests evaluate the formation of DBPs under prescribed laboratory conditions so that factors such as time, temperature, and chlorine dose are constant across all tests. THM and HAA formation potentials are typically higher than those observed in distribution system and serve as an approximate upper limit on the expected DBP formation. The models developed by Chen and Westerhoff (2010) are

$$\text{THMFP}_4 = 1147 (\text{UV})^{0.83} (\text{Br} + 1)^{0.27} \quad (19-5)$$

$$\text{HAAFP}_9 = 1151 (\text{DOC})^{0.17} (\text{UV})^{0.89} (\text{Br} + 1)^{-0.60} \quad (19-6)$$

where  $\text{THMFP}_4$  = THM formation potential for four THMs,  $\mu\text{g/L}$

$\text{HAAFP}_9$  = THM formation potential for nine HAAs,  $\mu\text{g/L}$

DOC = dissolved organic carbon conc.,  $\text{mg/L}$

UV =  $\text{UV}_{254}$  absorbance,  $\text{cm}^{-1}$

Br = bromide conc.,  $\text{mg/L}$

Chen and Westerhoff (2010) also provided coefficients for the estimation of numerous DBPs individually.

Caution should be exercised when using these models to estimate DBP formation for design or modification of treatment facilities. While such correlations give an indication of DBP formation based on average water quality conditions, they are not necessarily accurate for any specific site. Nevertheless, they can provide general guidance for the level of DBPs that may be formed. An example of the use of these equations is demonstrated in Example 19-3.

### Example 19-3 Estimation of THM and HAA formation potential

Estimate the THM and HAA formation potential for the following conditions: DOC = 4.0  $\text{mg/L}$ ,  $\text{UV}_{254}$  absorbance = 0.1  $\text{cm}^{-1}$ , and bromide = 0.05  $\text{mg/L}$ .

#### Solution

1. Estimate the THM formation potential using Eq. 19-5.

$$\text{THMFP}_4 = 1147 (0.1)^{0.83} (0.05 + 1)^{0.27} = 172 \mu\text{g/L}$$

2. Estimate the HAA formation potential using Eq. 19-6.

$$\text{HAAFP}_9 = 1151 (4)^{0.17} (0.1)^{0.89} (0.05 + 1)^{-0.60} = 182 \mu\text{g/L}$$

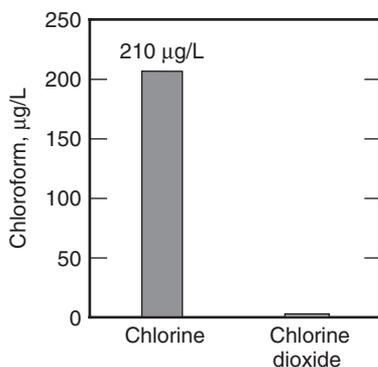

## Formation Control

Since implementation of the THM rule in 1979, a large amount of work has been conducted to identify and evaluate alternatives for reducing DBP formation (primarily THMs and HAAs). The following are practical alternatives for reducing the formation of chlorination by-products:

1. Use an alternate disinfectant/oxidant.
2. Reduce the free-chlorine contact time.
3. Reduce the concentration of NOM before chlorine addition.

### USE OF ALTERNATE DISINFECTANTS/OXIDANTS

Chlorine is not the only oxidant/disinfectant available to treat water. To reduce concern about chlorination by-products, substitution of another oxidant/disinfectant for chlorine may be a viable alternative. For example, neither ozone ( $O_3$ ) nor chlorine dioxide ( $ClO_2$ )—both of which are strong oxidants and disinfectants—produces measurable THMs or HAAs when applied to natural waters. If the source water contains a lot of humic acid that forms excessive amounts of chloroform, chlorine dioxide may be an appropriate alternative disinfectant to chlorine. The relative formation of chloroform with the addition of 10 mg/L of chlorine or chlorine dioxide to a solution containing 5 mg/L of humic acid is illustrated on Fig. 19-3 (Noack and Doerr, 1978). While 210  $\mu\text{g/L}$  chloroform was formed with chlorination, the addition of 10 mg/L of chlorine dioxide formed no detectable levels of chloroform.

**Figure 19-3**

Relative formation of chloroform with 10 mg/L doses of chlorine and chlorine dioxide to water containing 5 mg/L humic acid at pH 7.0 (adapted from Noack and Doerr, 1978).

The implications of the use of alternative disinfectants should be thoroughly investigated. Disinfectants such as ozone and chlorine dioxide, while not forming THMs and HAAs, do form other by-products, some of which are regulated and of significant health concern. For instance, Trussell and Umphres (1978) showed that the addition of up to 10 mg/L ozone to a water containing 10 mg/L humic acid and 1 mg/L bromide ion formed less than 4  $\mu\text{g/L}$  of THMs. However,  $Br^-$  originally present in the water could not be accounted for by summing the  $Br^-$  and  $HOBr$  present after ozonation. At the time it was not feasible to measure  $BrO_3^-$  at low levels. Since then it has been demonstrated that the addition of ozone to waters containing bromide ions results in the formation of bromate, which is now regulated.

Potassium permanganate ( $KMnO_4$ ) is an alternative to chlorine for oxidation at water treatment plants. While permanganate is a weak disinfectant, it is a good oxidant for the control of iron, manganese, and sulfide. Iron is sometimes strongly complexed and hard to remove. Potassium permanganate forms less THMs and HAAs than chlorine. Potassium permanganate addition to drinking water is not known to produce any regulated by-products,

but  $\text{KMnO}_4$  is a weak disinfectant, so additional chemical disinfection is necessary and may result in DBP formation.

#### **REDUCTION OF FREE-CHLORINE CONTACT TIME**

Minimizing the free-chlorine contact time can minimize DBP formation. Reducing contact time may be achieved by placing the chlorine addition point near the end of the treatment train and adding ammonia to the treated water at the point where the chlorine disinfection requirements have been met. Ammonia reacts with free chlorine and forms combined chlorine, which is much less reactive with NOM. Experience from full-scale plants indicates that THMs and HAAs do continue to form under combined chlorine conditions, but at a much lower rate compared to their formation under free-chlorine conditions.

Ammonia added at a mass ratio of less than 1 : 5 (between the  $\text{NH}_3 - \text{N}$  dose and the residual  $\text{Cl}_2$  concentration at the point of ammonia addition) will convert the free chlorine residual to monochloramine according to the following reaction (see Eq. 13-17 in Chap. 13):

The conversion of free chlorine to combined chlorine is an excellent strategy for limiting the formation of many chlorination by-products, especially THMs and HAAs. The extent of THM and HAA reduction is a function of how long the free chlorine is allowed to react with the NOM to form by-products before the ammonia is added to the water. Free chlorine contact time with the water is necessary to achieve the target disinfection goals, unless an alternative disinfectant is used, such as ozone or chlorine dioxide. When an alternate disinfectant is used for primary disinfection, little to no free-chlorine contact time may be required before ammonia addition to form chloramines for residual maintenance.

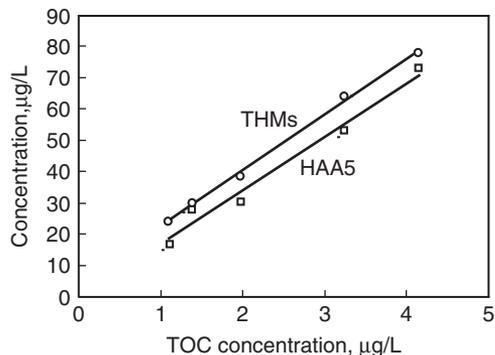

#### **REDUCTION OF CONCENTRATION OF NOM BEFORE CHLORINE ADDITION**

Based on Eq. 19-1, reducing the concentration of NOM will reduce the formation of chlorination by-products. The relationship between THM and HAA formation and NOM concentration was characterized in a 1994 study on Sacramento River water. As shown on Fig. 19-4, the concentration of THMs and HAAs increase with increasing the NOM concentration when using chlorination. Therefore, reducing the total organic carbon (TOC) concentration in natural water results in a corresponding decrease in the formation of by-products during exposure to chlorine. The relationship between NOM reduction and reduced DBP formation is the basis for the enhanced coagulation requirement in the D/DBP rule.

Several methods are available for removing NOM during drinking water treatment, including (1) enhanced coagulation, (2) adsorption on activated carbon, (3) ozone/biofiltration, (4) ion exchange, and (5) reverse osmosis. These treatment strategies are discussed in the following sections.

**Figure 19-4**

THM and HAA5 formation upon chlorination of Sacramento River water spiked with various doses of natural organic matter (adapted from Krasner et al., 1994). (Conditions: Temperature = 25°C, pH = 8.2; contact time = 3 h,  $\text{Br}^- < 0.010$  mg/L. Chlorine dose was set to achieve a 3-h free-chlorine residual of 0.5 to 1.5 mg/L.)

#### *Removal of NOM by enhanced coagulation*

Chemical coagulation and precipitation is primarily achieved with the addition of inorganic coagulants such as aluminum or ferric salts. Coagulants are traditionally used for removing suspended material from water, but they can also adsorb NOM. When chemical precipitates are removed from the water through clarification and filtration, the adsorbed NOM is removed as well, reducing the concentration of NOM available to react with the chlorine added downstream for disinfection. The process of practicing coagulation specifically for NOM removal is now commonly practiced and is known as enhanced coagulation. TOC removal of 15 to 50 percent can be achieved with enhanced coagulation. Enhanced coagulation is discussed in Sec. 9-5 of Chap. 9.

#### *Removal of NOM by adsorption on activated carbon*

A less common method of NOM removal is adsorption on activated carbon. A large number of studies have evaluated the removal of NOM with adsorption on activated carbon (e.g., Crittenden et al., 1987; Hooper et al., 1996; Sontheimer et al., 1988; Wood and DeMarco, 1980) and have found that significant removal of NOM with activated carbon can be very costly. A significant fraction of NOM is comprised of large molecular weight organic molecules that are poorly adsorbed on activated carbon, resulting in the use of a large amount of activated carbon to remove a small amount of NOM. Adsorption is discussed in Chap. 15.

#### *Removal of NOM by ozone/biofiltration*

Frequently, ozone's use for DBP control is as an alternate disinfectant (i.e., replacing chlorine), but in some cases it can also be used for precursor removal prior to chlorination. Natural organic matter in water contains a significant amount of high-MW organic material that is relatively resistant to biodegradation. Ozone breaks carbon-carbon double bonds and, in doing so, breaks the organics into smaller, more readily biodegradable material.

The increase in biodegradable material is characterized by an increase in assimilable organic carbon (AOC) or biodegradable dissolved organic carbon (BDOC) following ozonation. There is essentially no decrease in DOC, however, because ozonation cannot completely mineralize the complex organics to inorganic products. Biologically active filtration is effective at degrading the smaller organics, so the combined process of ozone and filtration is capable of achieving as much as 35 to 40 percent DOC removal. Ozonation is presented in Chap. 13 and biological filtration is presented in Sec. 11-8 of Chap. 11.

*Removal of NOM by ion exchange (MIEX)*

NOM in water is negatively charged, so it could be removed using ion exchange (IX) technology using anion exchange resins (Fu and Symons, 1990; Kim and Symons, 1991), using a conventional packed-bed configuration. Depending on the water quality and resin parameters, TOC reduction of 50 percent can be achieved with run lengths ranging from 500 to 5000 bed volumes (BVs) between regenerations. A limitation of conventional IX technology for NOM removal, however, is slow process kinetics. The slow exchange process is caused by slow rate of mass transfer coupled with the size of the beads.

An alternative IX technology (MIEX) has been developed that uses a smaller size of resin bead (<0.2 mm) (Singer and Bilyk, 2002) added to the water at a treatment plant as a slurry. The MIEX resin is allowed to contact the water for a short time and then settled to the bottom of the contactor, where it is collected, regenerated, and reused. To increase the bead settling velocity in the contactor, the beads are magnetized, which forces them to coalesce during settling to form larger masses, which then settle at a higher rate. The smaller bead size allows for faster removal kinetics.

A pilot study for the City of West Palm Beach, FL, found that THM formation potential was reduced by 70 percent using a process train that incorporated MIEX and coagulation, compared to water treated with enhanced softening (MWH, 2010). Use of MIEX also reduced coagulant use and sludge production by about 80 percent compared to enhanced coagulation alone. Significantly, the duration of free-chlorine contact time without excessive DBP formation was increased from about 3 min to nearly 4 h, long enough for the plant to get the disinfection CT credit it needed. As of the end of 2010, about 15 MIEX systems had been installed at treatment plants greater than 3785 m<sup>3</sup>/d (1 mgd) in North America. Additional information on MIEX and ion exchange is presented in Chap. 16.

*Removal of NOM by reverse osmosis*

Reverse osmosis using nanofiltration (NF) or reverse osmosis (RO) membranes can be used to remove NOM. With pore sizes less than 1 nm, these membranes can reject more than 90 percent of NOM and DBP precursors (Fu et al., 1994). With this rate of removal, reverse osmosis is the most

effective of the treatment processes for NOM removal discussed in this chapter. Reverse osmosis has been used effectively for NOM removal at a number of installations treating highly colored groundwater, in particular for treating Biscayne Aquifer water in South Florida.

Despite the high removal efficiency, other methods of NOM removal are frequently preferred because reverse osmosis has several disadvantages, including high capital cost, high operating cost, high energy consumption, and low recovery of product water compared to other treatment processes.

The low recovery of reverse osmosis is due to scaling caused by sparingly soluble salts that are concentrated during the reverse osmosis process. The cations that cause scaling are principally divalent cations (specifically  $\text{Ca}^{2+}$ ,  $\text{Ba}^{2+}$ , and  $\text{Sr}^{2+}$ ), thus, a membrane that can reject NOM without rejecting these cations would be able to operate at higher recovery. For instance, the Hydranautics NTR-7450 membrane has been reported to achieve 93 percent TOC removal but only 35 percent calcium removal when operating at 90 percent recovery (Fu et al., 1994). Reverse osmosis is discussed in additional detail in Chap. 17.

### **Removal of Chlorination By-products**

Technologies exist to remove some chlorination by-products after they are formed, but they are seldom practical compared to the by-product reduction strategies discussed above.

Chlorination by-products are organic chemicals, so they can be removed from water via several trace-chemical removal technologies. These include adsorption on activated carbon (Chap. 15) or, for the more volatile by-products, removal with aeration and air stripping (Chap. 14). Several researchers (e.g., Speth and Miltner, 1998; Crittenden et al., 1986) have evaluated the removal of chloroform with adsorption on GAC, but the adsorption capacity of GAC for chloroform is relatively low, requiring a high GAC replacement or regeneration frequency, possibly every few weeks. Similarly, air stripping is theoretically a viable approach for removing THMs from water because they are volatile chemicals (Umphres et al., 1983). However, DBPs, and THMs in particular, continue to be formed after they are removed as long as the water contains a chlorine residual. For this reason, coupled with the fact that HAAs are not removed, air stripping is a nonviable alternative for DBP removal.

## **19-3 Chloramine By-products**

---

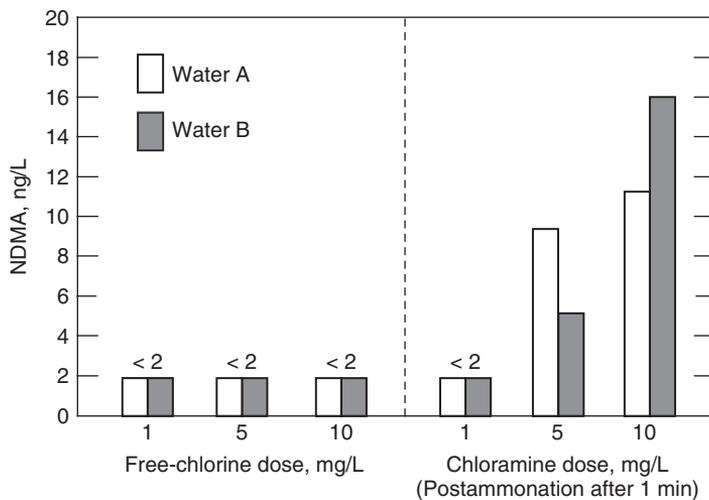

Converting free chlorine to combined chlorine (chloramines) via Eq. 19-4 after requirements for primary disinfection have been met has long been considered a cost-effective strategy to halt THM and HAA formation in chlorinated water while still complying with distribution system residual requirements. Most systems using chloramines engage in this practice. The practice is widely accepted in some countries, such as the United States,

the United Kingdom, Denmark, and Australia. It is not as widely accepted in countries that do not make a practice of maintaining distribution system residuals, such as the Netherlands, Germany, and Switzerland. In the United States in particular, with tighter regulatory standards being implemented on DBPs (see Chap. 4), an increasing number of water utilities are converting the disinfectant residual in their distribution systems from free chlorine to combined chlorine (Jacangelo and Trussell, 2002). The addition of ammonia to water containing a free-chlorine residual to form chloramines will almost completely halt the formation of THMs, HAAs, and most other chlorinated DBPs with the exception of chloropicrin, although, in some cases, a gradual but modest increase has been observed. Until recently, there were no known DBPs of significance formed by chloramine itself.

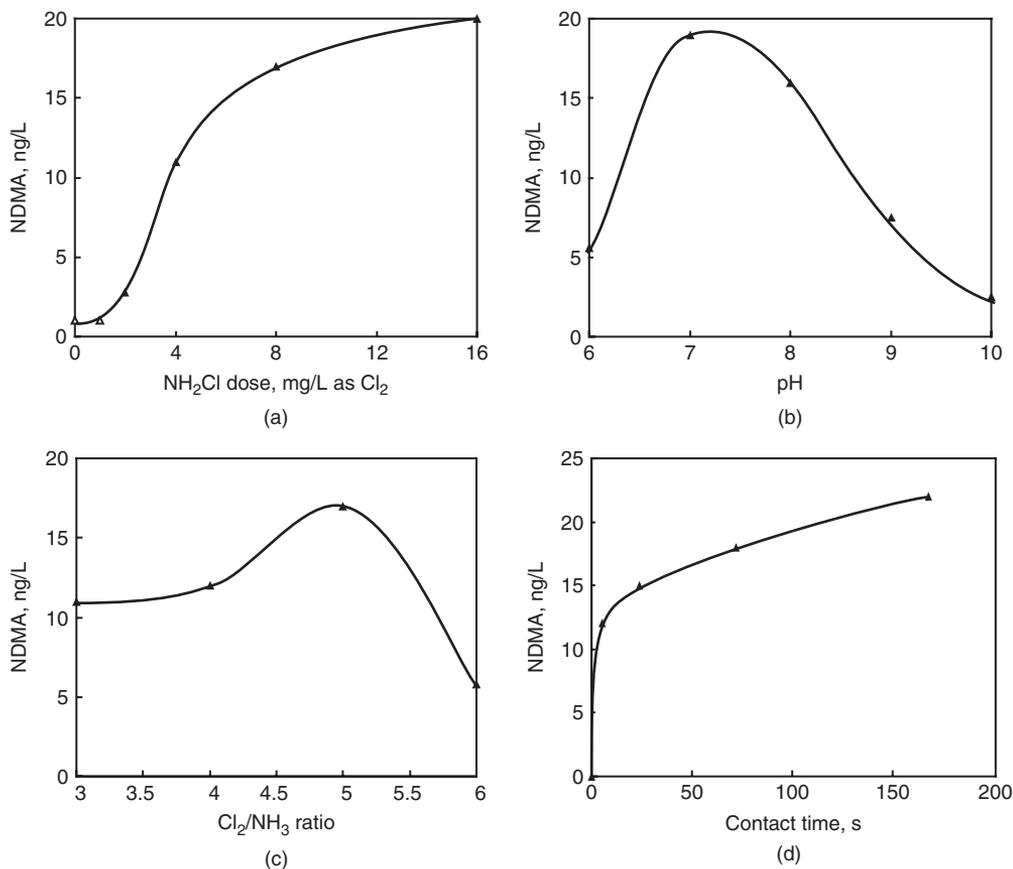

Around the year 2000, it was found that the reaction of combined chlorine with organic matter present in some waters may result in the formation of *N*-nitrosodimethylamine (NDMA) as a by-product (Najm and Trussell, 2000; Choi and Valentine, 2001, Mitch and Sedlak, 2002). The U.S. EPA currently classifies NDMA as a “probable human carcinogen,” and has estimated its  $10^{-6}$  cancer-risk level at 0.7 ng/L, which is well below the levels measured in chloraminated drinking water (Eaton and Briggs, 2000). No federal MCL has yet been established, but NDMA is on the Contaminant Candidate List (CCL3) released in 2010 and is being monitored as part of the Unregulated Contaminant Monitoring Regulation (UCMR). California has set an action limit of 10 ng/L (Cal DHS, 2002).

The chemical mechanism leading to the formation of NDMA is not completely resolved, but some principles have been established. NDMA formation in drinking water disinfection is a direct by-product of chloramine and not free chlorine, as shown on Fig. 19-5 (Najm and Trussell,

## Chemistry of Formation

**Figure 19-5** NDMA formation after chlorine and chloramine addition to two test waters (contact time = 24 h) (Adapted from Najm and Trussell, 2001).

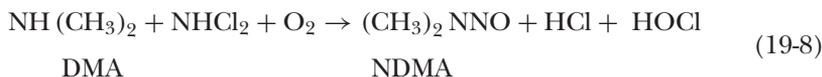

**Figure 19-6**

Factors influencing NDMA formation in the presence of chloramines: (a)  $\text{NH}_2\text{Cl}$  dose, (b) pH, (c)  $\text{Cl}_2:\text{NH}_3$  ratio, and (d) contact time.

2001). Najm and Trussell (2001) found that the NDMA concentration increased with increasing chloramine dose, and the sequence of addition of chlorine and ammonia had no significant effect on the final levels of NDMA formed. Further unpublished research by MWH engineers on untreated water from the West Branch of the California State Aqueduct has shown that NDMA formation during chloramination of that supply peaks at a pH of about 7 and at a  $\text{Cl}_2:\text{NH}_3$  ratio of approximately 5:1 on a weight basis (see Figs. 19-6a,b,c). Although significant NDMA formation occurs in the first few hours, it appears that the process continues at a slow pace for several days (see Fig. 19-6d). As a result of this prolonged formation time, the highest NDMA levels in the system are likely to be formed where the travel time is the longest.

Two pathways have been proposed for NDMA formation during chloramination. First, a mechanism based on the reaction of monochloramine

(NH<sub>2</sub>Cl) with unsymmetrical dimethylhydrazine (UDMH) was proposed (Choi and Valentine, 2001, 2002a, 2002b; Choi et al. 2002; Mitch and Sedlak, 2002). This mechanism accounted for the fact that NDMA formation was observed during chloramination, but it predicted yields that were too low. In addition, other work showed that one of the reaction steps was much slower than had been estimated (Yagil and Anbar, 1962). Subsequently, another mechanism was proposed, one that requires the presence of dichloramine (NHCl<sub>2</sub>) as well as oxygen (Schreiber and Mitch, 2005). The overall reaction takes on the following stoichiometry:

DMA is dimethylamine.

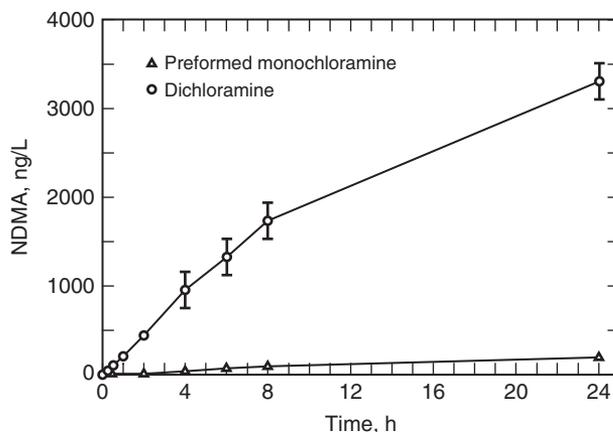

The California Department of Health Services conducted a survey of water systems in 1999 and found that 50 percent of the system samples had no NDMA (method detection level (MDL) = 1 ng/L) and 5 percent of the system samples had NDMA levels above 20 ng/L. More recently, the UCMR2 data summary released by the EPA in July, 2009, showed NDMA in 179 of 729 systems sampled, suggesting most chloraminated systems had detections (U.S. EPA, 2010b). The average NDMA level in samples with detections was 14 ng/L and the maximum was 630 ng/L. Studies have shown that higher NDMA levels are generally observed downstream of ion exchange (Loveland, 2001; Najm and Trussell, 2001) and following the use of some cationic polymers (Neiss et al., 2003; Wilczak et al., 2003).

Alternatives for minimizing NDMA formation can be gleaned from an examination of the circumstances that promote its formation. Generally, reducing the dose of chloramines, increasing the pH, and minimizing the contact time in the distribution system are all practices that will reduce NDMA formation. It also seems likely that either minimizing the use of polyDADMAC cationic polymers (see Chap. 9) or selecting carefully among them will also reduce the levels formed (Wilczak et al., 2003). Care in recycling filter waste washwater has also been shown to be of significance (Neiss et al., 2003). Recent work in wastewater reuse suggests that, consistent with the Schreiber–Mitch mechanism shown in Eq. 19-8, NDMA formation can be reduced by avoiding dichloramine formation. This potential formation control strategy is illustrated on Fig. 19-7 in which data on NDMA formation with dichloramine and preformed monochloramine are compared. Preformed monochloramine resulted in significantly lower NDMA formation than dichloramine.

NDMA can be removed by reverse osmosis (Chap. 17), photolysis, or advanced oxidation (Chap. 18). Although these alternatives may be practical for treating contaminated groundwater or water exiting ion exchange processes, they are not practical solutions when NDMA results

from chloramine use for disinfectant residual maintenance. As noted above, NDMA forms slowly in the distribution system, reaching a maximum concentration in the consumer's tap. As a result, any treatment for removal of NDMA would have to be applied at the consumer's tap. Preventing the formation of NDMA, as discussed above, may be the most economical approach.

## 19-4 Chlorine Dioxide By-products

Chlorine dioxide ( $\text{ClO}_2$ ) is a unique oxidant because it is a stronger disinfectant than free chlorine (see Fig. 13-5 in Chap. 13) but, when added to water containing NOM, does not break the C-C bond and therefore does not form halogenated organic molecules. Chlorine dioxide does, however, produce two inorganic by-products: chlorite ( $\text{ClO}_2^-$ ) and chlorate ( $\text{ClO}_3^-$ ). The presence of chlorite in drinking water is of concern because it is believed to have serious adverse health effects. In the United States, the Stage 1 D/DBP Rule set the MCL for chlorite in water at 1 mg/L. Although no MCL for chlorate exists at the federal level in the United States, the state of California limits it to 0.8 mg/L.

### Chemistry of Formation

There are several sources of chlorite and chlorate in drinking water, including some that are unrelated to the use of chlorine dioxide. Thus, the actual source needs to be identified before measures can be taken to reduce the concentrations. Chlorate can be present in the raw water entering a treatment plant due to agricultural use because sodium chlorate has been used as a herbicide for almost a century (Hayes and Laws, 1971). Chlorate salts are also used commercially as oxidizing agents in some industries (Clapper, 1979), which can result in significant levels of chlorate in raw

waters. Chlorate is a degradation product of chlorine in liquid hypochlorite solutions (see Chap. 13); thus, the use of liquid hypochlorite at water treatment plants may add chlorate into the water.

#### CHLORITE AND CHLORATE FORMATION DURING CHLORINE

##### DIOXIDE GENERATION

There are two sources of chlorite and chlorate related to the use of chlorine dioxide. The first is the process of chlorine dioxide generation itself. As shown in Eq. 13-37 in Chap. 13, chlorine dioxide can be generated by the controlled reaction between chlorine and sodium chlorite under very acidic conditions as follows:

When excess chlorine is present in the chlorine dioxide generator, however, chlorate can form according to the following simplified reaction:

In addition, residual chlorite may remain in the product solution if excessively high concentrations of sodium chlorite are used in the generator. The residual chlorite will then be injected into the process stream with the chlorine dioxide. New developments in chlorine dioxide generation technologies have improved the generator efficiency and greatly minimized the formation of chlorite and chlorate.

##### CHLORITE AND CHLORATE FORMATION AS BY-PRODUCTS

The second source of chlorite and chlorate in treatment plants using chlorine dioxide is formation as a by-product of the chlorine dioxide disinfection/oxidation reactions. Chlorine dioxide produces chlorite and chlorate as by-products in two ways. The first is through the oxidation of various water constituents such as reduced iron, manganese, or NOM. The reaction typically involves a one-electron transfer, resulting in the formation of chlorite as follows:

Second, under high-temperature and/or high-pH conditions, chlorine dioxide disproportionates to form chlorite and chlorate. The oxidation state of chlorine in chlorine dioxide is (+4), which is between that in chlorite (+3) and that in chlorate (+5), which allows an electron transfer to produce both by-products. The overall reaction is

Researchers have estimated that 50 to 70 percent (by mass) of the chlorine dioxide applied during drinking water treatment is converted to chlorite (Werderhoff and Singer, 1987). With this formation rate, the formation of chlorite limits the chlorine dioxide dose that can be applied during drinking water treatment unless chlorite removal technologies are implemented downstream, since the MCL for chlorite is 1 mg/L.

### Formation Control

There is currently no technology that can be implemented at a water treatment plant to reliably reduce the formation of chlorite as a decay product of chlorine dioxide (Eq. 19-11), except through reducing the chlorine dioxide demand. When the chlorine dioxide demand is reduced, a lower chlorine dioxide dose will have to be added, thus reducing the amount of chlorite formed. Reducing  $\text{ClO}_2$  demand is especially effective when chlorine dioxide is used to oxidize reduced substances such as iron, manganese, and color present in the source water. Partial oxidation of iron and manganese with other oxidants (e.g., permanganate) is one approach. When chlorine dioxide is used for disinfection downstream of chemical precipitation, the chlorine dioxide demand can be reduced with NOM removal through coagulation.

### Removal of Chlorine Dioxide By-products

The unpreventable production of chlorite is the primary obstacle to widespread use of chlorine dioxide in drinking water treatment. Because implementing mitigation measures to reduce chlorite formation is not feasible, a significant amount of work has been conducted to evaluate options for the destruction of chlorite after it is formed. While many options exist for chlorite destruction, the following discussion focuses on the most feasible options for a full-scale water treatment plant: (1) reduction with ferrous ion, (2) reduction with activated carbon, and (3) oxidation with ozone.

#### REDUCTION WITH FERROUS ION

Reduction with ferrous ion and activated carbon are based on the idea of reducing chlorite to chloride by the following half-reaction:

When ferrous ( $\text{Fe}^{2+}$ ) ion is added to the water, it releases the needed electrons to form ferric ( $\text{Fe}^{3+}$ ) ion with the following overall reaction:

The stoichiometric mass ratio of ferrous ion to chlorite in Eq. 19-14 is 3.3 : 1  $\text{mg Fe}^{2+}/\text{mg ClO}_2^-$ , as demonstrated in Example 19-4. This stoichiometry was validated by Iatrou and Knocke (1992), who also showed that adding ferrous ions (as  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ ) at a mass ratio of 3 : 1 ( $\text{mg Fe}^{2+}/\text{mg ClO}_2^-$ ) resulted in virtually complete reduction of chlorite in less than 1 min of reaction time (pH between 5 and 7; temperature between 5 and 25°C). These researchers also verified that the ferrous ion was oxidized to ferric ion, which then enhanced downstream coagulation and flocculation by precipitating as  $\text{Fe}(\text{OH})_3(\text{s})$ . These findings were confirmed by Griese et al. (1992) who, along with Iatrou and Knocke (1992), showed that no chlorate was formed from the reaction between chlorite and ferrous ions. Subsequently, Hurst and Knocke (1997) verified this approach under alkaline conditions (pH between 8 and 10) and studied the effect of dissolved oxygen on the  $\text{Fe}^{2+}$  dose required. Based on these results, a mass

ratio between 3.5 : 1 and 4 : 1 is more appropriate under high- $O_2$  conditions ( $>5$  mg/L) to satisfy the added demand for  $Fe^{2+}$ .

#### REDUCTION WITH ACTIVATED CARBON

Reduction with activated carbon is based on the fact that the surface of activated carbon is a good reducing agent and, therefore, may be used to reduce chlorite to chloride. Chlorite is removed by GAC and the removal efficiency increases with increasing EBCT. Research has shown, however, that the removal efficiency decreases rapidly over time (Dixon and Lee, 1991; Karpel Vel Leitner et al., 1996).

#### OXIDATION WITH OZONE

When ozone is added to water containing chlorite, the chlorite is oxidized to chlorate as shown in the following overall reaction:

Water treatment plants that use chlorine dioxide as a raw-water preoxidant and ozonation for disinfection can rely on the ozonation process to oxidize the chlorite by-product to chlorate. When chlorine dioxide use is followed by ozone, the chlorine dioxide dose can be increased in response to changing raw-water quality conditions without violating the chlorite standard in the finished water. This strategy is of limited value, however, when chlorate is an issue.

### Example 19-4 Calculating ferrous dosages for chlorite removal

Calculate the  $Fe^{2+}$  dose required to remove 1 mg/L of  $ClO_2^-$  using the stoichiometry of Eq. 19-14.

#### Solution

1. Calculate the molecular weight of  $ClO_2^-$ :

$$ClO_2^- + [35.5 + 2(16)] = 67.5 \text{ g/mol} = 67.5 \text{ mg/mmol}$$

2. Calculate the molar concentration of chlorite:

$$[ClO_2^-] = \frac{1 \text{ mg/L}}{67.5 \text{ mg/mmol}} = 0.0148 \text{ mmol/L}$$

3. Calculate the concentration of  $Fe^{2+}$ :

According to stoichiometric relationship given in Eq. 19-14, 4 mol  $Fe^{2+}$  are required to remove 1 mol chlorite.

$$\begin{aligned} [Fe^{2+}] &= (0.0148 \text{ mmol/L}) (4 \text{ mmol Fe/mmol}) (56 \text{ mg/mmol}) \\ &= 3.3 \text{ mg/L} \end{aligned}$$

## 19-5 Ozone By-products

---

Ozone is a very strong disinfectant, is commonly used in Europe, and is often evaluated as an alternative to free chlorine for primary disinfection when chlorinated DBPs are a problem. It is also one of the most effective oxidants for the destruction of chemicals that cause color, taste, and odor in drinking water. When applied to some raw waters, it has been shown to improve the downstream chemical coagulation, clarification, and granular filtration.

Ozone addition to water forms three types of by-products, as are listed in Table 19-1. The first type of by-product is inorganic bromate ( $\text{BrO}_3^-$ ). Bromate, which forms when bromide ion ( $\text{Br}^-$ ) is present during ozonation, is classified by the U.S. EPA as a “probable human carcinogen” with a  $10^{-6}$  cancer risk level of  $0.05 \mu\text{g}/\text{L}$  (U.S. EPA, 1998). Bromate is the most significant of the by-products formed by ozone.

The second type of by-product is low-molecular-weight (MW) organic molecules such as aldehydes, carboxylic acids, and ketoacids that form during reactions between ozone and NOM. It should be noted that by-products of the direct oxidation of NOM by ozone are not halogenated, that is, they do not contain chlorine or bromine. Ozone typically causes the partial oxidation of NOM to simpler organics and not the total oxidation of NOM to carbon dioxide and water (i.e., not complete mineralization of organic compounds to inorganic products). The low-MW organic by-products are not regulated by the U.S. EPA and are not believed to have significant adverse public health effects at the concentrations that occur in drinking water. Nevertheless, these by-products may still have negative impacts on municipal water systems because the by-products are more biodegradable than the high-molecular-weight “parent” NOM molecules. The increase in the biodegradability of the organic material present in the water is of concern because it can promote bacterial growth in the distribution system. The total concentration of the organic by-products is gauged by measuring the biodegradable dissolved organic carbon (BDOC) concentration or the assimilable organic carbon (AOC) concentration, which is believed to represent the more readily biodegradable fraction of the BDOC.

The third type of ozone by-product is brominated organics such as bromoform. As noted above, ozone does not react directly with NOM to produce halogenated by-products, but it does react with bromide. One product of the reaction with bromide is hypobromite ion ( $\text{OBr}^-$ ). At neutral pH, hypobromite ion protonates to form hypobromous acid ( $\text{HOBr}$ ). Hypobromous acid can, in turn, react with NOM to form brominated organics, as was discussed in Sec. 19-2. The concentration of bromide ion, NOM, and pH determine the quantity of brominated by-products formed. However, the concentrations of brominated by-products are at least one

order of magnitude less than those formed by chlorination (Singer and Reckhow, 1999).

The following sections focus on the formation and control of these ozonation by-products.

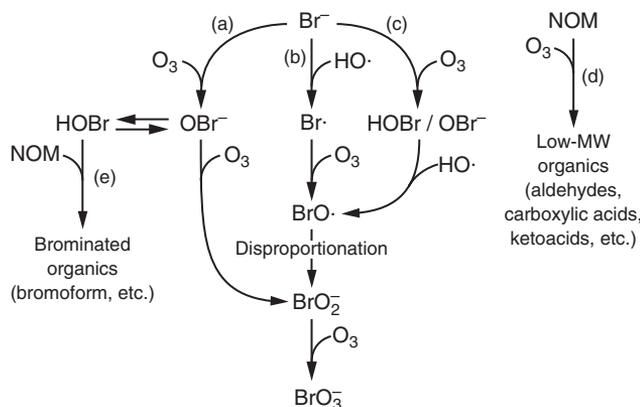

The reaction between ozone and bromide forms bromate by three distinct pathways, as shown schematically on Fig. 19-8. Two of the pathways involve hydroxyl radicals ( $\text{HO}\cdot$ ) as well as molecular ozone (see Chaps. 13 and 18 for more discussion on hydroxyl radical formation during ozonation). The direct pathway, which involves only molecular ozone and is shown as pathway (a) on Fig. 19-8, involves three sequential ozonation reactions, forming hypobromite and bromite ( $\text{BrO}_2^-$ ) before forming bromate, as given in the following reactions:

The kinetics of bromate formation with ozone are far more rapid (i.e., minutes) than those of THM formation with chlorine (i.e., hours to days). Equation 19-16 proceeds rapidly as a second-order reaction with a rate constant of  $160 \text{ M}^{-1} \text{ s}^{-1}$  at  $25^\circ\text{C}$  (see Table E-2 at the website listed in App. E).

$$r_{\text{OBr}} = k [\text{Br}^-] [\text{O}_3] \quad (19-19)$$

As was shown in Eq. 19-3, hypobromite is the conjugate base of hypobromous acid. When the pH is below the  $\text{p}K_a$  value ( $\text{p}K_a = 8.7$ ), the hypobromite is converted to hypobromous acid and the formation of bromite and bromate (as shown in Eqs. 19-17 and 19-18) will proceed more slowly, especially as the pH decreases.

**Figure 19-8**

Pathways for ozone DBP formation: (a) molecular ozone pathway for bromate formation, (b)  $\text{OH}\cdot/\text{O}_3$  pathway for bromate formation, (c)  $\text{O}_3/\text{OH}\cdot$  pathway for bromate formation, (d) low-MW organic formation, and (e) brominated organic formation. (Adapted from Song et al., 1997.)

Pathways (b) and (c) on Fig. 19-8 involve reactions with both ozone and hydroxyl radicals for bromate formation. Hydroxyl radicals can be produced by ozone reacting with NOM naturally present in water, or they can be generated in an advanced oxidation process by adding hydrogen peroxide or UV light with ozone. The hydroxyl radical pathways are complex and additional reaction steps not shown in Fig. 19-8 occur. The complete pathways as currently understood are available in the literature (Ozekin et al., 1998; von Gunten and Hoigné, 1994; von Gunten and Oliveras, 1998; Westerhoff et al., 1998).

In pathway (b) of Fig. 19-8, the reaction with hydroxyl radical occurs first to form bromide radical ( $\text{Br}\cdot$ ), followed by reaction with ozone to produce hypobromite radical ( $\text{BrO}\cdot$ ). In pathway (c), the reaction with ozone occurs first to form hypobromous acid or hypobromite, followed by the reaction with hydroxyl radical to produce the hypobromite radical. In both pathways,  $\text{BrO}\cdot$  will disproportionate to form bromite via either of the following reactions:

In natural waters without advanced oxidation (i.e.,  $\text{HO}\cdot$  only forms through reactions between NOM and  $\text{O}_3$ ), the  $\text{HO}\cdot$  concentration is relatively low after the first few seconds. Under these conditions,  $\text{O}_3$  reacts with  $\text{Br}^-$  more rapidly than  $\text{HO}\cdot$  does, so pathways (a) and (c) are the prime routes to bromate formation. In the next step, however, the pH is important.  $\text{HO}\cdot$  reacts with both  $\text{HOBr}$  and  $\text{OBr}^-$ , but  $\text{O}_3$  reacts only with  $\text{OBr}^-$ . At pH values of 7 to 8 (below the  $\text{p}K_a$  value of 8.7) the hypobromite is primarily in the form of  $\text{HOBr}$ , which slows the rate of pathway (a) and gives preference to pathway (c). Gillogly et al. (2001) reported that the  $\text{HO}\cdot$  pathways contribute to bromate formation far more than the molecular ozone pathway. Subsequent studies found that the molecular ozone pathway contributed only 10 to 30 percent of the formation of bromate during ozonation (von Gunten and Hoigné, 1992; Yates and Stenstrom, 1993; Westerhoff et al., 1998).

Pathway (d) in Fig. 19-8 represents the degradation of NOM by ozone to form various low-MW organic by-products including aldehydes, carboxylic acids, and others as listed in Table 19-1. The low-MW organics are strictly the products of NOM oxidation and do not contain bromine.

During the formation of  $\text{OBr}^-$  in pathway (a), the  $\text{OBr}^-$  is also in equilibrium with its conjugate acid,  $\text{HOBr}$ , as shown in Eq. 19-3. The  $\text{p}K_a$  is 8.7 at 25°C, so  $\text{HOBr}$  will be the predominant form in most natural waters. The  $\text{HOBr}$  can react with NOM, as shown in pathway (e), to form brominated organic by-products such as bromoform. However, pathway (e) is usually not significant for two reasons. First, bromide levels in natural waters seldom exceed 0.5 mg/L. If 50 percent of the bromide (0.25 mg/L) is converted to  $\text{OBr}^-$  and subsequently to  $\text{HOBr}$ , only 0.3 mg/L  $\text{HOBr}$

will be formed (which is equivalent to about 0.22 mg/L as chlorine, a relatively low dose). Therefore, the amount of bromoform that would form is expected to be quite small; Trussell and Umphres (1978) showed that the addition of 10 mg/L ozone to a natural water containing 1 mg/L bromide formed less than 1 µg/L of bromoform.

The second reason for the low formation of brominated organics is, although decreasing water pH favors the conversion of  $\text{OBr}^-$  to  $\text{HOBr}$ , it hinders the base-catalyzed haloform reaction required to form bromoform. It has been shown that bromoform formation upon ozonation decreased from 37 µg/L at pH 6 to approximately 15 µg/L at pH 8.5 (bromide = 1 mg/L; DOC = 3.4 mg/L; ozone dose = 10.2 mg/L) (Siddiqui and Amy, 1993).

As was described for THM and HAA formation with chlorine, empirical correlations have been developed to predict bromate formation based on measurable water quality parameters and operating conditions (Sadiq and Rodriguez, 2004; Song et al., 1997). The model by Song et al. (1997) considers bromate formation as a function of initial bromide concentration, ozone dose, pH, inorganic carbon concentration, DOC concentration,  $\text{NH}_3 - \text{N}$  concentration, and time. The model is

$$[\text{BrO}_3^-] = \frac{10^{-6.11} [\text{Br}^-]_0^{0.88} [\text{O}_3]^{1.42} \text{pH}^{5.11} [\text{IC}]^{0.18} (t)^{0.27}}{[\text{DOC}]^{1.88} [\text{NH}_3\text{-N}]^{0.18}} \quad (19-22)$$

where  $[\text{BrO}_3^-]$  = bromate conc. (for  $[\text{BrO}_3^-] \geq 2$ ), µg/L  
 $[\text{Br}^-]$  = initial bromide conc. (for  $100 \leq [\text{Br}^-] \leq 1000$ ), µg/L  
 $[\text{O}_3]$  = ozone dose (for  $1.5 \leq [\text{O}_3] \leq 6$ ), mg/L  
pH = pH (for  $6.5 \leq \text{pH} \leq 8.5$ )  
 $[\text{IC}]$  = inorganic carbon conc. (for  $1 \leq [\text{IC}] \leq 216$ ), mg/L as  $\text{CaCO}_3$   
 $t$  = reaction time, (for  $t \leq 30$ ), min  
 $[\text{DOC}]$  = DOC conc. (for  $1.5 \leq [\text{DOC}] \leq 6$ ), mg/L  
 $[\text{NH}_3\text{-N}]$  =  $\text{NH}_3\text{-N}$  conc. (for  $0.005 \leq [\text{NH}_3\text{-N}] \leq 0.7$ ), mg/L

The model can be applied similar to the models for THM and HAA formation shown in Example 19-3. As with other models for DBP formation based on multivariate regression, the results should be used with caution when predicting DBP formation for a specific site.

To minimize the formation of low-MW organic by-products such as aldehydes and carboxylic acids, the only viable options are to reduce the dose of ozone or remove NOM before adding ozone to the water. Reducing the ozone dose is usually not practical because the dose is determined by the oxidation or disinfection requirements. Options for the removal of NOM

**Estimating  
By-product  
Formation**

**Formation  
Control**

are the same as those discussed earlier in this chapter for minimizing the formation of chlorination by-products.

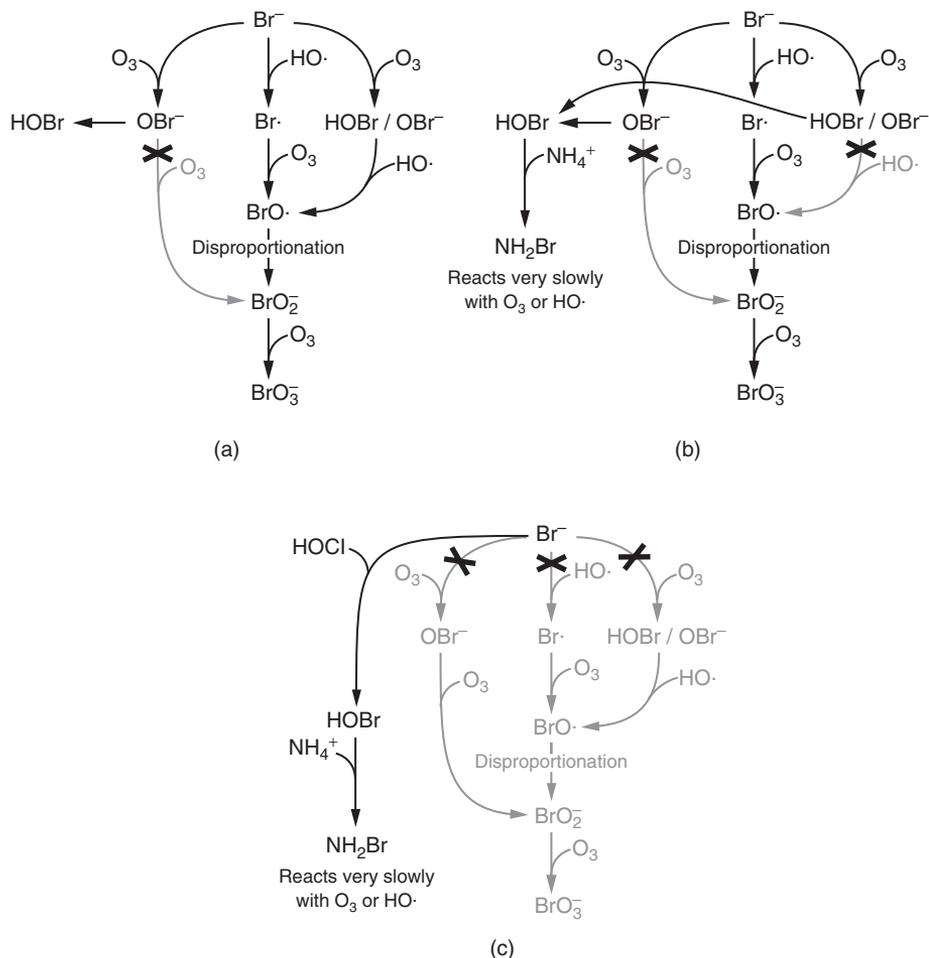

Similarly, bromate formation could be minimized by reducing the dose of ozone or removing bromide before adding ozone to the water. As noted above, reducing the ozone dose is usually not practical. Technologies exist to remove the bromide ion from water (ion exchange, reverse osmosis), but they are not viable options for minimizing DBP formation because of cost. Fortunately, several strategies can minimize bromate formation by chemically converting the bromide to a less reactive form or intercepting the reaction pathways to bromate formation. These measures include (1) pH depression, (2) ammonia addition, (3) conversion of bromide to bromamine by chlorine and ammonia addition, and (4) preoxidation with chlorine or chlorine dioxide.

#### **pH DEPRESSION**

Reducing the pH of water during ozonation is the most reliable and proven method for reducing bromate formation upon ozonation of bromide-containing waters. The rationale for this control strategy can be deduced from Fig. 19-8: The  $pK_a$  for the equilibrium reaction between HOBr and  $OBr^-$  is 8.7 at 25°C. Therefore, at lower pH values, a greater portion of the  $OBr^-$  is converted to HOBr, thus making it unavailable for the bromate formation reactions in the continuation of pathway (a), as shown on Fig. 19-9a. In addition, a reduction in pH reduces the ratio of  $HO\cdot$  to  $O_3$  in the water, decreasing the rate of all  $HO\cdot$  reactions in water and thus reducing the rate of bromated formation by the other pathways as well. The published literature includes many examples of the effect of pH on bromate formation, one of which is shown on Fig. 19-10a (Krasner et al., 1993). At an ozone dose necessary to achieve 0.5-log inactivation of *Giardia* cysts in the test water (3.4 mg/L), the bromate level formed at pH 8.0 was 2.6 times the level formed at pH 7.0 (13  $\mu\text{g/L}$  compared to 5  $\mu\text{g/L}$ ). With an ozone dose necessary for 2-log inactivation of *Giardia* cysts (6.0 mg/L), the bromate level formed at pH 8.0 was 3.6 times greater than the bromate level formed at pH 7.0 (58  $\mu\text{g/L}$  compared to only 16  $\mu\text{g/L}$ ). In other studies it has been shown that further reduction in bromate formation can be achieved as the pH is decreased to 6.5 or lower, although acid addition for bromate minimization must be followed by caustic addition for corrosion control in the distribution system.

#### **AMMONIA ADDITION**

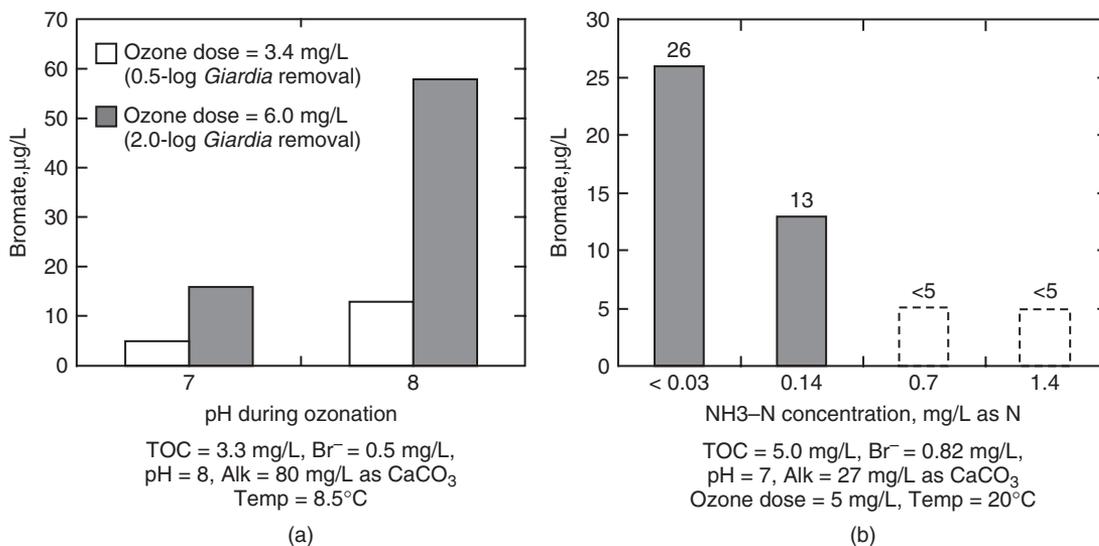

Because HOBr is a weak acid in equilibrium with  $OBr^-$ , a fraction of the oxidized bromide will exist as  $OBr^-$  even at low pH and still contribute to some bromate formation. To further minimize this fraction, ammonia can be added to serve as a “sink” for HOBr by transforming it to  $NH_2Br$  and creating a continuous driving force for the transformation of  $OBr^-$  to HOBr, as shown on Fig. 19-9b. The effect of ammonia addition on the formation of bromate in a natural water sample is shown on Fig. 19-10b

**Figure 19-9**

Effect of (a) pH adjustment, (b) ammonia addition, and (c) chlorine and ammonia addition on inhibition of bromate formation.

(Glaze et al., 1993). Under ambient conditions ( $\text{NH}_3\text{-N} < 0.03 \text{ mg/L as N}$ ), adding  $5 \text{ mg/L}$  of ozone resulted in the formation of  $26 \text{ }\mu\text{g/L}$  bromate. Increasing the ammonia-nitrogen concentration to  $0.7 \text{ mg/L}$  ( $\text{NH}_3\text{-N} = 0.7 \text{ mg/L as N}$ ) decreased the bromate level formed to less than the detection limit of  $5 \text{ }\mu\text{g/L}$ , which is a greater than 500 percent reduction in bromate formation. Combining pH depression and ammonia addition may be an effective strategy for some waters.

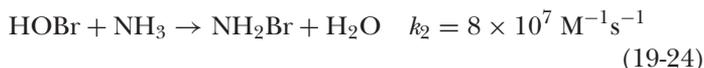

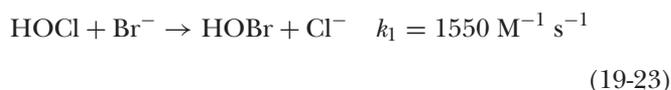

Unfortunately, while pH depression has been demonstrated to reduce bromate formation, some studies do not show a significant impact of ammonia addition on bromate formation. The reason for the mixed ammonia results is not yet clear. For now, the impact of ammonia addition on bromate formation should be evaluated on a case-by-case basis.

**Figure 19-10**

Effects of (a) pH (adapted from Krasner et al., 1993) and (b) ammonia (adapted from Glaze et al., 1993) on bromate formation during ozonation of natural water.

#### CONVERSION OF BROMIDE TO BROMAMINE

In 2004, the Southern Nevada Water Authority (SNWA) published the results of 3 years of studies it had been doing at the pilot scale (Neeman et al., 2004). After exploring preoxidation with chlorine and the addition of ammonia separately, the research moved to exploration of the addition of both chlorine and ammonia prior to ozonation. Pretreatment with 0.5 mg/L of chlorine followed by the addition of 0.1 mg/L of ammonia brought the bromate levels formed during ozonation from 20 to 25 µg/L to about 5 µg/L. SNWA patented the process and put the process in the public domain. Late that same year researchers at the Swiss Federal Institute of Aquatic Science and Technology (EAWAG) EAWAG in Switzerland published laboratory research designed to explain the results (Buffle et al., 2004). The bottom line is that the addition of the small amount of chlorine oxidizes the bromide to bromine; the subsequent addition of ammonia converts that bromine to bromamine, and, unlike the bromide ion, bromamine is not easily oxidized by ozone to bromate. As the EAWAG group describes it, the key reactions and their rate constants are

The oxidation of bromide is very rapid and the conversion to bromamine extremely fast. As a result, this method has the potential for preventing all mechanisms of bromate formation, as shown on Fig 19-9c. In the ozone contactor the oxidation of monobromamine is sluggish, masking the bromide from the ozone.

#### **PREOXIDATION WITH CHLORINE OR CHLORINE DIOXIDE**

SNWA studied preoxidation with chlorine to control bromate formation and found it unsatisfactory. A study at Contra Costa WD in Northern California explored the idea of preoxidation with chlorine dioxide with greater success (Zhou and Neeman, 2004). The requirements for success for this process remain somewhat elusive as substantial reductions have been achieved in some localities and not at others.

As noted earlier, ozone produces three types of by-products. Brominated organics are not produced in high enough concentration to warrant removal. Removal of the other two main types of ozonation by-products, bromate and low-MW organic by-products, are discussed below.

### **Removal of Ozonation By-products**

#### **BROMATE**

The chemistry of bromate ( $\text{BrO}_3^-$ ) is quite similar to that of nitrate ( $\text{NO}_3^-$ ): Both are monovalent anions, both are highly oxygenated, and both are at the top of their respective oxidation scales. Therefore, just like nitrate, bromate theoretically can be removed from water through the following water treatment technologies: (1) ion exchange, (2) reverse osmosis, (3) biological reduction, and (4) chemical reduction. However, these treatment technologies are not currently practical at full scale for bromate removal; the primary strategy for complying with the bromate MCL is to minimize its formation in the first place, as discussed previously. Nevertheless, the following discussion provides some insight into each option for process understanding and possible future use.

Most ion exchange (IX) resins have low selectivity for bromate that makes IX impractical for bromate removal from drinking water. Reverse osmosis (RO) can achieve greater than 90 percent removal of bromate. However, both RO and IX are more costly than any of the bromate formation control strategies discussed earlier in this chapter and produce a high-TDS residual stream that requires proper disposal. Because of these issues, RO and IX are generally impractical for bromate removal.

Bromate can be reduced biologically to bromide by denitrifying bacteria (Hijnen et al., 1995, 1999) when dissolved oxygen (DO) concentrations are low (<2.5 mg/L) and empty-bed contact times (EBCT) are high (>25 min) (Kirisits and Snoeyink, 1999; Kirisits et al., 2001). Similar to nitrification, bromate reduction is greatly inhibited by increased DO concentration. Unfortunately, this is a significant drawback to applying biological removal in a full-scale treatment plant because the DO concentration downstream of an ozonation process can be greater than 20 mg/L, especially when pure

oxygen is used for ozone generation. The requirement for high EBCT is also a drawback as typical EBCT values in a water treatment plant filter are significantly lower than 25 min.

Chemical reduction of bromate to bromide can be achieved using reducing agents such as ferrous ions ( $\text{Fe}^{2+}$ ) or the surface of activated carbon. Bromate can be reduced by  $\text{Fe}^{2+}$  under water treatment conditions according to the following reaction (Siddiqui et al., 1996):

Bromate reduction through the reaction shown in Eq. 19-26 is typically 40 to 80 percent, depending upon the dose of  $\text{Fe}^{2+}$ . The unique aspect of using ferrous as a reducing agent is that it is oxidized to ferric ( $\text{Fe}^{3+}$ ), which is used as a coagulant in water treatment. In plants that practice preozonation, a ferrous salt can be added to the rapid mix chamber downstream of the preozone contactor, which allows time for the reaction between ferrous ions and bromate to take place followed by the precipitation of the ferric coagulant formed. Even though the DO levels are high, because the rate of oxidation of  $\text{Fe}^{2+}$  with oxygen is quite slow, not all of the ferrous ions are oxidized. The residual iron passing through the treatment plant can cause aesthetic water quality problems, rendering this bromate removal option impractical unless subsequent iron removal strategies are employed (see Chap. 20).

#### LOW-MW ORGANIC BY-PRODUCTS

Ozonation of natural water forms various low-MW organic by-products such as aldehydes and carboxylic acids, all of which increase the concentration of the biodegradable organic matter (BOM) in the water. Due to the high biodegradation potential of these by-products, biologically active filtration downstream of ozonation has developed as the approach of choice for removing organic ozonation by-products. In typical dual-media filters (either anthracite–sand or GAC–sand), biological filtration will occur merely by allowing the water to pass through the filters without a disinfectant residual present. The effectiveness of BOM removal in a biological filter is affected by (1) BOM type and concentration, (2) filter media type (i.e., GAC, anthracite, and/or sand), (3) water temperature, and (4) EBCT through the filter. Additional details of biological filtration are presented in Sec. 11-8 of Chap. 11.

## Problems and Discussion Topics

---

- 19-1 For each common disinfectant used in drinking water treatment, address the following issues: (a) list the common by-products of each disinfectant, (b) identify method(s) that may be used to reduce the production of these by-products, and (c) identify methods that

- may be used to remove the by-products. Which strategy is better for each by-product—removal of the by-product or preventing the by-product from forming in the first place?
- 19-2 What is the mass concentration of 1  $\mu\text{M}$  concentrations of the following DBPs: chloroform, bromoform, dibromochloromethane, bromodichlorobromomethane, monochloroacetic acid, and monobromoacetic acid?
- 19-3 What methods can be used to reduce the concentration of NOM before disinfectants are added? Discuss their effectiveness, advantages, and disadvantages.
- 19-4 How can the formation of by-products of chlorine including brominated by-products be reduced?
- 19-5 Describe a comprehensive approach that disinfects the water and reduces the production of disinfection by-products. Be sure to describe the jar testing and chemical analyses of the raw and finished water that would be required to develop this approach.
- 19-6 What is the impact of increasing bromide ion concentration on the TTHMs?
- 19-7 Estimate the THM and HAA formation potential for the following conditions: DOC = 6.4 mg/L, UV<sub>254</sub> absorbance = 0.205 cm<sup>-1</sup>, and bromide = 0.13 mg/L.
- 19-8 Estimate the THM and HAA formation potential for the following conditions: DOC = 2.1 mg/L, UV<sub>254</sub> absorbance = 0.053 cm<sup>-1</sup>, and bromide = 0.0 mg/L.
- 19-9 Estimate the bromate formation for the following conditions: bromide concentration = 0.35 mg/L, ozone dose = 1.7 mg/L, pH = 7.5, inorganic carbon concentration = 165 mg/L, DOC concentration = 3.2 mg/L, NH<sub>3</sub>-N concentration = 0.005 mg/L, and time = 4 h.
- 19-10 Explain how ammonia addition can reduce the production of bromate when ozone is used to treat water.

## Terminology for Removal of Selected Constituents

Term	Definition
Carbonate hardness	Concentration of polyvalent ions that are associated with anions that comprise alkalinity (e.g. $\text{HCO}_3^-$ , $\text{CO}_3^{2-}$ ).
Denitrification	Reduction or conversion of nitrate to nitrogen gas.
Enhanced softening	Process of removing hardness and TOC from water using the lime-softening process.
Greensand	Sand that contains a greenish colored mineral called glauconite (iron potassium phyllosilicate) and is typically coated with manganese oxide, known as manganese greensand, and is used to remove insoluble ferric iron and manganese.
Hardness	Sum of the soluble concentrations of polyvalent ions (e.g., $\text{Ca}^{2+}$ , $\text{Mg}^{2+}$ ).
Natural radionuclotides	Molecules (e.g., radium-226, radon-222, uranium-238) that dissolve in groundwater as a result of radioactive gases and rock formations, and have unstable nuclei and emit energy in the form of ionizing radiation.
Noncarbonate hardness	Concentration of polyvalent ions in water that are associated with nonalkalinity anions (e.g., $\text{SO}_4^{2-}$ , $\text{Cl}^-$ ).
Recarbonation	Process of adding carbon dioxide to water lower the pH after softening.
Single-stage softening	Process of adding lime to water to remove only the calcium hardness from the water, leaving the magnesium hardness.
Softening	Process of removing hardness from water.
Split-flow lime treatment	Process of separating the water stream into two or more streams, softening the streams to various degrees and then blending them to obtain the desired water quality.
Two-stage excess lime-soda treatment	Process of adding an excess of lime to water to bring about the removal of both calcium and magnesium followed by stabilization of the water with soda ash treatment.

Water purveyors are continuously striving to provide their communities with potable water that is safe for human consumption and aesthetically acceptable. The primary focus of the previous chapters of this textbook has been the removal of the traditional constituents found in most natural waters. There are, however, a number of nontraditional constituents that must also be removed from some natural waters to provide potable water. The purpose of this chapter is to introduce and discuss the removal

of the most common of these nontraditional and emerging constituents, including arsenic, calcium, magnesium, nitrate, radionuclides, pharmaceutical and personal care products. However, before discussing the individual constituents, it will be helpful to review what constitutes traditional, nontraditional, and emerging constituents.

## 20-1 Traditional, Nontraditional, and Emerging Constituents

---

As discussed in Chap. 2, there are many constituents in water that impact potable water. The more common, also called traditional, constituents in most surface water supplies include turbidity, NOM, biological agents, taste and odor compounds, and low levels of synthetic organic compounds (SOCs). Low, but measurable, levels of SOCs are usually not specifically treated in present water treatment practices if their concentrations do not exceed their maximum contaminant level (MCL). In addition to the conventional constituents identified above, a variety of other constituents may be present in both surface waters and groundwaters. These other constituents are considered nontraditional in the sense that they are not encountered in most natural waters. For example, surface waters may contain inorganic constituents such as iron, manganese, hardness ( $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ), and other trace dissolved metals (e.g., Ba, Se, Ra). Groundwater sources may also contain iron, manganese, hardness, and other dissolved metals such as those described above. These nontraditional constituents in one way or another also impact the provision of potable water.

In addition to the traditional and nontraditional constituents in water, water purveyors need to be aware of emerging constituents. For example, perchlorate, *N*-nitrosodimethylamine (NDMA), methyl tertiary butyl ether (MTBE), arsenic, radium, and disinfection by-products are now cause for health concern and some are being regulated. Many of these emerging constituents can be difficult and expensive to remove using conventional water treatment practices. New innovative water treatment practices are also being developed to meet regulatory demands for these emerging constituents. For example, new-iron-oxide-based adsorbents were developed to treat water sources containing arsenic, UV technology is being used to treat NDMA in some water supplies, and modifications to conventional water treatment practices are being employed to reduce disinfection by-products (see Chaps. 13 and 19).

Several constituents in water that impact potable water and treatment processes that may be used to remove them are reported in Table 20-1. The performance of these treatment processes for a given constituent is presented subjectively in terms of removal efficiencies reported in various studies. The information presented in Table 20-1 can be used as a general guideline when a particular constituent must be removed. However,

constituents that comprise background water matrices can vary widely with respect to their number and concentration and can impact treatment process performance. Treatment processes that can be used in combination are not considered in Table 20-1.

## 20-2 Arsenic

---

Arsenic is widespread throughout our environment. For example, the crust of the Earth contains about 1.8 mg/kg of arsenic. Arsenic is typically composed of the minerals arsenopyrite ( $\text{FeAsS}$ ), orpiment ( $\text{As}_2\text{S}_3$ ), and realgar ( $\text{AsS}$ ). The lithosphere varies from less than 0.2 to about 15 mg As/kg of soil. In addition, the atmosphere contains about 0.02 to 2.8 ng/m<sup>3</sup> while the aquatic environment contains less than 0.010 µg/L (Aus Planer-Friedrich, 2001). Most commercial arsenic is obtained by heating arsenopyrite. Because arsenic is tasteless and colorless, it was well known as a poison for humans in the Middle Ages and was used as far back as AD 55 in the poisoning by Nero of Britannicus. Arsenic has also been used for medicinal purposes. In the early 1800s, arsenic was used as a remedy for curing anorexia, rheumatism, asthma, tuberculosis, and diabetes and the treatment of malaria until the discovery of penicillin. Commercial uses of arsenic today include wood preservatives (accounts for 90 percent usage), paints, dyes, metals, drugs, soaps, rat poison, and semiconductors.

In the past few decades, the long-term exposure to arsenic has become a major health concern throughout the world. More than 100 million people worldwide are ingesting drinking water from wells that contain arsenic. Among other potential health risks, recent research shows a strong dose-dependent relationship between arsenic exposure and accelerated development of atherosclerosis in the arteries leading to the brain. Studies have suggested that arsenic may cause liver, kidney, and bladder cancer (Smith et al., 1992). Pontius et al. (1994) summarized the health implications of arsenic on humans. More recently, the water industry has focused some of its efforts on arsenic occurrence in water supplies and methodologies for its removal.

The concentrations of arsenic in water from various places throughout the world are summarized in Table 20-2. Perhaps the most well known area of the world noted for arsenic problems is in Bangladesh. It is estimated that 28 to 35 million people are exposed to arsenic in drinking water wells with arsenic concentrations exceeding 0.05 mg/L, and between 200,000 to 270,000 arsenic-related deaths from cancer are expected in this country alone (Smith et al., 1992). The U.S. EPA has estimated that some 13 million people in the United States, primarily in the western states, are exposed to arsenic in drinking water at levels greater than 0.01 mg/L.

The World Health Organization (WHO) proposed limit on arsenic in drinking water is 0.01 mg/L, which is largely based on analytical capability.

**Table 20-2**

Source: Adapted from WHO (2001) Draft Report.

Developed countries such as the United States, European community, Japan, and Canada have adopted the 0.01-mg/L limit. The implications of these new regulations in terms of health and cost to society are discussed in several references (U.S. EPA, 2000, 2001; WHO, 2001; Health Canada, 2006). Presented below is a short summary of the forms of arsenic found in water followed by present treatment technologies for removing arsenic from water supplies.

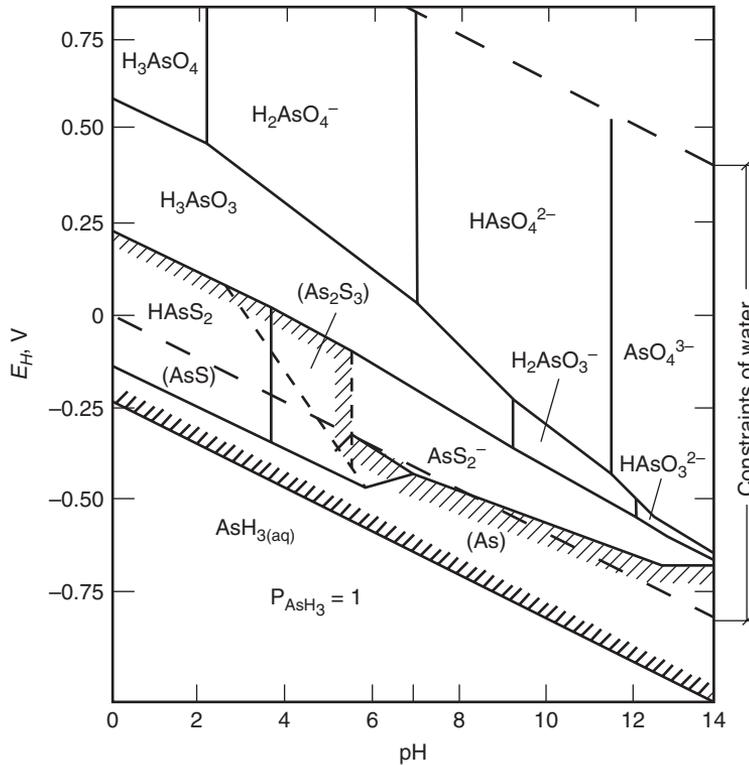

### Chemical Properties

A brief review of the chemical properties of arsenic in water is useful in understanding the treatment processes available for arsenic removal. Arsenic can occur in four oxidation states in water (+5, +3, 0, -3) but is usually found only in the trivalent [arsenite, As(III)] and pentavalent [arsenate, As(V)] states.

The predominance diagrams for arsenite and arsenate as a function of pH are shown on Fig. 20-1. In the pH range from 2 to 9, the undissociated form of arsenite ( $\text{H}_3\text{AsO}_3$ ) is the predominate species. Most natural As(III)-containing surface and groundwaters in the pH range of 6.5 to 8.5 will have As in the  $\text{H}_3\text{AsO}_3$  form. Arsenate ( $\text{HAsO}_4^{2-}$ ) will be present in the pH range from 7 to 11.5, which will most likely occur in the normal pH range for most water supplies. For pH values less than 7.0,  $\text{H}_2\text{AsO}_4^-$  will be the predominate species.

**Figure 20-1**  
Predominance diagram for As(III) and As(V) as function of pH. (Adapted from Gupta and Chen, 1978.)

**Figure 20-2**

The  $E_H$ -pH diagram for arsenic at 25°C and 1 atm with total arsenic  $10^{-5}$  mol/L and total sulfur  $10^{-3}$  mol/L. Solid species are enclosed in parentheses in cross-hatched area, which indicates solubility less than  $10^{-5.3}$  mol/L. (adapted From Ferguson and Gavis, 1972. Reprinted with permission.)

The  $E_H$ -pH diagram for arsenic in the presence of oxygen, sulfur, and water at 25°C and 1 atm is presented on Fig. 20-2. The  $E_H$ -pH diagram represents the equilibrium condition of arsenic under various redox potentials and pH conditions. For surface waters that are well aerated (oxidizing or high  $E_H$  conditions),  $H_2AsO_4^-$  becomes the dominant species at pH values less than about 6.9 and  $HAsO_4^{2-}$  becomes the dominant species at higher pH values. Usually little or no As(III) is present under oxidizing conditions. For well waters that contain little dissolved oxygen (mildly reducing or low  $E_H$  values),  $H_3AsO_3$  should be the dominant species for pH values less than about 9.2.

In the presence of relatively high concentrations of reduced sulfur, dissolved arsenic-sulfide species can be present. Reducing, acidic conditions will favor the formation of reduced sulfur species such as orpiment ( $As_2S_3$ ), realgar (AsS), or other sulfide-arsenic species. Waters high in arsenic are usually not expected where there is a high concentration of free sulfide. Thioarsenite species are more likely to be present at neutral and alkaline pH in the presence of very high sulfide concentrations. In addition, organic arsenic forms can be produced by biological activity in some surface waters but are not routinely measured.

**Treatment  
Strategies**

Treatment strategies for arsenic removal from water supplies include (1) conventional coagulation, (2) sorption with ferric and aluminum oxides, (3) ion exchange, and (4) membranes. More recently, the use of nonconventional adsorbents such as ferric and aluminum oxides have been evaluated as potential treatment alternatives for the removal of arsenic. A brief discussion of these treatment practices is presented and references are provided for further reading in this section.

**COAGULATION PROCESSES**

Traditionally, coagulation and filtration processes have been used to remove arsenic. Coagulants such as alum, ferric chloride, ferric sulfate, and lime have been used to remove arsenic to varying degrees. Coagulation processes usually require arsenic to be in the form of As(V); if arsenite, As(III), is present, it is usually oxidized first using chlorine, permanganate, or ozone. The mechanisms for As(V) removal by coagulation processes may be a combination of precipitation, coprecipitation, and adsorption. Edwards (1994) provides a discussion of the mechanisms associated with arsenic removal.

The performance results from several pilot- and full-scale studies using various coagulation processes are summarized in Table 20-3. Observed removals using ferric chloride have ranged from 81 to 100 percent using coagulant dosages from 5 to 304 mg/L. Typical doses for ferric salts are 5 to 30 mg/L and the pH is usually below 8.0. Alum coagulation has resulted in removals ranging from 23 to 100 percent with dosages from 6 to 50 mg/L. Typical dosages for alum are 10 to 50 mg/L and the pH is usually between 6 and 7.0. For Fe–Mn treatment processes, where the  $\text{Fe}^{2+}$  concentrations are greater than about 1.5 mg/L, around 80 to 90 percent of the As is removed. Plants that remove only Mn did not achieve significant removals of arsenic (McNeill and Edwards, 1997). Arsenic removals ranging from 60 to 90 percent have been observed in softening plants that use excess lime for  $\text{Mg}^{2+}$  treatment. For single-stage softening plants that only remove  $\text{Ca}^{2+}$ , arsenic removals of 0 to 40 percent have been observed. For source waters containing high levels of phosphate or silicate, coagulation can be less effective for arsenic removal. For waters containing sulfides, As(III) is precipitated as AsS and  $\text{As}_2\text{S}_3$ . Jar test screening is recommended at the bench level to evaluate different options for arsenic removal when using coagulants.

**SORPTION PROCESSES**

Because adsorption onto alum, ferric, and lime precipitates is a major arsenic removal mechanism, adsorbents composed of similar surface adsorption properties have been tested and also found to be promising for the removal of arsenic. Two promising granular adsorbents are activated alumina and granular ferric hydroxide (GFH) based adsorbents. The properties of these two granular adsorbents are reported in Table 20-4. In the fixed-bed

**Table 20-3**

mode of operation, these adsorbents were tested successfully at both the pilot and full scale in the United States and Europe on natural waters. The results of some studies that have been performed on these adsorbents are given in Table 20-5. The reported range of capacities for activated alumina is from 1000 to 13,000 bed volumes (BV) but typically around 10,000 BV. The GFH adsorbent capacities have ranged from 32,000 up to 85,000 BV depending upon the water quality. The GFH adsorbents are very attractive from a performance standpoint; however, at this time the cost is rather prohibitive for large systems. For both adsorbents, the capacities will depend upon water quality parameters such as temperature, pH, and competing constituents in the water matrix, which may include NOM and competing ions (e.g., phosphate, silicate, sulfate). For example, activated

**Table 20-5**  
Comparison of results for adsorbents in fixed beds in removing arsenic from water supplies

Adsorbent	Influent Arsenic Concentration, $\mu\text{g/L}$	Treatment Objective, $\mu\text{g/L}$	Bed Volumes Treated	Reference
Activated alumina	70	10	1,000	Benjamin et al. (2000)
	50	10	10,000	Benjamin et al. (2000)
	21	10	13,000	Clifford (1999)
	23	10	110,500	Simms and Azizian (1997)
	98	50	16,000	Clifford (1999)
	22	10	15,600	Clifford (1999)
	100	10	9,000	Rubel and Hathaway (1985)
Granular ferric hydroxide (GFH) based adsorbent	15–20	10	85,000	Driehaus et al. (1998)
	100	10	25,000	Thomson et al. (2005)
	100–180	—	34,000	Driehaus et al. (1998)
	21	—	37,000	Driehaus et al. (1998)
	16	—	32,000	Driehaus et al. (1998)

alumina performs best at pH values around 5.5 to 6.0 and drops off sharply above 7.0. It should also be noted that preoxidation of the water to convert any As(III) to As(V) is usually performed before the adsorption process.

In some cases, activated alumina can be regenerated with a strong base followed by a strong acid. Reported recoveries of arsenic from the regeneration process are about 75 percent. For small systems, one-time use may be more economical than regeneration, which will be required for large systems. A good discussion of the design and regeneration of activated alumina for fluoride removal is presented by Clifford (1999). The design parameters for arsenic removal may be similar; however, rapid small-scale and pilot testing may be used to develop site-specific design information. In addition, the use of powdered activated alumina coupled with membranes (microfiltration and ultrafiltration) may also be a promising treatment process.

Presently, the GFH adsorbent is used once and disposed of in a landfill. Regeneration techniques for GFH may be necessary to make it an economically viable process for large systems. Other adsorbents such as manganese greensand, manganese dioxide, hydrous iron oxide particles, and iron-oxide-coated sand may be promising if verified through pilot testing and if it can be demonstrated that these processes are viable and economically feasible at full scale.

#### ION EXCHANGE

Ion exchange can be a viable process for the removal of arsenic from natural waters. Design considerations for arsenic removal by ion exchange include (1) oxidation state of arsenic, (2) resin type, (3) background ion concentrations and type of ion, (4) empty-bed contact time (EBCT), (5) regenerant strength and level, and (6) spent-brine reuse and treatment. Some of the design considerations for arsenic removal by ion exchange are discussed in this section, and an in-depth discussion is presented in Clifford (1999).

From the speciation diagram given on Fig. 20-1, As(V) is present as monovalent  $\text{H}_2\text{AsO}_4^-$  and divalent  $\text{HAsO}_4^{2-}$  in the pH range of natural waters, 6 to 9. If As(III) is present in the water, it usually exists as a neutral species, which cannot be removed by ion exchange and must be oxidized to As(V) prior to ion exchange treatment. For waters with total dissolved solids (TDS) concentrations less than about 500 mg/L and sulfate concentrations less than about 120 mg/L, anion ion exchange can be an economically attractive process for arsenic removal (Frey and Edwards, 1997). At low TDS and sulfate concentrations the competition for resin exchange sites with arsenic is low, and reasonable exchange capacity for arsenic can be achieved. However, for waters containing high sulfate and TDS levels, ion exchange may not be a viable process (Clifford and Ghurye, 1998b). For waters having high pH and alkalinity and low sulfate concentration, As(V) can be effectively treated with an anion exchange resin in the chloride form (Clifford and Lin, 1986).

*Type of strong-base resin*

With respect to the type of strong-base anion (SBA) exchange resin, no significant difference in performance has been observed among the various resins and both type 1 and type 2 polystyrene resins may provide slightly higher breakthrough capacities than other SBA resins. For waters containing arsenic and nitrate,  $\text{HAsO}_4^{2-}$  has a poor affinity for monovalent nitrate-selective resins and should be avoided. When using conventional SBA resins, another concern is nitrate peaking or chromatographic overshoot due to the ions having different affinities for the resin. Nitrate has a slightly lower affinity than arsenic for standard SBA resins (see Chap. 16, Table 16-4) and will increase in liquid-phase concentration as it is pushed through the column and eventually will be present in the effluent at a much higher concentration than the influent concentration. The nitrate effluent concentration can sometimes exceed the effluent guidelines for nitrate in the water. Care should be taken to shorten the arsenic loading cycle time such that the nitrate standard is not exceeded. Nitrate will typically appear in the effluent just before arsenic breakthrough. In addition, lowering the pH to produce monovalent arsenic is not effective because  $\text{H}_2\text{AsO}_4^-$  affinity is much less than  $\text{HAsO}_4^{2-}$  (Clifford, 1999).

Based on pilot studies for arsenic removal, it has been shown that arsenic leakage (see Chap. 16) can develop during exhaustion cycles, but the observed concentrations (0.2 to 0.8  $\mu\text{g}/\text{L}$ ) are well below the proposed MCL of 10  $\mu\text{g}/\text{L}$ . Arsenic leakage increases when particulate iron concentrations in the water increase due to the adsorption of the arsenic onto the iron particles. Steps should be taken to provide particulate filtration prior to the ion exchange process.

*General design considerations*

Typical EBCTs for arsenic removal range from 1.5 to 3.0 min and other operational parameters are similar to those presented in Table 16-1 in Chap. 16. Arsenic-loaded SBA resins can be regenerated easily with NaCl. Because arsenic is a divalent ion, it undergoes selectivity reversal in the presence of high-ionic-strength solutions and consequently is easy to remove from the resin during regeneration. In addition, regeneration superficial velocities greater than 0.02 m/h were found to work best for arsenic because they resulted in higher arsenic recoveries.

Down-flow co-current regeneration has been shown to be more effective for regenerating arsenic-laden resins than the conventional countercurrent mode of regeneration (Clifford and Ghurye, 1998a). Co-current is more effective because at the end of the exhaustion cycle the arsenic that is exchanged onto the resin bed is located near the feed end of the bed. Consequently, when the regenerant is passed through the bed in the down-flow mode, the regenerant is contacted with the highest arsenic resin concentration. Down-flow co-current regeneration will reduce arsenic leakage.

*Brine management*

Brine reuse and treatment are important in the removal of arsenic by ion exchange (see also Chap. 21). Field studies have demonstrated that arsenic-laden resin could be regenerated successfully using spent brine for over 20 regeneration cycles before arsenic leakage exceeded 10  $\mu\text{g/L}$  (Clifford, 1999). Sodium chloride was added to the spent-brine solution to maintain a 1.0 N NaCl solution concentration. The concept of brine reuse should be investigated because it can provide significant cost savings with respect to lowering the salt requirements and brine disposal volume. Waste brine containing arsenic needs to be treated prior to disposal. Arsenic can be precipitated using  $\text{FeCl}_3$ , alum, or lime. For a brine waste containing 90 mg/L of As(V) and 50,000 mg/L TDS, about 12 times the stoichiometric quantity of  $\text{FeCl}_3$  is required to reduce the As(V) concentration to less than 5 mg/L. Arsenic removal is very pH dependent, and greater than 99 percent As(V) can be removed from the brine solution using an iron-to-arsenic ratio of 20 : 1 at a final pH of around 5.5. Consequently, pH adjustment should be included in brine disposal evaluations.

**MEMBRANES**

A number of studies have been conducted to evaluate the use of membranes for arsenic removal (Moore et al., 2008; Ghurye et al., 2004; Brandhuber and Amy, 1998; Chang et al., 1994; Hering and Elimelech, 1996; Thompson and Chowdhury, 1993). In one study, several ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO) membranes were evaluated for arsenic removal from two spiked groundwater sources from Southern California (Brandhuber and Amy, 1998). Based on these studies, guidelines for arsenic removal using membrane treatment are summarized in Table 20-6. The combined treatment using coagulation and membranes can be used to effectively remove arsenic, and if arsenic is in particulate form, large-pore-size membranes may be effective in As removal. The As(III) form can only be removed by RO; otherwise it must be preoxidized, forming As(V) before membrane treatment. Reverse osmosis and NF can effectively remove the dissolved form of As(V), and tight UF membranes may be effective as well. Waters high in dissolved organic carbon (DOC) may inadvertently cause poor arsenic removal due to membrane fouling.

## 20-3 Iron and Manganese Removal

---

The fundamental concepts involved with removal of soluble iron and manganese are similar and the two often occur together in water supplies. These soluble species are typically unstable when exposed to oxidants such as dissolved oxygen and when processed in a water treatment plant will usually form precipitate during treatment, in the distribution piping system, or at the point of use. However, depending upon which treatment processes are used, it may be important to control these precipitation reactions. The

**Table 20-6**

Guidelines for the use of membranes for arsenic removal in water treatment<sup>a</sup>

most common treatment approach is to precipitate all the soluble forms of iron and manganese so that these constituents can be removed in other processes such as sedimentation and filtration. In addition to controlling the soluble species, colloidal and/or particulate iron and manganese are also important and must be considered in the overall removal. Consequently, the following sections provide a brief discussion of the background of these species, as well as their chemistry as related to redox properties, followed by control methods.

Iron is the fourth most abundant element in the Earth's crust, making up about 5.6 percent of the mass (McMurry and Fay, 2003). Common mineral sources (deposits) of iron include ferric oxides and hydroxides such as hematite ( $\text{Fe}_2\text{O}_3$ ) and ferric hydroxide [ $\text{Fe}(\text{OH})_3$ ]. Ferric hydroxide gives rocks and soils their red and yellowish color. Sedimentary forms of iron may include sulfides, such as pyrite and marcasite; two minerals with identical composition ( $\text{FeS}_2$ ) but different crystalline structures; carbonates such as siderite ( $\text{FeCO}_3$ ); and mixed oxides such as magnetite ( $\text{Fe}_3\text{O}_4$ ). The ferrous oxides and sulfides are the usual sources of dissolved iron in groundwaters. Weathering of iron silicates can produce dissolved iron in surface water; however, this is a relatively slow process.

#### OCCURRENCE AND IMPORTANCE IN WATER SUPPLIES

The interactions between iron-bearing soils or rock formations and water surrounding it can dissolve iron into the water. Iron is relatively soluble in a reducing environment or in natural waters, such as some low-oxygen-containing groundwaters and low-oxygen surface water, such as hypolimnetic waters of eutrophic lakes, large rivers, and reservoirs. In these waters, iron may be found in the reduced or ferrous form ( $\text{Fe}^{2+}$ ) such as

## Iron

ferrous sulfate ( $\text{FeSO}_4$ ) and ferrous bicarbonate [ $\text{Fe}(\text{HCO}_3)_2$ ], hydroxide forms, or complexed with NOM. Low-alkalinity (<50 mg/L as  $\text{CaCO}_3$ ) groundwaters may contain up to 10 mg/L of total iron. Also, some water treatment plant operators have observed high concentrations of iron in the raw water obtained from the hypolimnetic zone of reservoirs during periods of stagnation and stratification as it is seasonally mobilized from reduced lake sediments (Stumm and Lee, 1961).

Correspondingly, iron is very insoluble in an oxidizing environment or in natural waters containing sufficient quantities of dissolved oxygen. Depending upon the water quality, iron can exist in three physical forms: as large oxidized particles, small oxidized colloidal particles, and the soluble

reduced form. The smaller particles can often pass through filters of 0.45  $\mu\text{m}$  pore size or smaller and are therefore classified as soluble in many operational schemes. For example, oxygenated surface waters (pH 5 to 8) typically have total iron concentrations in the range of 0.05 to 0.2 mg/L. In these waters, iron species present may consist of solids of large oxidized particles or small colloidal particles of ferric hydroxide sorbed onto clay particles, organic colloids, and other suspended solids and precipitates.

The U.S. EPA (1991) Secondary Drinking Water Regulations limit iron to 0.3 mg/L for taste and aesthetic reasons. The only advantage of having iron in water is for nutritional value, but only 1 to 2 mg/d is needed and most humans intake about 7 to 35 mg/d. Thus, daily consumption of water is not a major source of iron. There are several disadvantages of having iron in water supplies. Iron ions impart a metallic taste, and the taste threshold is reported to be around 0.1 to 0.2 mg/L of ferrous sulfate or ferrous chloride as  $\text{Fe}^{2+}$ . Ferrous iron may precipitate as ferric hydroxide after oxidation and stain laundry and household fixtures such as bathtubs, porcelain basins, glassware, and dishes. Iron may discolor industrial products such as textiles and paper. Threshold values for industrial and commercial uses of iron are listed in Table 20-7. Iron precipitates can clog pipes and support the growth of iron bacteria (*Crenothrix* and *Gallionella*), which can cause taste and odor problems.

#### CHEMICAL PROPERTIES

While the chemistry of iron oxidation is complex and not clearly understood, there are some useful physical/chemical relationships that can be used to interpret observations made in water treatment facilities. Parameters that affect iron oxidation and its rate include water temperature and pH and constituents in the water such as dissolved oxygen (DO), bicarbonate, NOM, sulfate, dissolved silica, and particles. Many of these parameters are discussed below to help explain iron oxidation.

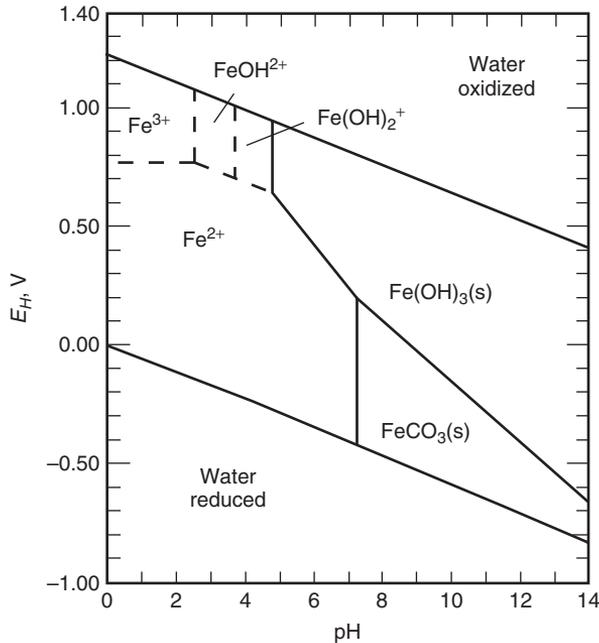

An  $E_H$ -pH diagram for iron is presented on Fig. 20-3. The equilibrium form of various iron species that would be expected under the conditions stated, at any specific  $E_H$ -pH combination, is shown with the boundary defined by the  $E_H$ -pH limit of water. The solid forms of iron are shown with an (s). Under reducing conditions ( $E_H < 0$ ), over a wide range of pH, iron solubility is low and pyrite tends to precipitate. Under oxidizing conditions ( $E_H > 0$ ) and pH values above 5.0, iron tends to precipitate to ferric hydroxide [ $\text{Fe}(\text{OH})_3$ ]. Between these two regions ferrous iron is quite soluble, and this region corresponds to typical  $E_H$ -pH conditions of groundwater (pH 5 to 9 and  $E_H$  0.20 to  $-0.10$  V).

The stoichiometric expressions for the oxidation of ferrous iron using DO and some commonly used oxidants are shown in Table 20-8. In addition, the quantity of oxygen required, the alkalinity consumed, and an estimate of the sludge produced are also provided in Table 20-8.

**Table 20-8**  
Oxidation reactions for iron

Oxidant	Reaction	Equation Number	Oxidant Needed, mg/mg Fe <sup>2+</sup>	Alkalinity Used, mg/mg Fe <sup>2+</sup>	Sludge Produced, <sup>a</sup> kg/kg Fe <sup>2+</sup>
Oxygen	$4\text{Fe}(\text{HCO}_3)_2 + \text{O}_2 + 2\text{H}_2\text{O} \rightarrow 4\text{Fe}(\text{OH})_3 + 8\text{CO}_2$	20-1	0.14	1.80	1.9
Chlorine	$2\text{Fe}(\text{HCO}_3)_2 + \text{Ca}(\text{HCO}_3)_2 + \text{Cl}_2 \rightarrow 2\text{Fe}(\text{OH})_3 + \text{CaCl}_2 + 6\text{CO}_2$	20-2	0.64	2.70	1.9
Chlorine dioxide	$\text{Fe}(\text{HCO}_3)_2 + \text{NaHCO}_3 + \text{ClO}_2 \rightarrow \text{Fe}(\text{OH})_3 + \text{NaClO}_2 + 3\text{CO}_2$	20-3	1.21	2.70	1.9
Potassium permanganate	$3\text{Fe}(\text{HCO}_3)_2 + \text{KMnO}_4 + 2\text{H}_2\text{O} \rightarrow 3\text{Fe}(\text{OH})_3 + \text{MnO}_2 + \text{KHCO}_3 + 5\text{CO}_2$	20-4	0.94	1.50	2.43

<sup>a</sup>Sludge weight is based on Fe(OH)<sub>3</sub> as the precipitate; however, it is likely that portions of the sludge will contain FeCO<sub>3</sub>.

**Figure 20-3**

Forms of iron in water as function of redox potential versus pH constructed with total iron activity  $10^{-7}$  M or  $5.6 \mu\text{g/L}$ ,  $96 \text{ mg/L SO}_4^{2-}$ ,  $\text{CO}_2$  species at  $1000 \text{ mg/L HCO}_3^-$ , temperature at  $25^\circ\text{C}$ , and pressure of 1 atm (adapted from Langmuir, 1997).

#### KINETICS OF IRON OXIDATION

In the absence of iron complexed with NOM and pH values greater than 5.5, the rate of oxygenation of  $\text{Fe}^{2+}$  iron was found to be first order with respect to  $\text{Fe}^{2+}$  and  $\text{O}_2$  and second order with respect to  $\text{OH}^-$  ion (Stumm and Lee, 1961). Based on these experimental observations, the following expression was proposed:

$$-\frac{d[\text{Fe}^{2+}]}{dt} = k[\text{Fe}^{2+}][\text{OH}^-]^2 P_{\text{O}_2} = k_r[\text{Fe}^{2+}] \quad (20-5)$$

where  $[\text{Fe}^{2+}]$  = aqueous-phase ferrous iron concentration, mol/L  
 $k$  = rate constant, typically  $8.0(\pm 2.5) \times 10^{13} \text{ L}^2/\text{mol}^2 \cdot \text{min} \cdot \text{atm}$  at  $20^\circ\text{C}$  (Stumm and Morgan, 1996)  
 $[\text{OH}^-]$  = aqueous-phase hydroxide ion concentration, mol/L  
 $P_{\text{O}_2}$  = partial pressure of oxygen, atm  
 $k_r$  = pseudo-first-order constant,  $\text{min}^{-1} = k[\text{OH}^-]^2 P_{\text{O}_2}$

The oxygenation rate of  $[\text{Fe}^{2+}]$  is very dependent upon pH, as shown in Eq. 20-5. The dependence of the oxygenation rate of  $\text{Fe}^{2+}$  on pH is shown on Fig. 20-4. The y axis represents the log of the rate of oxygenation of  $\text{Fe}^{2+}$  with respect to time and is obtained by rearrangement of Eq. 20-5 as

$$k[\text{OH}^-]^2 P_{\text{O}_2} = -\frac{d[\text{Fe}^{2+}]}{[\text{Fe}^{2+}] dt} = -\frac{d \ln [\text{Fe}^{2+}]}{dt} \quad (20-6)$$

### Example 20-1 Theoretical stoichiometric calculation

A 100,000-m<sup>3</sup>/d raw-water source containing 5 mg/L ferrous iron is oxidized to ferric hydroxide with oxygen. Calculate the quantity of oxygen required, alkalinity consumed as CaCO<sub>3</sub>, and quantity of sludge produced as ferric hydroxide.

#### Solution

1. Determine the quantity of oxygen required using Eq. 20-1 in Table 20-8:

Dissolved oxygen required

$$\begin{aligned}
 &= (5 \text{ Fe}^{2+} \text{ mg/L}) (0.14 \text{ mg O}_2/\text{mg Fe}^{2+}) \\
 &\quad (100,000 \text{ m}^3/\text{d}) (1 \text{ kg}/10^6 \text{ mg}) (10^3 \text{ L}/\text{m}^3) \\
 &= 70 \text{ kg/d}
 \end{aligned}$$

2. Determine the quantity of alkalinity consumed as CaCO<sub>3</sub> using the values shown in Table 20-8:

Quantity alkalinity consumed

$$\begin{aligned}
 &= (5 \text{ mg Fe}^{2+}/\text{L}) (1.80 \text{ mg alkalinity}/\text{mg Fe}^{2+}) \\
 &\quad (100,000 \text{ m}^3/\text{d}) (1 \text{ kg}/10^6 \text{ mg}) (10^3 \text{ L}/\text{m}^3) \\
 &= 900 \text{ kg/d}
 \end{aligned}$$

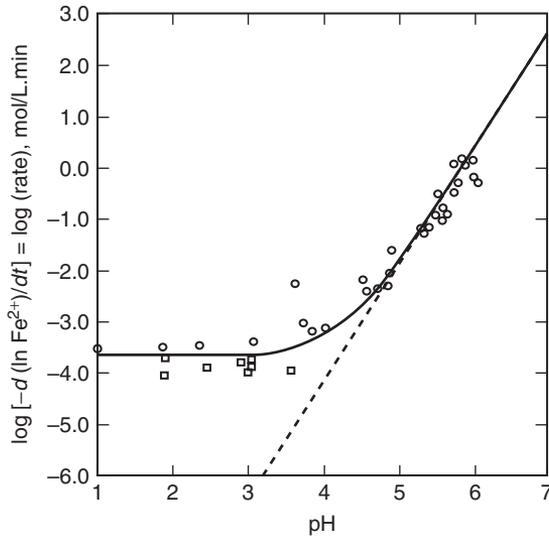

3. Estimate the quantity of sludge produced as ferric hydroxide using values from Table 20-8:

Sludge produced as Fe(OH)<sub>3</sub>

$$\begin{aligned}
 &= (5 \text{ mg Fe}^{2+}/\text{L}) (1.90 \text{ mg sludge}/\text{mg Fe}^{2+}) \\
 &\quad (100,000 \text{ m}^3/\text{d}) (1 \text{ kg}/10^6 \text{ mg}) (10^3 \text{ L}/\text{m}^3) \\
 &= 950 \text{ kg/d}
 \end{aligned}$$

#### Comment

Oxygen addition is seldom used to precipitate iron because iron is typically complexed to NOM and the oxidation kinetics are too slow.

**Figure 20-4**

Oxidation rate of  $\text{Fe}^{2+}$  by oxygen for  $P_{\text{O}_2} = 0.20$  atm and temperature =  $25^\circ\text{C}$ . (Adapted from Singer and Stumm, 1970.)

Assuming the oxygen partial pressure is constant, Eq. 20-6 can be written as

$$-\frac{d \ln [\text{Fe}^{2+}]}{dt} = k' [\text{OH}^-]^2 \quad (20-7)$$

where  $k'$  = rate constant,  $\text{L/mol} \cdot \text{min}$ ,  $= kP_{\text{O}_2}$

Taking the logarithms of both sides and substituting  $K_w/[\text{H}^+]$  for  $[\text{OH}^-]$ , the following expression for the log of the rate of oxygenation of  $\text{Fe}^{2+}$  can be obtained (Snoeyink and Jenkins, 1980):

$$\log (\text{rate}) = \log (k'') + 2 \text{pH} \quad (20-8)$$

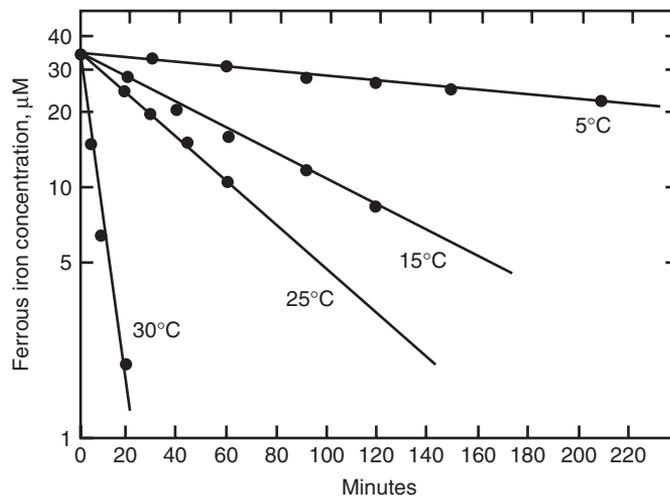

where  $k'' = \text{constant}$ ,  $k' K_w^2$

#### *Effect of pH*

For pH values greater than 5.5, the experimental data and Eq. 20-5 are in agreement, and the rate of oxygenation of  $\text{Fe}^{2+}$  increases by 100-fold per pH unit. For pH values less than about 3.5, the oxygenation of  $\text{Fe}^{2+}$  is independent of pH.

#### *Effect of temperature*

The effect of temperature on the rate of oxygenation of  $\text{Fe}^{2+}$  appears to be large when data are plotted as shown on Fig. 20-5 (Sung and Morgan, 1980). However, when the data on Fig. 20-5 are normalized with respect to changes in  $K_w$  and  $\text{O}_2$  solubility with temperature, the change in the value of the rate constants is small (Sung and Morgan, 1980).

**Figure 20-5**

Impact of temperature on oxygen kinetics of  $\text{Fe}^{2+}$ . The experiments were conducted in 0.11 M ionic strength and adjusted with  $\text{NaClO}_4$ . The alkalinity was equal to  $9.0 \times 10^{-3}$  M as  $\text{HCO}_3^-$ , pH was equal to 6.82,  $P_{\text{O}_2}$  was 0.2 atm, and the initial  $\text{Fe}^{2+}$  concentration was 0.0347 M. (Adapted from Sung and Morgan, 1980.)

#### *Effect of ionic strength*

The impact of ionic strength on the oxygenation rate of  $\text{Fe}^{2+}$  is shown in Table 20-9. Increasing the ionic strength by a factor of about 10 from 0.009 to 0.11 M decreases the rate by about a factor of 4 from  $4.0 \times 10^{13}$  to  $1.2 \times 10^{13} \text{ M}^{-2} \cdot \text{atm}^{-1} \cdot \text{min}^{-1}$ . The time required for 50 percent reduction of the  $\text{Fe}^{2+}$  concentration in seawater is nearly 100 times larger than values observed for freshwater (Kester et al., 1975). The presence of  $\text{Cl}^-$  and  $\text{SO}_4^{2-}$  is believed to form complexes with the  $\text{Fe}^{2+}$  ion and inhibit oxygenation (Tamura et al., 1976).

**Table 20-9**

Impact of ionic strength on oxygenation rate constant for  $\text{Fe}^{2+}$

Ionic Strength, mol/L	$k$ , $(\text{mol/L})^{-2} \cdot \text{atm}^{-1} \cdot \text{min}^{-1}$
0.009	$4.0 \pm 0.6 \times 10^{13}$
0.012	$3.1 \pm 0.7 \times 10^{13}$
0.020	$2.9 \pm 0.6 \times 10^{13}$
0.040	$2.2 \pm 0.5 \times 10^{13}$
0.060	$1.8 \pm 0.3 \times 10^{13}$
0.110	$1.2 \pm 0.2 \times 10^{13}$

<sup>a</sup> $T = 25^\circ\text{C}$ ; alkalinity =  $9 \times 10^{-3}$  M  $\text{HCO}_3^-$ ;  $[\text{Fe}^{2+}]_0 = 34.7 \mu\text{M}$ ;  $P_{\text{O}_2} = 0.20$  atm; pH = 6.84.

Sources: Adapted from Faust and Aly (1998).

*Effect of complexing agents*

Organic complexing agents can also impact the oxygenation of  $\text{Fe}^{2+}$ . Humic and tannic acids or other NOM can bind or complex iron and slow down the kinetics of oxidation. Iron complexed with NOM, often referred to as filterable iron because it is soluble, is usually associated with water sources high in organic color. The chemistry of NOM and its interactions with metals are very complex and considerable research has been performed to elucidate the chemical nature of these yellow-colored organic iron complexes (Liao et al., 1982; Thurman, 1985). Soluble  $\text{Fe}^{2+}$  has been shown to not complex in the presence of humic acid at low pH values ( $\text{pH} < 5$ ), but increasing the pH ( $\text{pH} > 8.0$ ) can result in the formation of a soluble  $\text{Fe}^{2+}$  complex. This complexing ability was attributed to greater dissociation of carboxyl groups of the humic acid. It was proposed that humic acids could chemically reduce  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$  followed by complexation of the  $\text{Fe}^{2+}$  with the humic acids. The presence of humic and tannic acids has also been shown to inhibit the oxygenation of  $\text{Fe}^{2+}$  (Theis and Singer, 1974). In addition, organically bound  $\text{Fe}^{2+}$  cannot be effectively oxidized by the use of aeration (Kawamura, 2000).

Even though manganese makes up a very small percentage of the Earth's crust (<0.1 percent), it is abundant in rocks and soils. Manganese is an essential nutrient for both humans and plants. Typical daily intake is about 10 mg, the majority of which comes from food sources. For plants, manganese moves as an enzyme activator and in animals it is important in growth and in nervous system functioning.

**Manganese****OCCURRENCE AND IMPORTANCE IN WATER**

Manganese is similar to iron in that it is usually present in the +2 oxidation state ( $\text{Mn}^{2+}$ ) in anoxic groundwaters and in the hypolimnion region of reservoirs and eutrophic lakes. When the groundwater is pumped to the surface and when the hypolimnetic waters are mixed, the  $\text{Mn}^{2+}$  is exposed to oxygen and begins to undergo a series of oxidation reactions to  $\text{Mn}^{4+}$ . This oxidation is accompanied by a decrease in pH and DO concentration and the formation of  $\text{MnO}_2$  precipitate. Manganese may cause aesthetic problems such as laundry and fixture staining. Manganese concentrations around 0.2 to 0.4 mg/L may also impart an unpleasant taste to water and can promote the growth of microorganisms in reservoirs and distribution systems. Consumer complaints have been documented with manganese concentrations as low as 20  $\mu\text{g/L}$  (Sly et al., 1990). The U.S. EPA (1991) specifies a secondary MCL for manganese of 50  $\mu\text{g/L}$ .

**CHEMICAL PROPERTIES**

Typically manganese occurs in the form of oxides and hydroxides. Manganese has eight oxidation states [ $\text{Mn}^0$ ,  $\text{Mn}^{2+}$ ,  $\text{Mn}_3\text{O}_4(\text{s})$ ,  $\text{Mn}_2\text{O}_3(\text{s})$ ,  $\text{MnO}_2$ ,  $\text{MnO}_4^{3-}$ ,  $\text{MnO}_4^{2-}$ , and  $\text{MnO}_4^-$ ]. At pH values of most natural waters,

### Example 20-2 Time required for Fe<sup>2+</sup> oxidation from a groundwater

Groundwater with a soluble Fe<sup>2+</sup> concentration of 5.0 mg/L is to be oxidized by aeration to a Fe<sup>2+</sup> concentration of 0.3 mg/L. The raw-water pH is 7.0 with a temperature of 10°C, and it is assumed that P<sub>O<sub>2</sub></sub> is in equilibrium with the atmosphere. A typical pseudo-first-order rate constant for the oxygenation of Fe<sup>2+</sup> is 0.168 min<sup>-1</sup>. For steady-state operation and a flow rate of 10,000 m<sup>3</sup>/d (2.64 mgd), calculate and compare the minimum hydraulic detention time and reactor volume for the oxidation of Fe<sup>2+</sup> to Fe<sup>3+</sup> for a completely mixed flow reactor (CMFR) and for a plug flow reactor (PFR).

#### Solution

1. Determine the steady-state residence time for the CMFR using Eq. 6-37:

$$\begin{aligned}\tau_{\text{CMFR}} &= \frac{C_{A0} - C_A}{kC_A} = \frac{\text{Fe}_0^{2+} - \text{Fe}^{2+}}{k'\text{Fe}^{2+}} = \frac{(5.0 - 0.3) \text{ mg/L}}{(0.168 \text{ min}^{-1})(0.3 \text{ mg/L})} \\ &= 93 \text{ min}\end{aligned}$$

2. Determine the CMFR volume:

$$\begin{aligned}V_{\text{CMFR}} &= Q\tau_{\text{CMFR}} = (93 \text{ min})(10,000 \text{ m}^3/\text{d})(1 \text{ d}/1440 \text{ min}) \\ &= 645 \text{ m}^3\end{aligned}$$

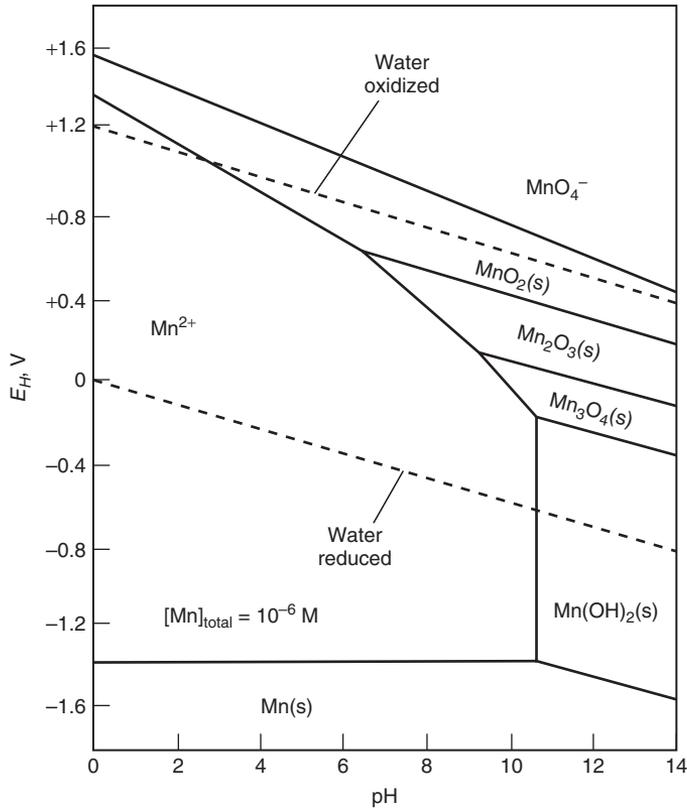

3. Determine the steady-state residence time for the PFR using Eq. 6-65:

$$\tau_{\text{PFR}} = \frac{1}{k} \ln \left( \frac{C_{A0}}{C_A} \right) = \frac{1}{0.168 \text{ min}^{-1}} \ln \left( \frac{5.0}{0.3} \right) = 16.7 \text{ min}$$

4. Determine the PFR volume:

$$V_{\text{PFR}} = (16.7 \text{ min})(10,000 \text{ m}^3/\text{d})(1 \text{ d}/1440 \text{ min}) = 116 \text{ m}^3$$

5. Compare the PFR and CMFR detention times and values. As discussed in Chap. 6, the PFR is much more efficient than a CMFR. In most cases bench and/or pilot tests will be used to determine the kinetics for the water source of interest because the impact of both colloidal and particulate iron will have to be evaluated. However, this calculation can be used to provide some preliminary insight into the minimum contact times required for Fe<sup>2+</sup> removal.

**Figure 20-6**

Forms of manganese in water as function of redox potential versus pH at a water temperature of 25°C. (Adapted from Pourbaix, 1966, 1974.)

aqueous  $\text{Mn}^{2+}$  is the predominant form of manganese, as shown on the  $E_H$ -pH diagram on Fig. 20-6. Concentrations of  $\text{Mn}^{2+}$  on the order of 0.1 to 1.0 mg/L are common, although in low-pH waters higher concentrations can occur. Oxidation of  $\text{Mn}^{2+}$  can thermodynamically lead to three different oxides of manganese depending upon the  $E_H$  and pH— $\text{MnO}_2$ ,  $\text{Mn}_2\text{O}_3$ , and  $\text{Mn}_3\text{O}_4$ , with the predominant form being  $\text{MnO}_2$ .

#### KINETICS OF OXIDATION

Three oxidation states of manganese important in drinking water are  $\text{Mn}^{2+}$  (soluble),  $\text{Mn}^{4+}$  (as  $\text{MnO}_2$  precipitate), and  $\text{Mn}^{7+}$  (as  $\text{MnO}_4^-$  strong oxidant). The  $\text{Mn}^{2+}$  state can be removed from water via oxidation, but aeration is not a very effective treatment option unless the pH is greater than about 9.0. The reaction sequence for oxygenation of  $\text{Mn}^{2+}$  is suggested as (Faust and Aly, 1998)

**Table 20-10**  
Oxidation reactions for manganese

Oxidant	Reaction	Equation Number	Oxidant Needed, mg/mg Mn <sup>2+</sup>	Alkalinity Used, mg/mg Mn <sup>2+</sup>	Sludge Produced <sup>a</sup> , kg/kg Mn <sup>2+</sup>
Oxygen	$2\text{MnSO}_4 + 2\text{Ca}(\text{HCO}_3)_2 + \text{O}_2 \rightarrow 2\text{MnO}_2 + 2\text{CaSO}_4 + 2\text{H}_2\text{O} + 4\text{CO}_2$	20-12	0.29	1.80	1.58
Chlorine	$\text{Mn}(\text{HCO}_3)_2 + \text{Ca}(\text{HCO}_3)_2 + \text{Cl}_2 \rightarrow \text{MnO}_2 + \text{CaCl}_2 + 2\text{H}_2\text{O} + 4\text{CO}_2$	20-13	1.29	3.64	1.58
Chlorine dioxide	$\text{Mn}(\text{HCO}_3)_2 + 2\text{NaHCO}_3 + 2\text{ClO}_2 \rightarrow \text{MnO}_2 + 2\text{NaClO}_2 + 2\text{H}_2\text{O} + 4\text{CO}_2$	20-14	2.46	3.64	1.58
Potassium permanganate	$3\text{Mn}(\text{HCO}_3)_2 + 2\text{KMnO}_4 \rightarrow 5\text{MnO}_2 + 2\text{KHCO}_3 + 2\text{H}_2\text{O} + 4\text{CO}_2$	20-15	1.92	1.21	2.64

<sup>a</sup>Sludge weight is based on MnO<sub>2</sub> as the precipitate. It may be conservative in some cases.  
Source: ASCE/AWWA (1990).

The rate of conversion of  $\text{Mn}^{2+}$  to  $\text{MnO}_2$  also involves an autocatalytic process where the formation of  $\text{MnO}_2$  solid provides for adsorption of  $\text{Mn}^{2+}$  and accelerates conversion of  $\text{Mn}^{2+}$  to  $\text{MnO}_2$ . Because of this catalytic effect, not all the  $\text{Mn}^{2+}$  that is removed from the process is converted to  $\text{MnO}_2$  and may simply be adsorbed onto  $\text{MnO}_2$ . The products of manganese oxygenation appear to be nonstoichiometric and show various degrees of oxidation ranging from about  $\text{MnO}_{1.3}$  to  $\text{MnO}_{1.9}$  depending upon the pH (Stumm and Morgan, 1996). The general stoichiometric expressions for the oxidation of manganese using DO and some commonly used oxidants are displayed in Table 20-10 along with the quantity of oxygen required, the alkalinity consumed, and an estimate of the sludge produced. The values shown in Table 20-10 may be used to estimate the quantity of oxidant required, alkalinity consumed, and quantity of sludge produced for manganese oxidation. As discussed above, the extent of oxygenation of manganese is not accounted for by the stoichiometry of the oxidation alone and assuming that the sludge is  $\text{MnO}_2$  will be conservative in terms of oxidant requirement.

Although the mechanism of this reaction is not understood completely, the following general expression may be used to describe the oxidation in a CMBR:

$$-\frac{d[\text{Mn}^{2+}]}{dt} = k_1[\text{Mn}^{2+}] + k_2[\text{Mn}^{2+}][\text{MnO}_2(\text{s})] \quad (20-16)$$

where  $k_1, k_2$  = respective rate constants for oxidative and autocatalytic pathways  
 $[\text{Mn}^{2+}]$  = aqueous-phase manganese ion concentration, mol/L  
 $[\text{MnO}_2(\text{s})]$  = manganese oxide precipitate concentration, mol/L

An alternative rate expression has been presented for the oxidation of  $\text{Mn}^{2+}$  to  $\text{MnO}_2$  using potassium permanganate (Knocke et al., 1991):

$$-\frac{d[\text{Mn}^{2+}]}{dt} = k_1[\text{Mn}^{2+}][\text{KMnO}_4][\text{OH}^-]^{1.1} + k_2([\text{Mn}^{2+}] - [\text{Mn}^{2+}]_e)[\text{MnO}_2(\text{s})] \quad (20-17)$$

where  $k_1$  = rate constant for oxidative pathway,  $9.55 \times 10^{12} \text{ s}^{-1} (\text{mol/L})^{-2.1}$   
 $[\text{Mn}^{2+}]$  = aqueous-phase  $\text{Mn}^{2+}$  ion concentration, mol/L  
 $[\text{KMnO}_4]$  = aqueous-phase  $\text{KMnO}_4$  concentration, mol/L  
 $[\text{OH}^-]$  = aqueous-phase hydroxide ion concentration, mol/L  
 $k_2$  = rate constant for autocatalytic pathway,  $8.7 \times 10^3 \text{ s}^{-1} (\text{mol/L})^{-1}$   
 $[\text{Mn}^{2+}]_e$  = aqueous-phase  $\text{Mn}^{2+}$  ion concentration in finished water, mol/L  
 $[\text{MnO}_2(\text{s})]$  = manganese oxide precipitate concentration, mol/L

Similar to  $\text{Fe}^{2+}$ , the rate of  $\text{Mn}^{2+}$  oxidation is dependent on  $P_{\text{O}_2}$  and  $[\text{OH}^-]$ , as shown in the equation

$$\frac{d[\text{Mn}^{2+}]}{dt} = k_3 P_{\text{O}_2} [\text{OH}^-] [\text{Mn}^{2+}] = k [\text{Mn}^{2+}] \quad (20-18)$$

where  $k_3$  = rate constant,  $\text{L}^2/\text{mol}^2 \cdot \text{min} \cdot \text{atm}$

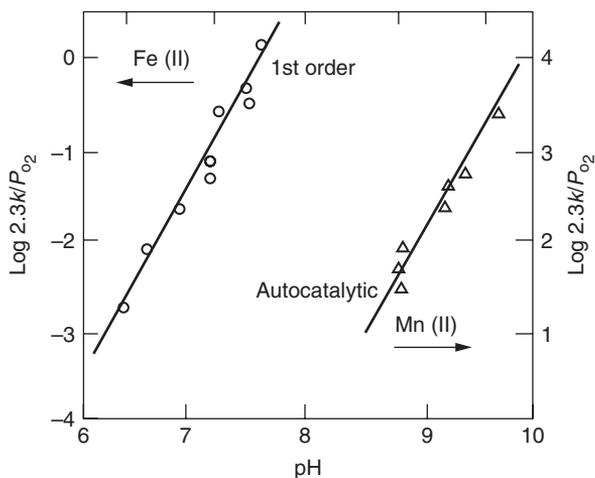

$$k = \text{pseudo-first-order constant, min}^{-1} = k_3 P_{\text{O}_2} [\text{OH}^-]$$

The oxygenation rate dependence of both  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  as a function of pH is shown on Fig. 20-7 (Stumm and Morgan, 1996). The  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  states have the same slope but occur at much different pH ranges. The oxidation rate of  $\text{Mn}^{2+}$  is very low for pH values less than about 9.0. In the pH range encountered in water treatment, the use of oxygenation for the removal of manganese is not practical and alternative oxidants are typically used.

The presence of DOC in the water is not considered in Examples 20-2 and 20-3. Typically, the DOC in natural water will react with  $\text{Fe}^{2+}$  or  $\text{Mn}^{2+}$  to form organic complexes. Knocke et al. (1991) found that  $\text{Mn}^{2+}$  does not appear to be readily complexed by humic and fulvic acids, but  $\text{Fe}^{2+}$  is readily complexed. Complexed  $\text{Fe}^{2+}$  is not well oxidized by either  $\text{KMnO}_4$  or  $\text{ClO}_2$ . However, preliminary studies indicated that alum coagulation may have an important role in the removal of complexed  $\text{Fe}^{2+}$ .

### Treatment Strategies for Iron and Manganese

Several different treatment methods have been used to remove iron and manganese from drinking water supplies, including (1) oxidation using oxygen (aeration), chlorine, chlorine dioxide, potassium permanganate, or ozone followed by precipitate removal by sedimentation and filtration; (2) ion exchange; (3) lime softening; and (4) sequestering chemicals. Design considerations and performance information are provided for each process in the following discussion.

**Figure 20-7**  
Comparison of impact of pH on oxidation rate of  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  by oxygen. (Adapted from Stumm and Morgan, 1996.)

### Example 20-3 Time required for $\text{Mn}^{2+}$ oxidation by potassium permanganate

The flow rate through a treatment process is 10,000  $\text{m}^3/\text{d}$  (2.64 mgd). After removing the soluble iron from groundwater by aeration, 2 mg/L of Mn(II) ion is present. Potassium permanganate ( $\text{KMnO}_4$ ) is added at a dose of 4.0 mg/L ( $2.53 \times 10^{-5}$  mol/L) to oxidize Mn(II) ion ( $\text{Mn}^{2+}$ ) to a concentration of 0.1 mg/L. The groundwater pH is 7.0 with a temperature of  $10^\circ\text{C}$ , and it is assumed that 5 mg/L ( $5.75 \times 10^{-5}$  mol/L) of manganese dioxide ( $\text{MnO}_2$ ) is in equilibrium with 0.1 mg/L of  $\text{Mn}^{2+}$ . For steady-state operation, calculate and compare the minimum hydraulic detention time and volume for the oxidation of  $\text{Mn}^{2+}$  to  $\text{MnO}_2$  for a completely mixed flow reactor (CMFR) and for a plug flow reactor (PFR). Assume the  $[\text{Mn}^{2+}]_e$  concentration is zero.

#### Solution

1. Calculate the pseudo-first-order rate constant.
  - a. Write the rate equation for the oxidation of  $\text{Mn}^{2+}$ . The rate equation for the oxidation of  $\text{Mn}^{2+}$  to  $\text{MnO}_2$  shown in Eq. 20-17 can be simplified to a pseudo-first-order reaction rate as follows:

$$-\frac{d[\text{Mn}^{2+}]}{dt} = k_1[\text{Mn}^{2+}][\text{KMnO}_4][\text{OH}^-]^{1.1} + k_2([\text{Mn}^{2+}] - [\text{Mn}^{2+}]_e)[\text{MnO}_2(\text{s})]$$

$$-\frac{d[\text{Mn}^{2+}]}{dt} = k'[\text{Mn}^{2+}]$$

where  $k'$  = pseudo-first-order rate constant

- b. Determine  $k'$  for the given reaction conditions:

$$\begin{aligned} k' &= k_1[\text{KMnO}_4][\text{OH}^-]^{1.1} + k_2[\text{MnO}_2(\text{s})] \\ &= [9.55 \times 10^{12} \text{ s}^{-1} \cdot (\text{mol/L})^{-2.1}] \\ &\quad \times (2.53 \times 10^{-5} \text{ mol/L})(10^{-7} \text{ mol/L})^{1.1} \\ &\quad + [8.7 \times 10^3 \text{ s}^{-1}(\text{mol/L})^{-1}](5.75 \times 10^{-5} \text{ mol/L}) \\ &= 4.82 + 0.50 = 5.3 \text{ s}^{-1} = 319 \text{ min}^{-1} \end{aligned}$$

2. Determine the steady-state residence time and volume for the CMFR using Eq. 6-24.

a. Determine the steady-state residence time:

$$\begin{aligned}\tau_{\text{CMFR}} &= \frac{[\text{Mn}^{2+}]_0 - [\text{Mn}^{2+}]}{k'[\text{Mn}^{2+}]} = \frac{(2 - 0.1)\text{mg/L}}{(319 \text{ min}^{-1})(0.1 \text{ mg/L})} \\ &= 5.96 \times 10^{-2} \text{ min}\end{aligned}$$

b. Estimate the CMFR volume:

$$\begin{aligned}V_{\text{CMFR}} &= \tau_{\text{CMFR}} Q \\ &= (5.96 \times 10^{-2} \text{ min})(10,000 \text{ m}^3/\text{d})(1 \text{ d}/1440 \text{ min}) \\ &= 0.414 \text{ m}^3\end{aligned}$$

3. Determine the steady-state residence time and volume for the PFR.

a. Calculate the required residence time using Eq. 6-70:

$$\tau_{\text{PFR}} = \frac{1}{k'} \ln \left( \frac{[\text{Mn}^{2+}]_0}{[\text{Mn}^{2+}]} \right) = \frac{1}{319 \text{ min}} \ln \left( \frac{2}{0.1} \right) = 9.4 \times 10^{-3} \text{ min}$$

b. Estimate the required volume:

$$\begin{aligned}V_{\text{PFR}} &= \tau_{\text{PFR}} Q \\ &= (9.73 \times 10^{-3} \text{ min})(10,000 \text{ m}^3/\text{d})(1\text{d}/1440 \text{ min}) \\ &= 0.065 \text{ m}^3\end{aligned}$$

#### OXIDATION WITH AIR

Aeration can be used to provide DO to the water to convert  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  to  $\text{Fe}(\text{OH})_3$  and  $\text{MnO}_2$ , respectively. From a stoichiometric standpoint, 1 mg of oxygen can oxidize 7 mg of soluble  $\text{Fe}^{2+}$  and 3.4 mg soluble  $\text{Mn}^{2+}$  (see Tables 20-8 and 20-10). However, the rate of oxidation is slow and not practical for  $\text{Mn}^{2+}$  at typical pH values for natural waters. Even at a pH of 9.5, it takes about 1 h detention time for  $\text{Mn}^{2+}$  to oxidize. In comparison, iron can be completely oxidized in about 15 min at pH values around 7.5 to 8.0 when not complexed with NOM.

A number of aeration devices used to supply oxygen to water have been discussed in Chap. 14. Diffused aeration is one process where air diffusers are located along or near the bottom of a tank that is 3 to 5 m (12 to 15 ft) deep. The volumetric air-to-water ratio is typically around 0.75 to 1.0

and the average oxygen transfer efficiency is only around 5 to 10 percent. Diffused aeration is not used very often because it is not very effective in terms of oxygen transfer.

A more commonly used and effective aeration device is the coke tray aerator. This process contains a series of three to five perforated stainless steel trays 0.3 to 0.45 m (1.0 to 1.5 ft) apart that contain 5- to 10-cm-diameter crushed coke or limestone or plastic random packing. The packing provides air-water contact area as the water flows down through the trays while air flows across the trays providing oxygen to the water for oxidation to take place. The water-loading rate is typically around 600 to 800 L/m<sup>2</sup> · min (15 to 20 gpm/ft<sup>2</sup>). After a short period of operation, the iron deposits will coat the surface of the coke and assist in the oxidation process. Eventually the oxidation products will build up on the coke and begin to clog the system and the coke must be cleaned or replaced (ASCE/AWWA, 1990). This process is effective for soluble iron removal but not for iron that is organically bound. A baffled basin, which will provide 15 to 30 min additional contact time for oxidation to take place, is used following the aeration device. The oxidized insoluble iron is then removed by filtration. When iron concentrations are greater than 5 mg/L, the addition of alum after aeration followed by flocculation and sedimentation may be required prior to filtration (Kawamura, 2000).

#### OXIDATION WITH CHLORINE

Traditionally, iron and manganese were controlled using chlorine alone or combined with potassium permanganate under alkaline pH conditions followed by alum coagulation, clarification, and filtration. Free-chlorine doses as high as 5 mg/L have been used effectively to oxidize soluble Fe<sup>2+</sup> ions as well as organically bound iron. However, in the current regulatory climate using such high doses of chlorine may not be desirable from a disinfection by-product (DBP) formation control standpoint. The stoichiometric reactions for chlorination of Fe<sup>2+</sup> and Mn<sup>2+</sup> are shown in Tables 20-8 and 20-10, respectively. Oxidation of Fe<sup>2+</sup> requires about 0.64 mg chlorine/mg Fe<sup>2+</sup> while Mn<sup>2+</sup> oxidation requires 1.29 mg chlorine/mg Mn<sup>2+</sup>. Because the rate of oxidation is pH dependent, a pH of 8.0 to 8.5 is needed to provide Fe<sup>2+</sup> oxidation times of about 15 to 30 min. Oxidation of Mn<sup>2+</sup> requires 2 to 3 h and is not effective under these conditions. If ammonia is present in the water, it will consume chlorine and form chloramines, which will significantly reduce the rate of oxidation for both Fe<sup>2+</sup> and Mn<sup>2+</sup>.

A common process for iron and manganese removal incorporates prechlorination, alum coagulation, sedimentation, and filtration. In this process, the filter media is conditioned with permanganate to form a manganese oxide coating on the surface of the media. The Mn<sup>2+</sup> and Fe<sup>2+</sup> will readily adsorb onto the media but can desorb if not oxidized. Chlorine addition just prior to filtration can be used to oxidize the adsorbed Mn<sup>2+</sup>

and  $\text{Fe}^{2+}$  and convert them to oxides providing further adsorption sites for oxidation to take place. Any DO in the water can also oxidize adsorbed  $\text{Fe}^{2+}$ . This process has proven to be effective for  $\text{Mn}^{2+}$  removal to levels less than 0.02 mg/L and requires minimum process control. The advantage of this process is that the chlorine addition can be easily controlled depending upon the concentration of  $\text{Mn}^{2+}$  in the water, thus minimizing the formation of DBPs. When  $\text{Mn}^{2+}$  concentrations in the raw water are low and chlorination is shut off, the oxides will gradually be stripped off but can be reestablished when the chlorine is again added.

#### **OXIDATION WITH CHLORINE DIOXIDE**

Chlorine dioxide ( $\text{ClO}_2$ ) is a stronger oxidant than free chlorine and can effectively oxidize soluble  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  ions. The observed removal of soluble  $\text{Mn}^{2+}$  is slightly greater than predicted from the stoichiometry shown in Table 20-10, due to adsorption of  $\text{Mn}^{2+}$  on the  $\text{MnO}_x$  solids that are formed during oxidation (Knocke et al., 1991). When the  $\text{ClO}_2$  dosages used are greater or equal to the theoretical stoichiometric quantity, the observed  $\text{Mn}^{2+}$  removal is very close to the theoretical prediction, which is attributed to the adsorbed  $\text{Mn}^{2+}$  on the  $\text{MnO}_x$  being oxidized. Overall, the observed oxidation reaction of  $\text{Mn}^{2+}$  by  $\text{ClO}_2$  appears to be a one-electron transfer with chlorite being the oxidant by-product. Oxidation of  $\text{Fe}^{2+}$  by  $\text{ClO}_2$  shows a five-electron transfer resulting in  $\text{Cl}^-$  being the oxidant by-product. Consequently, the dosage requirement for  $\text{Fe}^{2+}$  oxidation is about 10 times less than for  $\text{Mn}^{2+}$ . These results have been verified by tests using  $\text{ClO}_2$  as the oxidant (Knocke et al., 1991).

The rate of reaction for  $\text{Mn}^{2+}$  and  $\text{Fe}^{2+}$  with  $\text{ClO}_2$  is quite fast. In the absence of NOM and for pH values of 5.5 or greater, complete oxidation for  $\text{Mn}^{2+}$  can occur in about 20 s or less. In the presence of NOM and the same pH range, complete  $\text{Mn}^{2+}$  oxidation also requires about 20 s. The impact of NOM on  $\text{Mn}^{2+}$  oxidation is observed to be small, as it does not appear to complex with NOM (Knocke et al., 1991). Oxidation of soluble  $\text{Fe}^{2+}$  by  $\text{ClO}_2$  requires about 5 s at a pH value of 5.5, and faster rates are possible at higher pH values. However, when  $\text{Fe}^{2+}$  is complexed with NOM, it becomes highly resistant to oxidation and must be removed by other processes that remove NOM, such as coagulation, or activated carbon treatment.

#### **POTASSIUM PERMANGANATE AND GREENSAND FILTRATION**

Soluble  $\text{Fe}^{2+}$  can also be oxidized using  $\text{KMnO}_4$  at a similar rate, but the cost of  $\text{KMnO}_4$  is higher than the cost of chlorine. Oxidation times for soluble and particulate  $\text{Mn}^{2+}$  in the presence of NOM are very fast (<20 s) at pH 5.5 and the rate increases as the pH increases. Soluble  $\text{Fe}^{2+}$  can also be oxidized using  $\text{KMnO}_4$  at a similar rate, but because the cost of  $\text{KMnO}_4$  is much higher than the cost of chlorine, the process is usually not practical. In applications where  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  are both present,  $\text{Fe}^{2+}$  is usually oxidized first using chlorine followed by the addition of  $\text{KMnO}_4$

### Example 20-4 Stoichiometric calculation for Fe<sup>2+</sup> oxidation by chlorine

A process treating 100,000 m<sup>3</sup>/d groundwater containing 5 mg/L of ferrous iron (Fe<sup>2+</sup>) is being treated with chlorine. Calculate the quantity of chlorine required to oxidize ferrous to ferric hydroxide, alkalinity consumed as CaCO<sub>3</sub>, and quantity of sludge produced given the oxidation reactions for iron using chlorine as shown in Table 20-8.

#### Solution

1. Determine the quantity of chlorine required using the values for the chlorine reaction shown in Table 20-8:

$$\begin{aligned} \text{Chlorine required} &= (5 \text{ mg Fe}^{2+}/\text{L})(0.64 \text{ mg Cl}_2/\text{mg Fe}^{2+}) \\ &\quad (100,000 \text{ m}^3/\text{d})(10^3 \text{ L/m}^3) (1 \text{ kg}/10^6 \text{ mg}) \\ &= 320 \text{ kg/d} \end{aligned}$$

2. Determine the quantity of alkalinity consumed for the chlorine reaction shown in Table 20-8:

$$\begin{aligned} \text{Alkalinity consumed} &= (5 \text{ mg Fe}^{2+}/\text{L})(2.70 \text{ mg alkalinity}/\text{mg Fe}^{2+}) \\ &\quad (100,000 \text{ m}^3/\text{d})(10^3 \text{ L/m}^3)(1 \text{ kg}/10^6 \text{ mg}) \\ &= 1350 \text{ kg/d} \end{aligned}$$

3. Determine the quantity of sludge produced for the chlorine reaction shown in Table 20-8:

$$\begin{aligned} \text{Sludge produced as Fe (OH)}_3 &= (5 \text{ mg Fe}^{2+}/\text{L})(1.90 \text{ mg sludge}/\text{mg Fe}^{2+}) \\ &\quad (100,000 \text{ m}^3/\text{d})(10^3 \text{ L/m}^3) (1 \text{ kg}/10^6 \text{ mg}) \\ &= 950 \text{ kg/d} \end{aligned}$$

for Mn<sup>2+</sup> oxidation. The oxidation of Fe<sup>2+</sup> complexed with NOM requires contact times greater than 1 h and oxidant dosages above the theoretical stoichiometric amount. As a result, oxidation with KMnO<sub>4</sub> is not a practical process for removal of Fe<sup>2+</sup> complexed with NOM.

A typical process for the removal of soluble Fe<sup>2+</sup> and Mn<sup>2+</sup> involves adding KMnO<sub>4</sub> as a solution ahead of a filter. After the addition of KMnO<sub>4</sub>

and an alkali (if required), the oxidized water is delivered to a specially prepared filter. The contact time after the oxidant addition is typically 5 min at 20°C or 10 min at 1°C which is more than enough time for  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  oxidation as mentioned above. The filter media may be natural greensand, but silica sand and/or anthracite may also be used. Silica sand or anthracite are first treated with  $\text{KMnO}_4$  to provide a manganese oxide coating on the media. Under normal conditions, the coating can be applied by controlled operation for several days with optimum  $\text{KMnO}_4$  feed rates. Partial or marginal treatment may occur during the coating process. Once the coating is applied completely, satisfactory removals are usually maintained. The process is more efficient at pH values above 7.5.

The filtration process generally used for iron and manganese removal is pressure filtration. Filtration and backwash rates typically range from 240 to 480 m/d (4 to 8 gpm/ft<sup>2</sup>) and 480 to 1200 m/d (8 to 20 gpm/ft<sup>2</sup>), respectively, depending on the media size, temperature, and supplemental scour. Greensand media require periodic regeneration with a  $\text{KMnO}_4$  solution. Greensand filter depths are similar to those used in conventional filtration applications; however, greensand media usually have an effective size less than 0.3 mm.

The applied dose of  $\text{KMnO}_4$  should be controlled carefully because permanganate gives an easily detectable pink color in water at concentrations in the 0.05-mg/L range. Controlling the dose range is critical in avoiding consumer complaints. Some waters, such as reservoirs, experiencing periodic hypolimnologic episodes, may have seasonal variations in  $\text{Mn}^{2+}$ . Consequently, bench- and pilot-scale studies are important in determining the required dosing rate associated with these variations.

#### **OXIDATION WITH OZONE**

Ozone can be used to oxidize  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  but is more costly than other oxidation methods and consequently is not practiced in the United States. However, ozonation has been used successfully in Europe for both  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  removal with conventional treatment processes combined with preozonation, and when preozonation is part of a process train for other treatment purposes,  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  oxidation occurs as incidental to the primary process purpose. The stoichiometric requirements for oxidation of  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  are 0.43 mg  $\text{O}_3$ /mg  $\text{Fe}^{2+}$  and 0.87 mg  $\text{O}_3$ /mg  $\text{Mn}^{2+}$ . Ozonation will not impact the removal of  $\text{Fe}^{2+}$  complexed with NOM in subsequent conventional processes. Based on practical experience, overdosing with ozone will lead to the formation of various forms of permanganate and, if present, result in a pink color.

#### **ION EXCHANGE PROCESS**

Ion exchange processes may be used for removing low concentrations (<0.5 mg/L) of  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  from groundwaters. The majority of ion exchange applications for  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  are limited to treatment of

### Example 20-5 Theoretical stoichiometric calculation for $\text{Fe}^{2+}$ and $\text{Mn}^{2+}$ removal using $\text{KMnO}_4$

A groundwater containing  $5 \text{ g/m}^3 \text{ Fe}^{2+}$  and  $2 \text{ g/m}^3 \text{ Mn}^{2+}$  is processed at a flow rate of  $100,000 \text{ m}^3/\text{d}$ . Potassium permanganate ( $\text{KMnO}_4$ ) is used to oxidize the  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$ . Calculate the quantity of potassium permanganate required, alkalinity consumed as  $\text{CaCO}_3$ , and quantity of sludge produced. Use the oxidation reactions for iron and manganese using  $\text{KMnO}_4$  as shown in Tables 20-8 and 20-10, respectively.

#### Solution

1. Determine the quantity of potassium permanganate required.
  - a. Compute the amount of  $\text{KMnO}_4$  needed for  $\text{Fe}^{2+}$  oxidation for the reaction shown with potassium permanganate in Table 20-8:

$$\begin{aligned} & \text{KMnO}_4 \text{ required due to } \text{Fe}^{2+} \\ &= \left( 5 \text{ g Fe}^{2+}/\text{m}^3 \right) \left( 0.94 \text{ g KMnO}_4/\text{g Fe}^{2+} \right) \\ & \quad \left( 100,000 \text{ m}^3/\text{d} \right) \left( 1 \text{ kg}/10^3 \text{ g} \right) \\ &= 470 \text{ kg/d} \end{aligned}$$

- b. Calculate the  $\text{KMnO}_4$  required due to  $\text{Mn}^{2+}$  for the reaction shown with potassium permanganate in Table 20-10:

$$\begin{aligned} & \text{KMnO}_4 \text{ required due to } \text{Mn}^{2+} \\ &= \left( 2 \text{ g Mn}^{2+}/\text{m}^3 \right) \left( 1.92 \text{ g KMnO}_4/\text{g Fe}^{2+} \right) \\ & \quad \left( 100,000 \text{ m}^3/\text{d} \right) \left( 1 \text{ kg}/10^3 \text{ g} \right) \\ &= 384 \text{ kg/d} \end{aligned}$$

- c. Calculate the total  $\text{KMnO}_4$  required:

$$\text{Total KMnO}_4 \text{ required} = 470 + 384 = 854 \text{ kg/d}$$

2. Determine the quantity of alkalinity consumed as  $\text{CaCO}_3$ .
  - a. Calculate the quantity of alkalinity consumed due to  $\text{Fe}^{2+}$  for the reaction shown with potassium permanganate in Table 20-8:

$$\begin{aligned} & \text{Alkalinity consumed due to } \text{Fe}^{2+} \\ &= \left( 5 \text{ g Fe}^{2+}/\text{m}^3 \right) \left( 1.50 \text{ g alkalinity}/\text{g Fe}^{2+} \right) \\ & \quad \left( 100,000 \text{ m}^3/\text{d} \right) \left( 1 \text{ kg}/10^3 \text{ g} \right) \\ &= 750 \text{ kg/d} \end{aligned}$$

- b. Calculate the quantity of alkalinity consumed due to  $\text{Mn}^{2+}$  for the reaction shown with potassium permanganate in Table 20-10:

$$\begin{aligned} & \text{Alkalinity consumed due to } \text{Mn}^{2+} \\ &= (2 \text{ g Mn}^{2+}/\text{m}^3) (1.21 \text{ g alkalinity/g Fe}^{2+}) \\ & \quad (100,000 \text{ m}^3/\text{d}) (1 \text{ kg}/10^3 \text{ g}) \\ &= 242 \text{ kg/d} \end{aligned}$$

- c. Calculate the total quantity of alkalinity consumed:

$$\text{Total alkalinity consumed} = 750 + 242 \text{ kg/d} = 992 \text{ kg/d}$$

3. Determine the quantity of sludge produced.  
a. Calculate the sludge produced from  $\text{Fe}^{2+}$  oxidation for the reaction shown with potassium permanganate in Table 20-8:

$$\begin{aligned} & \text{Sludge produced due to Fe}^{2+} \\ &= (5 \text{ g Fe}^{2+}/\text{m}^3) (2.43 \text{ g sludge/g Fe}^{2+}) \\ & \quad (100,000 \text{ m}^3/\text{d}) (1 \text{ kg}/10^3 \text{ g}) \\ &= 1215 \text{ kg/d} \end{aligned}$$

- b. Calculate the sludge produced from  $\text{Mn}^{2+}$  oxidation for the reaction shown with potassium permanganate in Table 20-10:

$$\begin{aligned} & \text{Sludge produced due to Mn}^{2+} \\ &= (2 \text{ g Mn}^{2+}/\text{m}^3) (2.64 \text{ g sludge/g Fe}^{2+}) \\ & \quad (100,000 \text{ m}^3/\text{d}) (1 \text{ kg}/10^3 \text{ g}) \\ &= 528 \text{ kg/d} \end{aligned}$$

- c. Calculate the total sludge produced from  $\text{Mn}^{2+}$  and  $\text{Fe}^{2+}$  oxidation:

$$\begin{aligned} \text{Sludge produced due to Mn}^{2+} &= 1215 + 528 \\ &= 1743 \text{ kg dry solids/d} \end{aligned}$$

### Comment

The values computed in this example were derived from a theoretical stoichiometric calculation point of view. In practical application,  $\text{Fe}^{2+}$  is usually oxidized first using chlorine followed by the addition of  $\text{KMnO}_4$  for  $\text{Mn}^{2+}$  because the cost of  $\text{KMnO}_4$  is much higher than the cost of chlorine.

industrial water and for point-of-use treatment systems for single-family dwellings using groundwater. Usually a strong-acid cation (SAC) exchange resin in the sodium form is used. The separation factors for several cations for a polystyrene resin sometimes found in groundwater are shown in Table 16-7. The separation factors for  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  are slightly lower than for  $\text{Ca}^{2+}$ , and the  $\text{Mn}^{2+}$  separation factor is slightly lower than  $\text{Mg}^{2+}$ . For waters containing moderate to high hardness,  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  may be removed, but the regeneration frequency will be higher than for waters that are low in hardness.

The use of SAC resins will not remove  $\text{Fe}^{2+}$  complexed with NOM; however, SBA resins have been reported to remove up to 95 percent of  $\text{Fe}^{2+}$  complexed with NOM (Clifford, 1999). The City of Santa Monica, California, removes about 1.0 mg/L of iron from a 30,000-m<sup>3</sup>/d (7.5-mgd) groundwater flow by a process of aeration and filtration through 0.762 m (30 in.) of ion exchange media. The water is softened in the filtering stage. The principal design parameters for this system include aeration with 10 min contact time and volumetric air-to-water ratio of 0.75; unbaffled contact basin with 60 min contact time; and 9.8 m/h (4 gpm/ft<sup>2</sup>) filtration rate through a polystyrene resin bed with an effective size of 0.4 mm. The resin requires periodic acid treatment due to fouling of the surface by oxidation. Effective resin life is about 12 years.

#### MEMBRANE PROCESS

Reverse osmosis membranes can be very effective for the removal of soluble  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$ . However, as discussed in Chap. 17, even a small amount of oxidized iron and manganese can foul membranes and cause a decrease in their effectiveness. Pretreatment systems are typically used to remove oxidized iron and manganese prior to treatment with RO. In recent work in the Netherlands, it was found that  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  were removed effectively when the feed water was under anaerobic conditions (Kartinen and Martin, 2001). Two full-scale RO plants were involved in these studies, with  $\text{Fe}^{2+}$  concentrations ranging from 11 to 25 mg/L  $\text{Fe}^{2+}$ . In addition, fouling of the membranes was found to be considerably less under anaerobic operating conditions.

#### STABILIZATION PROCESS

Stabilization of soluble  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  is the opposite of oxidation. The chemical used for stabilization in water treatment is sodium hexametaphosphate ( $\text{NaPO}_3$ )<sub>6</sub> (SHMP), commonly known as polyphosphate, glassy phosphate, or polysilicate. This chemical is available in crystal, granular, or liquid form and is highly soluble. Chemical addition should occur before the water has a chance to come in contact with air or chlorine to ensure that the  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  are still in the soluble state. However, stabilization agents can be aggressive compounds with respect to metals, and

they may dissolve precipitated iron and manganese or promote dissolution of metallic pipe materials.

The high phosphate content (66 percent  $P_2O_5$ ) of SHMP results in the formation of phosphate as a by-product of the reaction, which can promote biological growth. Where treated water is stored in open reservoirs, SHMP must be used with caution; otherwise, algal blooms and slimes may result. It should also be noted that stabilization does not remove  $Fe^{2+}$  and  $Mn^{2+}$  but merely holds it in an aesthetically acceptable condition that will degrade with time. Stabilized  $Fe^{2+}$  and  $Mn^{2+}$  will also appear on analytical tests. Feed rates for SHMP are typically less than 2 mg/L but should be determined by testing. Stabilization may be considered for waters if the  $Fe^{2+}$  is in the range of 0.3 to 1.0 mg/L and/or if the  $Mn^{2+}$  content is between 0.05 and 0.1 mg/L. The additive demand of polyvalent cations must be considered.

#### LIME TREATMENT

Lime treatment is effective in removing both  $Fe^{2+}$  and  $Mn^{2+}$ . Excellent removals are obtained if the water is preaerated, the pH exceeds 9.8 during the process, and sufficient alkalinity ( $>20$  mg/L as  $CaCO_3$ ) is present. Softening is more costly than other processes for  $Fe^{2+}$  and  $Mn^{2+}$  removal because of the high capital costs. High iron and manganese removals preclude recalcination of lime sludge due to impurity of the sludge.

## 20-4 Softening

---

Theoretically, the hardness of water is defined as the sum of the soluble concentrations of polyvalent cations—all expressed as equivalent concentrations of calcium carbonate. *Carbonate hardness* is defined as the concentration of  $Ca^{2+}$  and  $Mg^{2+}$  and other polyvalent cations in water that are associated with the anions that comprise alkalinity (e.g.,  $HCO_3^-$ ,  $CO_3^{2-}$ ). Similarly, *noncarbonate hardness* is defined as the concentration of  $Ca^{2+}$  and  $Mg^{2+}$  and other polyvalent cations in water that are associated with nonalkalinity anions (e.g.,  $SO_4^{2-}$ ,  $Cl^-$ ). For example, carbonate hardness would be present in water after dissolution of  $CaCO_3$  and  $MgCO_3$ , whereas noncarbonate hardness would appear if  $CaSO_4$ ,  $CaCl_2$ ,  $MgSO_4$ , and  $MgCl_2$  were dissolved in the water. In water treatment, total hardness is usually expressed as the sum of the carbonate hardness and noncarbonate hardness.

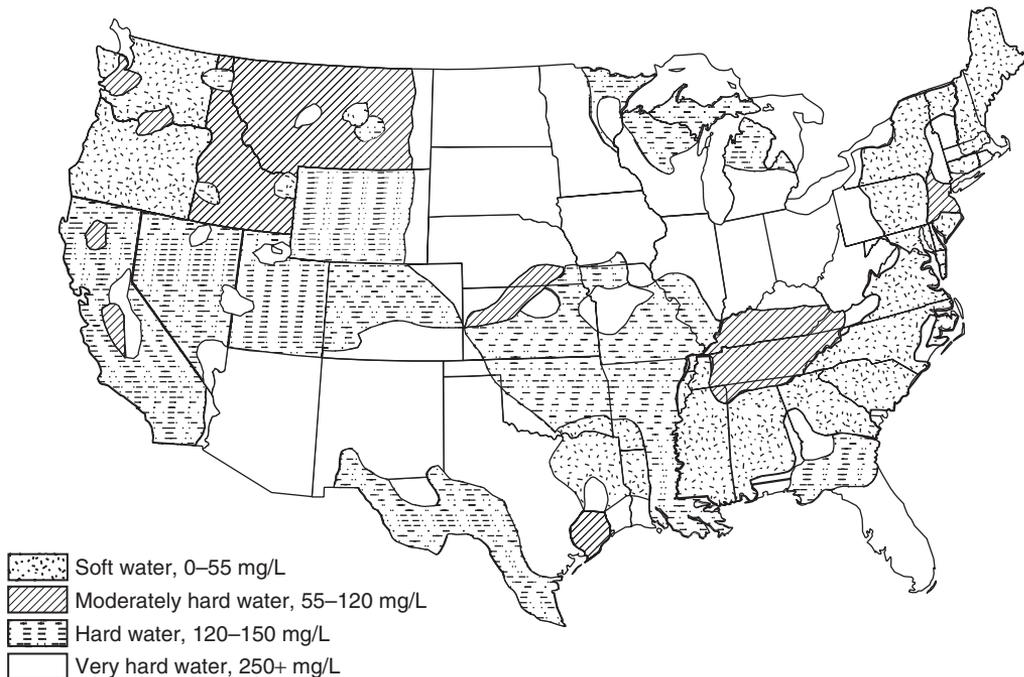

Water treatment issues related to hardness removal have traditionally been related to aesthetics, although there is some nutritional benefit. The presence of hardness causes scale in pipes and hot-water heaters, high soap consumption, and the deterioration of fabrics. Removing hardness, termed *softening*, may be accomplished either by chemical precipitation as insoluble compounds, ion exchange, or membrane processes. Hardness has been removed successfully using ion exchange or low-pressure softening membranes. These processes are discussed in Chaps. 16 and 17, respectively.

The purpose of this section is to present the removal of hardness by means of chemical precipitation. Topics to be considered include (1) sources of hardness, (2) occurrence of hardness, (3) chemical precipitation methods, and (4) types of process configurations.

Hardness in natural waters usually comes from the dissolution of minerals from geologic formations that contain calcium and magnesium. Two of the most common forms are calcite ( $\text{CaCO}_3$ ) and dolomite [ $\text{CaMg}(\text{CO}_3)_2$ ]. Calcite, or *chalis*, the Greek word for “lime,” is one of the most common minerals and makes up about 4 percent by weight of the Earth’s crust. Calcite can dissolve in weak acidic environments such as in some groundwaters. Dolomite makes up approximately 2 percent by weight of the Earth’s crust. The mineral was named after French geologist Deodat de Dolomieu (1750–1801). Dolomite does not easily dissolve in acidic environments as calcite and is more often found in tropical marine environments. Groundwaters rich in dissolved magnesium usually contain a significant quantity of salt, which is thought to be essential in the formation of dolomite.

The distribution of hard waters in the United States is shown on Fig. 20-8. Although waters above 150 mg/L hardness (as  $\text{CaCO}_3$ ) are considered very

### Sources of Hardness

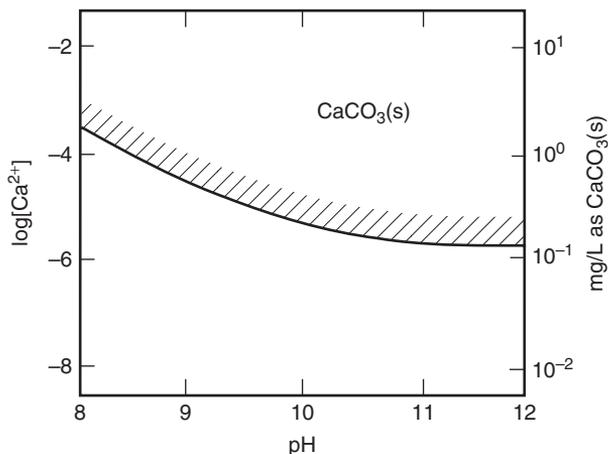

**Figure 20-8**

Distribution of hard water in United States. The areas shown define approximate hardness values for municipal water supplies. (Reprinted with permission from Ciaccio, 1971.)

hard, many utilities do not soften the water. Some utilities soften water when the total hardness exceeds 150 mg/L. The finished water hardness produced by a utility softening plant may vary from a low of 50 mg/L to a high of 150 mg/L depending upon the process configuration, economics, and public acceptance. A historical goal has been between 80 and 100 mg/L for both aesthetics and corrosion control (AWWA, 1969).

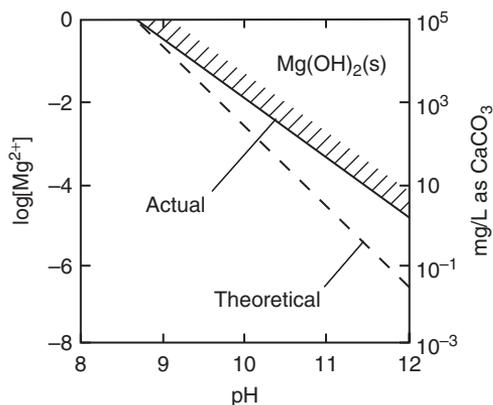

### Softening by Chemical Precipitation

Precipitation softening relies on the relative insolubilities of calcium carbonate and magnesium hydroxide. The choice of precipitating chemicals depends upon the raw-water quality, which complicates the selection of the optimum treatment process, although the chemistry is straightforward. The equilibrium solubilities of calcium carbonate and magnesium hydroxide for typical water chemistry are shown on Figs. 20-9 and 20-10. As shown,

**Figure 20-9**

Solubility of  $\text{CaCO}_3$  as function of pH ( $K_{\text{sp}} = 4 \times 10^{-9}$ );  $C_T = 2 \times 10^{-3}$  mol/L.

**Figure 20-10**

Solubility of  $\text{Mg}(\text{OH})_2$  as function of pH ( $K_{\text{sp}} = 2.5 \times 10^{-11}$ ). Solid line is for solubility in 23 waters determined by Thompson et al. (1972).

within the normal concentration range of each cation and pH found in water treatment, it is necessary to increase the pH for both calcium and magnesium precipitation. The chemicals most commonly used to precipitate calcium and magnesium are lime and caustic soda. The choice of the two depends upon the water quality and economics. When the carbonate hardness is adequate, the softening required can be accomplished by pH adjustment alone, and both calcium carbonate and magnesium hydroxide can be precipitated.

When carbonate hardness is too low, the carbonate content must be supplemented by soda ash (sodium carbonate). The minimum hardness that can be achieved depends on the solubilities of the calcium carbonate and magnesium hydroxide at the pH of softening as well as the subsequent processes. Lime-soda ash softening has been a traditional process for the removal of hardness, consisting of both carbonate and noncarbonate hardness, from water supplies.

Lime is sold commercially in the forms of quicklime and hydrated lime. Quicklime is granular and usually greater than 90 percent CaO with magnesium oxide the primary impurity. Although quicklime is less expensive than hydrated lime, it must be hydrated or slaked to  $\text{Ca}(\text{OH})_2$  before it is used for softening. Quicklime is usually crushed in a slaker and fed to form a slurry containing about 5 percent calcium hydroxide. Powdered, hydrated lime contains about 70 percent  $\text{Ca}(\text{OH})_2$  and is prepared for use in the softening process by fluidizing in a tank containing a turbine mixer. Soda ash is a grayish-white powder and is nearly 98 percent sodium carbonate. Soda ash may be added simultaneously with lime to the treatment train or it may be added sequentially, following the addition of lime.

Aside from eliminating the aesthetic problems associated with hardness, lime softening has many potential health benefits as well. The use of lime softening can effectively remove heavy metals (e.g., lead, chromium, mercury, arsenic), iron and manganese, turbidity, and some organic compounds including a substantial amount of NOM and kill algae, bacteria, and viruses. More recently, the U.S. EPA has termed a variation of the lime-softening process as *enhanced softening* because the TOC removals can be as high as 40 to 80 percent depending upon the pH. When TOC removals are high, significant control of THMs and HAAs can be achieved when using chlorine for disinfection.

The principal reactions involved in the precipitation of hardness depend on whether the hardness is carbonate or noncarbonate. Chemical reactions for the removal of carbonate and noncarbonate hardness are presented and discussed below, along with treatment process options.

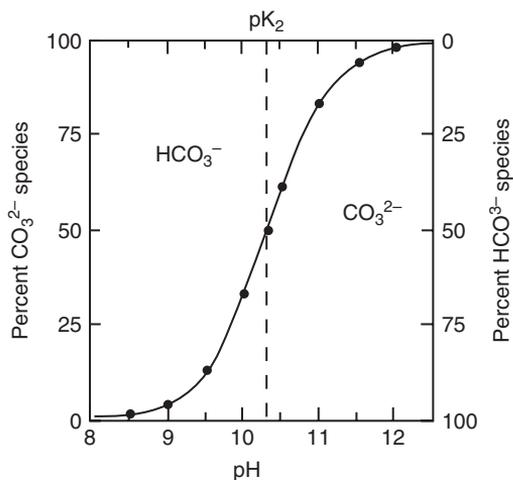

**LIME SOFTENING: CARBONATE HARDNESS**

The chemical reactions for lime softening are

When lime is added to water, it will first react with any free  $\text{CO}_2$ , forming a calcium carbonate precipitate as shown in Eq. 20-19, and does not reduce any hardness. This reaction will take place first as  $\text{CO}_2$  is a stronger acid than  $\text{HCO}_3^-$ . The conversion of bicarbonate to carbonate as a function of pH is shown on Fig. 20-11. Complete conversion would require a pH value greater than 12 to attain complete utilization of the bicarbonate alkalinity for calcium precipitation, as shown on Fig. 20-11. In practice, when alkalinity is present as bicarbonate, the optimum pH for maximum calcium carbonate precipitation may be as low as 9.3 because a significant amount of carbonate is in equilibrium with bicarbonate and more carbonate is formed as precipitation occurs.

The overall reaction for the removal of magnesium when alkalinity is present as bicarbonate (i.e., magnesium carbonate hardness) is given by Eq. 20-21. Based on practical experience, it has been found that a pH value of at least 10.5 or greater is required for effective  $\text{Mg}(\text{OH})_2$  precipitation. The range of lime dosages in excess of the stoichiometric amount required to raise the pH for precipitation of  $\text{MgCO}_3$  as  $\text{Mg}(\text{OH})_2$  has been reported to be from 30 to 70 mg/L as  $\text{CaCO}_3$  (Degrémont, 2007; Faust and Aly, 1998; Hammer and Hammer, 2001). Jar testing is recommended to obtain

**Figure 20-11**

Distribution of carbonate and bicarbonate species as function of pH (25°C).

a more precise amount of excess lime required for effective  $\text{Mg}(\text{OH})_2$  precipitation for a given water source.

**LIME-SODA SOFTENING: CARBONATE AND NONCARBONATE HARDNESS**

Sometimes there may be a lack of carbonate alkalinity present to react with the lime and it becomes necessary to add an external source. Typically, soda ash,  $\text{Na}_2\text{CO}_3$ , is used, as shown in the reaction

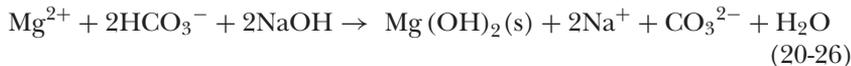

The calcium noncarbonate hardness in Eq. 20-23 may be present in the untreated water or may result from the precipitation of magnesium noncarbonate hardness, as shown in Eq. 20-22. For both reactions, the amount of soda ash required depends upon the amount of noncarbonate hardness to be removed.

**CAUSTIC SODA SOFTENING: CARBONATE AND NONCARBONATE HARDNESS**

Caustic soda ( $\text{NaOH}$ ) is an alternative to the use of lime softening when there is insufficient carbonate hardness present in the raw water to react with lime. The choice between using soda ash and caustic soda will depend upon the economics and other factors such as the ease of handling ( $\text{NaOH}$  is purchased as a 50 percent solution) and magnesium content. Some concern has been expressed about the use of sodium-containing compounds because, when noncarbonate hardness is removed, both use of soda ash and caustic soda result in the replacement of the divalent hardness ions with sodium.

The reactions for caustic soda are

In Eqs. 20-24, 20-25, and 20-26 the sodium carbonate that is formed is available for calcium carbonate precipitation. In situations where more sodium carbonate is formed than there is calcium noncarbonate hardness to remove, the excess must remain in solution. This presents a problem of very high carbonate alkalinity, which can be reduced by acidification, but none of the excess sodium will precipitate. In contrast, when lime is used, the excess calcium is precipitated as the carbonate. Calcium carbonate precipitation is particularly important in those cases where high pH (and

the concomitant high caustic alkalinity) must be attained to precipitate magnesium as  $\text{Mg}(\text{OH})_2$ .

#### RECARBONATION: PH ADJUSTMENT

When the pH of the water after softening is greater than the saturation pH ( $\text{pH}_s$ ), it is necessary to reduce the pH. The addition of  $\text{CO}_2$  is the most common and economical method for precipitation of excess calcium and pH reduction. When excess caustic (noncarbonate) alkalinity is present, the following reaction occurs:

When  $\text{CO}_3^{2-}$  is formed, it will react to precipitate any calcium that is present above the saturation of calcium carbonate. Adding additional  $\text{CO}_2$  will then lower the pH to a point of saturation equilibrium, as shown in the reaction

Historically,  $\text{CO}_2$  was produced by the combustion of diesel fuel or natural gas either under water or in external burners, but the combustion process only yields about 12 percent  $\text{CO}_2$ . Bulk pressurized/liquefied  $\text{CO}_2$  is now commonly available and widely used because it is more convenient and the operation and maintenance problems associated with  $\text{CO}_2$  generation are eliminated.

In the case of waters that only require selective calcium removal, the lime-treated water will be supersaturated with calcium carbonate and the pH will be between 10.0 and 10.6. The addition of carbon dioxide to the water will convert the carbonate ions, to bicarbonate ions, as shown by the reaction

For waters that require calcium and magnesium removal, excess lime is added to precipitate the magnesium carbonate as magnesium hydroxide at a pH above 11.0. Enough carbon dioxide is needed to convert the excess hydroxide ions to carbonate ions and then all the carbonate ions to bicarbonate ions. Conversion of the excess hydroxide ions to carbonate ions will drop the pH to about 10.0 to 10.5, and the calcium hydroxide is converted to calcium carbonate precipitate and the magnesium hydroxide is converted to soluble magnesium carbonate (if it has not been removed), as shown in the reactions (Benfield and Morgan, 1999)

As stated above, additional carbon dioxide is required to lower the pH to about 8.4 to 8.6 (Benfield and Morgan, 1999). In this case, the calcium carbonate that was precipitated will dissolve in the bicarbonate form and

the magnesium carbonate will also convert to the bicarbonate form, as shown by the reactions

In a water treatment plant, the recarbonation process may take place in single or double stages. The double-stage process, sometimes called the “split recarbonation” process, according to Eqs. 20-29 and 20-30, is only practiced in a few plants as it is much more mechanically and land intensive than a single-stage process. However, the water quality produced by the two-stage process is softer and lower in alkalinity than single-stage softening when magnesium reduction is desired.

When the softened water contains little or no excess caustic alkalinity, only single-stage recarbonation is possible. It is used to reduce the pH to the saturation pH. Usually the final pH is around 8.5 to 9.0.

As discussed in Chap. 10, reactor/clarifiers and sludge blanket clarifiers are typically used for lime-softening plants. For these systems, flocculation and sedimentation times are around 20 min and 1 to 2 h, respectively. Based on kinetic studies, it has been found that about 20 to 30 min of contact time is required for  $\text{Ca}^{2+}$  to precipitate as  $\text{CaCO}_3(\text{s})$  and approach equilibrium conditions (Alexander and McClanahan, 1975). The pH is also a factor in the kinetics of  $\text{Ca}^{2+}$  precipitation, as the kinetics of  $\text{CaCO}_3$  formation increase with an increase in pH in the range of 9.0 to 12 (Faust and Aly, 1998). Recycling  $\text{CaCO}_3$  sludge to provide a seeding effect for  $\text{Ca}^{2+}$  precipitation will increase the kinetics of  $\text{CaCO}_3$  formation in a significant way.

The kinetics of recarbonation are more efficient than  $\text{CaCO}_3$  precipitation and contact times in the  $\text{CO}_2$  diffusion and recarbonation tanks are typically a minimum of 3 and 20 min, respectively. A typical basin has baffled channels and walls and is about 3.7 m (12 ft) deep.

For the softening processes describe above, there are several process trains that are used in practice. Specific process train selection depends upon the raw-water quality and the treated-water quality objectives. Single-stage, two-stage, and split-stream treatment softening are discussed below.

#### SINGLE-STAGE SOFTENING

Single-stage softening, sometimes called *undersoftening*, is used for waters that do not require the removal of magnesium hardness. A typical process schematic of the single-stage process is shown on Fig. 20-12a. Lime is added to the raw water either upstream of the reactor/clarifier in a separate flash mix process or into the reactor/clarifier. Flash mixers are used because mixing with a conventional mechanical mixer will cause precipitation

### Kinetics of Lime Softening and Recarbonation

### Types of Softening Process Configurations

formation on the blades, resulting in the dislodging and release of  $\text{CaCO}_3$ . The pH of the water leaving the flash mixer is about 10.2 to 10.5. Soda ash can be added in the flash mix if noncarbonate hardness is present either with the lime or sequentially after the lime has been added.

As discussed in Chap. 10 (see Table 10-8), reactor/clarifiers and sludge blanket clarifiers are typically used for water-softening processes. Where reactor/clarifiers are used, lime sludge is frequently recycled to the head of the process train to improve the efficiency of the softening process. This recycle provides a seeding effect for the  $\text{CaCO}_3$  particles to flocculate.

Following sedimentation, the lime-treated water will pass through a recarbonation reactor where the addition of  $\text{CO}_2$  is used to reduce the pH from 10.2 to 10.5 to around 8.7 to 9.0. After recarbonation, particles that may form are removed by filtration. The water is usually softened to a final hardness of about 70 to 100 mg/L as  $\text{CaCO}_3$  and it is very close to the  $\text{pH}_s$  value. Sometimes postchlorination is sufficient to reduce the pH to the  $\text{pH}_s$ , eliminating the need for the recarbonation step.

#### **TWO-STAGE SOFTENING**

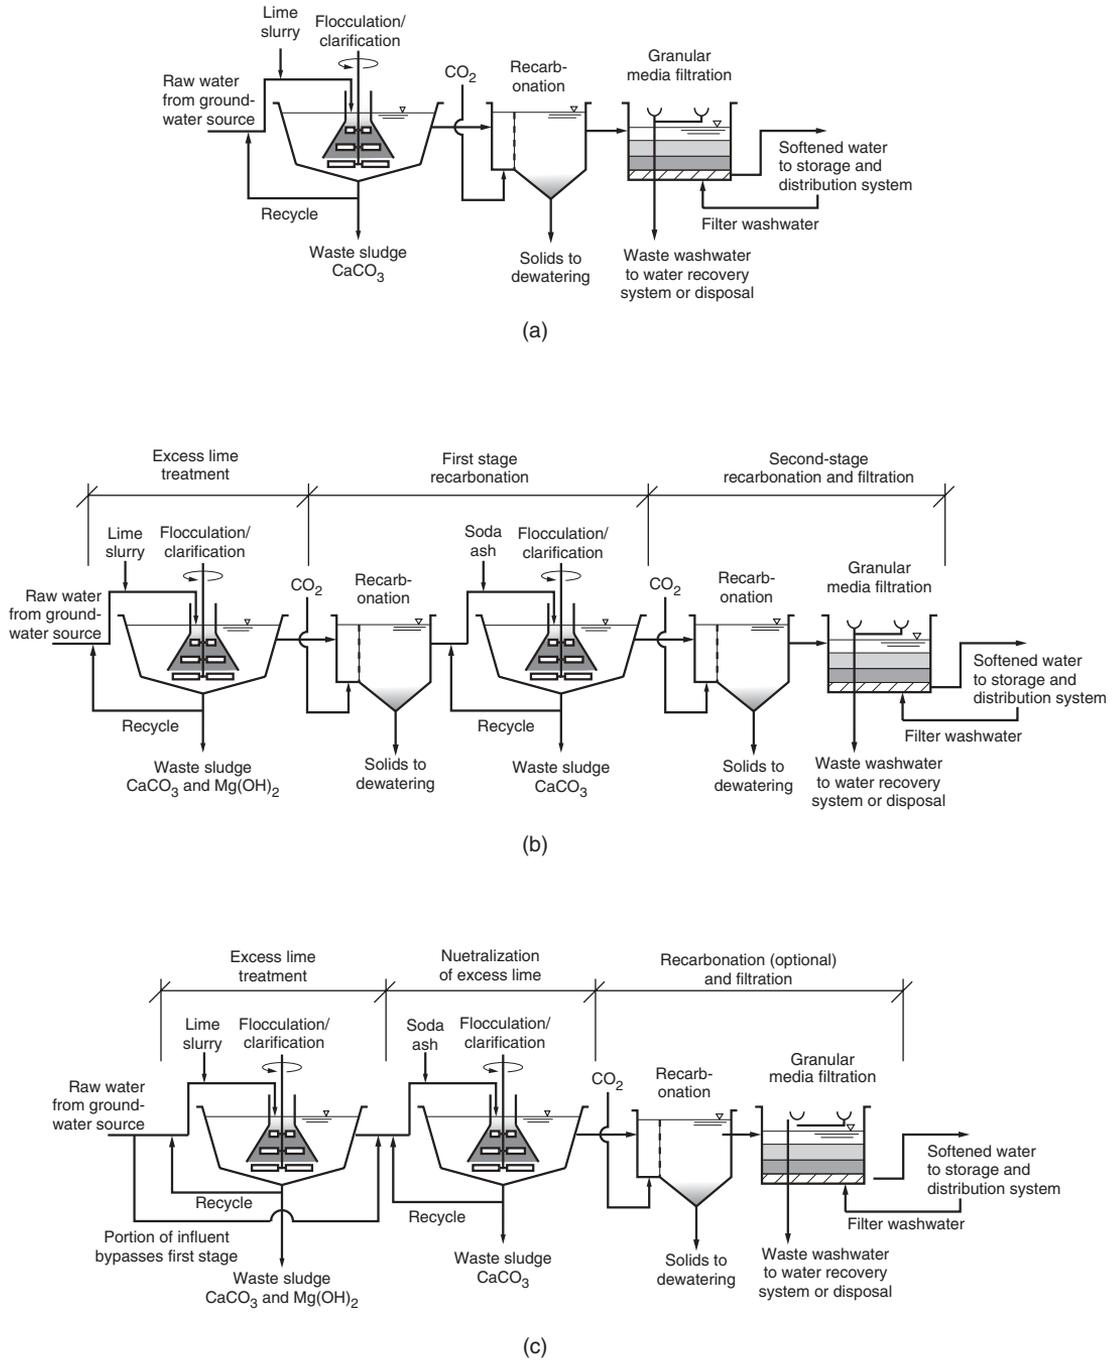

Sometimes postchlorination is sufficient to reduce the pH to the saturation pH ( $\text{pH}_s$ ), eliminating the need for the recarbonation step. A schematic of the split recarbonation process is shown on Fig. 20-12b. Excess lime is added with a flash mixer to raise the pH to 11.0 or higher to precipitate magnesium. After sedimentation,  $\text{CO}_2$  recarbonation is used to reduce the pH to about 10.0 to 10.6 and soda ash is added to precipitate the excess lime added for magnesium removal. The second-stage precipitation step is followed by sedimentation and then the second stage of  $\text{CO}_2$  recarbonation is used to lower the pH value around 8.3 to 8.5. Filtration is used to remove any particles formed from the second recarbonation step.

#### **SPLIT-TREATMENT SOFTENING**

Split-treatment configurations consist of separating the process water into two or more streams, treating the streams to various degrees with different process treatment techniques, and then blending them to obtain the desired effluent water quality. Three split-stream configurations that have been practiced are (1) parallel softening and coagulation, (2) parallel lime softening and ion exchange or reverse osmosis, and (3) split treatment with excess lime. The first two processes are discussed briefly first, as they are used less frequently, followed by a more detailed discussion of the split treatment with excess lime process.

#### **PARALLEL SOFTENING AND COAGULATION**

For waters high in magnesium, turbidity, and/or color, parallel softening and coagulation can sometimes be economical and cost effective. In this process, part of the water to be treated is softened with excess lime to remove calcium and magnesium hardness. The remaining part of the water to be treated is coagulated to remove turbidity and color and as a result will

**Figure 20-12** Process flow diagrams of common softening treatment techniques: (a) single-stage lime treatment; (b) two-stage excess lime-soda treatment, and (c) split-flow lime treatment.

be low in alkalinity. The waters are then blended to a balance of good color, turbidity, and hardness. A third stream has also been used in some cases to provide additional hardness for neutralization of excess caustic alkalinity in the softened water stream.

#### PARALLEL LIME SOFTENING AND ION EXCHANGE OR REVERSE OSMOSIS

This process modification can be used to soften raw waters with high noncarbonate and dissolved solids concentrations. Part of the water stream is treated with lime softening and the other part is softened with ion exchange or reverse osmosis. The use of ion exchange can be attractive when there is high noncarbonate hardness in the raw water, when the use of soda ash or caustic soda would not be economical, or in the case of an existing ion exchange plant. Reverse osmosis can be used instead of ion exchange for demineralization if the raw water requires additional reduction in dissolved solids.

#### SPLIT TREATMENT WITH EXCESS LIME

This process is used when magnesium must be reduced and the raw water contains very little noncarbonate hardness. A schematic of the excess lime split-stream process is shown on Fig. 20-12c. Part of the water is treated with excess lime softening for both calcium and magnesium hardness removal. In this part, the magnesium hardness can be removed down to its practical solubility limit of 10 mg/L. The other part of the water is bypassed and blended with the softened water prior to sedimentation. The alkalinity of the bypassed raw water is used to neutralize the excess caustic alkalinity required to reduce the magnesium in the treated water. Because the free carbon dioxide in the bypassed water is used to neutralize the excess lime of the processed stream, a recarbonation step is usually not needed. When the treatment objective of magnesium is chosen, a mass balance on the magnesium is used to determine the ratio of the bypass to treated flow, as given by the equation

$$X = \frac{[\text{Mg}^{2+}]_e - [\text{Mg}^{2+}]_t}{[\text{Mg}^{2+}]_0 - [\text{Mg}^{2+}]_t} \quad (20-35)$$

where  $X$  = ratio of bypassed flow  
 $[\text{Mg}^{2+}]_e$  = magnesium hardness concentration, mg/L as  $\text{CaCO}_3$  in finished water (Typically magnesium hardness is less than 50 mg/L as  $\text{CaCO}_3$  such that the level of total hardness in the finished water is less than 80 to 100 mg/L as  $\text{CaCO}_3$ )  
 $[\text{Mg}^{2+}]_0$  = magnesium hardness concentration (mg/L as  $\text{CaCO}_3$ ) in raw water  
 $[\text{Mg}^{2+}]_t$  = magnesium hardness concentration (mg/L as  $\text{CaCO}_3$ ) in excess lime treated water before blending

Split treatment works best for groundwaters. For surface waters, where color, taste, and odor may cause problems, the two-stage process is usually

preferred. As discussed above, total hardness levels up to 120 mg/L as  $\text{CaCO}_3$  are acceptable by some consumers so the calcium hardness in the finished water can be as high as 80 mg/L as  $\text{CaCO}_3$ .

An estimate of the chemical dosages for lime softening can be made using a number of different methods: (1) chemical stoichiometry, (2) the solution of simultaneous equilibria equations, (3) the use of softening diagrams, and (4) laboratory studies. All have applications in estimating chemical dosages with experimental methods providing results that most closely approximate plant performance. The chemical stoichiometry is typically used to obtain predesign information for planning and preliminary cost estimation. The solution of simultaneous equilibria equations is usually more rigorous as it involves numerical solution of a series of simultaneous equilibrium expressions. A number of programs such as RIDEQL, the MINEQL series, and the WATEQ series developed by the U.S. Geological Survey (Ball et al., 1979) can be used. These programs are typically used for research in the area of equilibrium and kinetics. The use of softening diagrams involves the use of Caldwell–Lawrence (CL) diagrams for estimating chemical dosages for the lime-softening process (Caldwell and Lawrence, 1953; Lowenthal and Marias, 1976; Merrill and Sanks, 1977). These diagrams were developed to enable equilibrium calculations to be made with less special training. A good discussion and application of this approach have been presented elsewhere (Benefield and Morgan, 1999; Sanks, 1978). The fourth approach, laboratory studies, is discussed in Chap. 9. Estimating chemical dosages for softening based on stoichiometry is illustrated below.

### **Chemical Dose Calculations for Lime–Soda Ash Softening**

#### **CHEMICAL DOSAGES BASED ON STOICHIOMETRY**

The stoichiometric method is based on the assumption that all of the relevant reactions go to completion. Corrections can be made for the solubility of calcium carbonate and for the excess hydroxide alkalinity required for magnesium hydroxide precipitation. The chemical requirements can be estimated using the guidelines presented in Table 20-11. The guidelines were developed based on the stoichiometric expressions discussed previously (Eqs. 20-19 through 20-35) and the discussion of various lime-softening processes. The lime required as 100 percent  $\text{CaO}$  is calculated by noting that it serves the function of  $\text{CO}_2$  removal, bicarbonate conversion to carbonate, and magnesium reduction. Use of the information in Table 20-11 for estimating the chemical dosages required for the various lime-softening processes is illustrated in Examples 20-6 and 20-7.

The soda ash requirement can be estimated from Eq. 20-23 by noting that soda ash is used only for noncarbonate hardness reduction because it requires about 1.9 times as much 100 percent  $\text{Na}_2\text{CO}_3$  as 100 percent  $\text{CaO}$  to remove the same amount of hardness. Further, because soda ash is more expensive on a mass basis than  $\text{CaO}$ , it is desirable to minimize the amount of soda ash used (i.e., the amount of noncarbonate hardness

**Table 20-11**

Summary of chemical dosage calculations required for lime and lime–soda ash softening<sup>a</sup>

Process	Required Chemical Dosage Calculations
<p><b>Single-stage lime:</b> For waters with high calcium, low magnesium, and carbonate hardness</p>	<p>Lime addition for softening:  <math display="block">\text{CaO} = \{ \text{carbonic acid concentration} \} + \{ \text{calcium carbonate hardness} \}</math>           Soda ash addition for softening:  <math display="block">\text{Na}_2\text{CO}_3 = \text{none}</math>           Carbon dioxide for pH adjustment after softening:  <math display="block">\text{CO}_2 = \left\{ \begin{array}{l} \text{estimated} \\ \text{carbonate alkalinity} \\ \text{of softened water} \end{array} \right\} = \left\{ \begin{array}{l} \text{source} \\ \text{water} \\ \text{alkalinity} \end{array} \right\} - \left\{ \begin{array}{l} \text{source} \\ \text{water} \\ \text{hardness} \end{array} \right\} + \left\{ \begin{array}{l} \text{estimated residual} \\ \text{calcium hardness} \\ \text{of softened water} \end{array} \right\}</math> </p>
<p><b>Excess lime:</b> for waters with high calcium, high magnesium, and process may be one or two stages</p>	<p>Lime addition for softening:  <math display="block">\text{CaO} = \left\{ \begin{array}{l} \text{carbonic acid} \\ \text{concentration} \end{array} \right\} + \left\{ \begin{array}{l} \text{total} \\ \text{alkalinity} \end{array} \right\} + \left\{ \begin{array}{l} \text{magnesium} \\ \text{hardness} \end{array} \right\} + \left\{ \begin{array}{l} \text{excess} \\ \text{lime dose} \end{array} \right\}</math>           Soda ash addition for softening:  <math display="block">\text{Na}_2\text{CO}_3 = \text{none}</math>           Carbon dioxide for pH adjustment after softening:  <math display="block">\text{CO}_2 = \left\{ \begin{array}{l} \text{source} \\ \text{water} \\ \text{alkalinity} \end{array} \right\} - \left\{ \begin{array}{l} \text{source} \\ \text{water total} \\ \text{hardness} \end{array} \right\} - \left\{ \begin{array}{l} \text{excess} \\ \text{lime} \\ \text{dose} \end{array} \right\} + \left\{ \begin{array}{l} \text{estimated residual} \\ \text{magnesium hardness} \\ \text{of softened water} \end{array} \right\} + 2 \left\{ \begin{array}{l} \text{estimated residual} \\ \text{calcium hardness} \\ \text{of softened water} \end{array} \right\} + \left\{ \begin{array}{l} \text{excess} \\ \text{lime} \\ \text{dose} \end{array} \right\}</math> </p>
<p><b>Single-stage lime–soda ash:</b> for water with high calcium, low magnesium, and carbonate and noncarbonate hardness</p>	<p>Lime addition for softening:  <math display="block">\text{CaO} = \{ \text{carbonic acid concentration} \} + \{ \text{calcium carbonate hardness} \}</math>           Soda ash addition for softening:  <math display="block">\text{Na}_2\text{CO}_3 = \{ \text{calcium noncarbonate hardness} \} \text{ and/or } \{ \text{magnesium noncarbonate hardness} \}</math>           Carbon dioxide for pH adjustment after softening:  <math display="block">\text{CO}_2 = \left\{ \begin{array}{l} \text{source} \\ \text{water} \\ \text{alkalinity} \end{array} \right\} + \left\{ \begin{array}{l} \text{soda} \\ \text{ash} \\ \text{dose} \end{array} \right\} - \left\{ \begin{array}{l} \text{source water} \\ \text{calcium} \\ \text{hardness} \end{array} \right\} + \left\{ \begin{array}{l} \text{estimated residual} \\ \text{calcium hardness} \\ \text{of softened water} \end{array} \right\}</math> </p>

**Excess lime-soda ash:** for waters with high calcium, high magnesium, and carbonate and noncarbonate hardness; process may be one or two stages

Lime addition for softening:

$$\text{CaO} = \left\{ \begin{array}{l} \text{carbonic} \\ \text{acid} \\ \text{concentration} \end{array} \right\} + \left\{ \begin{array}{l} \text{calcium} \\ \text{carbonate} \\ \text{concentration} \end{array} \right\} + 2 \left\{ \begin{array}{l} \text{magnesium} \\ \text{carbonate} \\ \text{hardness} \end{array} \right\} + \left\{ \begin{array}{l} \text{magnesium} \\ \text{noncarbonate} \\ \text{hardness} \end{array} \right\} + \left\{ \begin{array}{l} \text{excess} \\ \text{lime} \\ \text{requirement} \end{array} \right\}$$

Soda ash addition for softening:

$$\text{Na}_2\text{CO}_3 = \left\{ \begin{array}{l} \text{calcium} \\ \text{noncarbonate} \\ \text{hardness} \end{array} \right\} + \left\{ \begin{array}{l} \text{magnesium} \\ \text{noncarbonate} \\ \text{hardness} \end{array} \right\}$$

Carbon dioxide for pH adjustment after softening:

$$\text{CO}_2, \text{ first stage} = \left\{ \begin{array}{l} \text{estimated} \\ \text{hydroxide alkalinity} \\ \text{of softened water} \end{array} \right\} = \left\{ \begin{array}{l} \text{excess} \\ \text{lime} \\ \text{dose} \end{array} \right\} + \left\{ \begin{array}{l} \text{estimated residual} \\ \text{magnesium hardness} \\ \text{of softened water} \end{array} \right\}$$

$$\text{CO}_2, \text{ second stage} = \left\{ \begin{array}{l} \text{estimated} \\ \text{hydroxide alkalinity} \\ \text{of softened water} \end{array} \right\} = \left\{ \begin{array}{l} \text{source} \\ \text{water} \\ \text{alkalinity} \end{array} \right\} - \left\{ \begin{array}{l} \text{soda} \\ \text{ash} \\ \text{dose} \end{array} \right\} + \left\{ \begin{array}{l} \text{source} \\ \text{water total} \\ \text{hardness} \end{array} \right\} + \left\{ \begin{array}{l} \text{estimated residual} \\ \text{hardness of} \\ \text{softened water} \end{array} \right\}$$

<sup>a</sup>All quantities are expressed as mg/L as CaCO<sub>3</sub>.

removed). Minimizing the use of soda ash can be done by reducing the residual carbonate hardness to a minimum or allowing the hardness of the finished water to be higher or both.

### Example 20-6 Single-stage selective calcium removal

A 50-ML/d raw-water source is to be softened to reduce the hardness. The mineral analysis of the raw water is given below. The average raw-water temperature and pH were found to be 10°C and pH 7.0, respectively. Using the given information, determine the total, carbonate, and noncarbonate hardness present in the raw and finished waters; the kilograms per day of lime, soda ash, and CO<sub>2</sub> needed for selective calcium softening; and the kilograms per day of CaCO<sub>3</sub> solids produced. Draw the initial and final bar diagrams of the raw and softened water. Assume the residual calcium hardness in the softened water is 30 mg/L as CaCO<sub>3</sub>.

Constituent	Unit	Value
H <sub>2</sub> CO <sub>3</sub> *	mg/L	72
Ca <sup>2+</sup>	mg/L	75
Mg <sup>2+</sup>	mg/L	6.1
Na <sup>+</sup>	mg/L	36.8
Alkalinity	mg/L as CaCO <sub>3</sub>	195
SO <sub>4</sub> <sup>2-</sup>	mg/L	60
Cl <sup>-</sup>	mg/L	25

#### Solution

1. Develop a summary table for the chemical constituents and the conversion of all the concentrations to meq/L and mg/L as CaCO<sub>3</sub>:

Chemical Constituent	Concentration, mg/L	Equivalent	Molecular Weight	Equivalent Weight	Concentration, meq/L	mg/L as CaCO <sub>3</sub>
H <sub>2</sub> CO <sub>3</sub> *	72.0	2	62.0	31.0	2.32	116.0
Ca <sup>2+</sup>	75.0	2	40.0	20.0	3.75	187.5
Mg <sup>2+</sup>	6.1	2	24.4	12.2	0.50	25.0
Na <sup>+</sup>	36.8	1	23.0	23.0	1.60	80.0
Total cation					5.85	292.5
Alk (HCO <sub>3</sub> )	195.0	2	100.0	50.0	3.90	195
SO <sub>4</sub> <sup>2-</sup>	60.0	2	96.0	48.0	1.25	62.5
Cl <sup>-</sup>	25.0	1	35.5	35.5	0.70	35
Total anion					5.85	292.5

As a check, the constituent anions and cations should balance as shown.

2. Construct a bar diagram of the raw water that includes the chemical constituents that are important for softening. In the development of the bar diagrams, the cation constituents are placed on the top of the diagram and the anions are placed on the bottom. In relationship to the order of cations to anions on the bar diagram, they are placed according to their reactivity to lime. For example, as stated above, lime will first react with  $\text{H}_2\text{CO}_3^*$  ( $[\text{CO}_2]_{\text{aq}}$ ) followed by  $\text{HCO}_3^-$  and then the rest of the nonreacting anions. The order for the cations is  $\text{Ca}^{2+}$  followed by  $\text{Mg}^{2+}$  and then the rest of the cations as shown below.

116	0.0		187.5	212.5		292.5
$\text{H}_2\text{CO}_3^*$		$\text{Ca}^{2+}$	$\text{Mg}^{2+}$		$\text{Na}^+$	
		$\text{HCO}_3^-$		$\text{SO}_4^{2-}$		$\text{Cl}^-$
116	0.0		195	257.5		292.5

3. Determine the total hardness, carbonate hardness, and noncarbonate hardness.
  - a. The total hardness can be calculated from the table as the sum of the calcium and magnesium ions as  $\text{CaCO}_3$  or taken directly from the bar chart:

$$\text{Total hardness} = (187.5 + 25) = 212.5 \text{ mg/L as CaCO}_3$$

- b. The carbonate hardness is simply the sum of the calcium and magnesium ions associated with bicarbonate ions. From the bar diagram of the raw water, all the calcium is associated with bicarbonate and only a small amount of the magnesium is associated with the rest of the bicarbonate. Because all the bicarbonate is associated with calcium and magnesium, the carbonate hardness is simply equal to bicarbonate alkalinity as  $\text{CaCO}_3$  as shown by the following:

$$\begin{aligned} \text{Carbonate hardness} &= 187.5 + (195 - 187.5) \\ &= 195 \text{ mg/L as CaCO}_3 \end{aligned}$$

- c. From the bar chart, the noncarbonate hardness is simply the magnesium ions not associated with carbonate hardness:

$$\begin{aligned} \text{Noncarbonate hardness} &= 212.5 - 195.0 \\ &= 17.5 \text{ mg/L as CaCO}_3 \end{aligned}$$

4. Calculate the lime, soda ash, and carbon dioxide dosages required for selective calcium softening.

a. From Table 20-11, the lime requirement for single-stage treatment is given as

$$\text{CaO required} = \text{carbonic acid concentration} \\ + \text{calcium carbonate hardness concentration}$$

or from the bar diagram:

$$\begin{aligned} \text{CaO required} &= [(116 \text{ mg CaCO}_3/\text{L}) + (187.5 \text{ mg CaCO}_3/\text{L})] \\ &\quad \times (28 \text{ mg CaO}/50 \text{ mg CaCO}_3) \\ &= 170 \text{ mg/L} \\ &= (170 \text{ mg CaO/L})(1 \text{ kg}/10^6 \text{ mg})(50 \times 10^6 \text{ L/d}) \\ &= 8500 \text{ kg/d} \end{aligned}$$

b. Because there is sufficient alkalinity to precipitate calcium, no soda ash is required.

c. From Table 20-11, the carbon dioxide requirement for selective calcium removal is equal to the estimated carbonate alkalinity of the softened water:

$$\begin{aligned} \text{Estimated carbonate alkalinity of softened water} \\ &= \text{source water alkalinity} \\ &\quad - \text{source water calcium hardness} \\ &\quad + \text{estimated residual calcium hardness of softened water} \end{aligned}$$

Assuming the residual calcium hardness in the softened water is 30 mg/L as CaCO<sub>3</sub>, the CO<sub>2</sub> can be calculated as

$$\begin{aligned} \text{Estimated carbonate alkalinity of softened water} \\ &= (195 - 187.5 + 30.0) \text{ mg CaCO}_3/\text{L} \\ &= 37.5 \text{ mg CaCO}_3/\text{L} \end{aligned}$$

$$\begin{aligned} \text{CO}_2 \text{ required} \\ &= (37.5 \text{ mg CaCO}_3/\text{L}) \\ &\quad \times (22.0 \text{ mg CO}_2/50 \text{ mg CaCO}_3) = 16.5 \text{ mg/L} \\ &= (16.5 \text{ mg CO}_2/\text{L})(1 \text{ kg}/10^6 \text{ mg})(50 \times 10^6 \text{ L/d}) \\ &= 825 \text{ kg/d} \end{aligned}$$

5. Determine the quantity of precipitated solids. The quantity of precipitated solids will be equal to the sum of the  $\text{H}_2\text{CO}_3^*$  precipitated as  $\text{CaCO}_3$  (see Eq. 20-19) and two times the calcium carbonate hardness precipitated as  $\text{CaCO}_3$  (see Eq. 20-20) because an equivalent amount of lime was added to remove the calcium as bicarbonate, minus the solubility of  $\text{CaCO}_3$ :

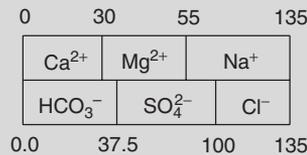

$$\begin{aligned}\text{CaCO}_3 \text{ solids produced} &= [(116.0 + 2 \times 187.5 - 30.0) \text{ mg CaCO}_3/\text{L}] \\ &\quad \times 1 \left(1 \text{ kg}/10^6 \text{ mg}\right) \left(50 \times 10^6 \text{ L}/\text{d}\right) \\ &= 23,050 \text{ kg}/\text{d}\end{aligned}$$

6. Calculate the total, carbonate, and noncarbonate hardness present in finished water. In this water, the final hardness will be the sum of the soluble calcium and the magnesium carbonate hardness plus the magnesium noncarbonate hardness:

$$\begin{aligned}\text{Total final hardness of softened water} \\ &= [(30 + 7.5) + (17.5)] \text{ mg}/\text{L} \\ &= 55 \text{ mg}/\text{L as CaCO}_3\end{aligned}$$

$$\begin{aligned}\text{Final noncarbonate hardness of softened water} \\ &= 17.5 \text{ mg}/\text{L as CaCO}_3\end{aligned}$$

7. Draw a bar diagram of the finished water.

#### DETERMINATION OF CARBONIC ACID CONCENTRATION FOR SOFTENING CALCULATIONS

Some laboratories may provide the carbonic acid concentration,  $\text{H}_2\text{CO}_3^*$ . If the concentration of  $\text{H}_2\text{CO}_3^*$  is not given, then it can be calculated from carbonic acid equilibria. The applicable equilibrium equations for the carbonic acid system are

Because the dissolved fraction of the total  $\text{CO}_2$  in water is small and hydrolyzes to  $\text{H}_2\text{CO}_3$ , the  $\text{H}_2\text{CO}_3^*$  concentration is taken as the sum

of  $\text{CO}_2$  and  $\text{H}_2\text{CO}_3$  concentrations. The equilibrium constants for the stoichiometric equations (Eqs. 20-36 and 20-37) are

$$K_1 = \frac{[\text{H}^+][\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3^*]} \quad (20-38)$$

$$K_2 = \frac{[\text{H}^+][\text{CO}_3^{2-}]}{[\text{HCO}_3^-]} \quad (20-39)$$

where  $K_1$  = first dissociation constant for carbonic acid  
 $K_2$  = second dissociation constant for carbonic acid

Both  $K_1$  and  $K_2$  have been correlated to temperature and can be calculated from the expressions (Rossum and Merrill, 1983)

$$K_1 = 10^{14.8435 - 3404.71/T - 0.032786T} \quad (20-40)$$

$$K_2 = 10^{6.498 - 2909.39/T - 0.02379T} \quad (20-41)$$

where  $T$  = water temperature, K

The total carbonic species concentration,  $C_T$ , in water is represented by the expression

$$C_T = [\text{H}_2\text{CO}_3^*] + [\text{HCO}_3^-] + [\text{CO}_3^{2-}] \quad (20-42)$$

where  $C_T$  = total carbonic species concentration, mol/L

The ionization fractions of these species defined for each species are

$$\alpha_0 = \frac{[\text{H}_2\text{CO}_3^*]}{C_T} \quad (20-43)$$

$$\alpha_1 = \frac{[\text{HCO}_3^-]}{C_T} \quad (20-44)$$

$$\alpha_2 = \frac{[\text{CO}_3^{2-}]}{C_T} \quad (20-45)$$

Based on Eqs. 20-42 through 20-45, the following expressions can be used to calculate the ionization fractions based on acid reactions in natural waters (i.e., alkalinity is in the form of bicarbonate alkalinity):

$$\alpha_0 = \frac{1}{1 + K_1/[\text{H}^+] + K_1K_2/[\text{H}^+]^2} \quad (20-46)$$

$$\alpha_1 = \frac{1}{[\text{H}^+]/K_1 + 1 + K_2/[\text{H}^+]} \quad (20-47)$$

$$\alpha_2 = \frac{1}{[\text{H}^+]^2/(K_1K_2) + [\text{H}^+]/K_2 + 1} \quad (20-48)$$

Given the alkalinity, pH, and temperature of the water, Eqs. 20-42 through 20-48 can be used to calculate the  $\text{H}_2\text{CO}_3^*$  concentration (procedure adapted from Benefield and Morgan, 1999).

### Example 20-7 Single-stage excess lime softening

A 50-ML/d raw-water source is to be softened to reduce the hardness. The mineral analysis of the raw water is given below. The average raw-water temperature and pH were found to be 15°C and 7.2, respectively. Using the given information, determine the carbonic acid concentration in the raw water; the total carbonate and noncarbonate hardness present in the raw and finished water; the kilograms per day of lime, soda ash, and CO<sub>2</sub> needed for selective calcium softening; and the kilograms per day of CaCO<sub>3</sub> solids produced. Draw the initial and final bar diagrams of the raw and softened water. The residual calcium and magnesium hardnesses in the softened water are 30 and 20 mg/L as CaCO<sub>3</sub>, respectively. Use an excess lime dose of 30 mg/L as CaCO<sub>3</sub>.

Constituent	Unit	Value
Ca <sup>2+</sup>	mg/L	60
Mg <sup>2+</sup>	mg/L	20
Na <sup>+</sup>	mg/L	15.9
Alk(HCO <sub>3</sub> <sup>-</sup> )	mg/L as CaCO <sub>3</sub>	240
SO <sub>4</sub> <sup>2-</sup>	mg/L	12
Cl <sup>-</sup>	mg/L	10

#### Solution

- Develop a summary table for the chemical constituents and the conversion of all the concentrations to meq/L and mg/L as CaCO<sub>3</sub>. Because the H<sub>2</sub>CO<sub>3</sub><sup>\*</sup> was not given, it must first be determined from the alkalinity, pH, and temperature.
  - The carbonic acid concentration can be determined from Eq. 20-42 if it is assumed that at pH = 7.2 the alkalinity is primarily made up of bicarbonate alkalinity:

$$C_T = [\text{H}_2\text{CO}_3^*] + [\text{HCO}_3^-] + [\text{CO}_3^{2-}] = [\text{H}_2\text{CO}_3^*] + [\text{HCO}_3^-] + 0$$

- The  $C_T$  value can be determined from the pH, temperature, and bicarbonate alkalinity using Eqs. 20-44, 20-47, 20-40, and 20-41 as shown:

$$\alpha_1 = \frac{1}{\frac{[\text{H}^+]}{K_1} + 1 + K_2/[\text{H}^+]}$$

$$C_T = \frac{[\text{HCO}_3^-]}{\alpha_1}$$

$$\begin{aligned}
 K_1 &= 10^{14.8435 - 3404.71/T(K) - 0.032786T(K)} \\
 &= 10^{14.8435 - 3404.71/288\text{ K} - 0.032786 \times 288\text{ K}} = 3.79 \times 10^{-7} \\
 K_2 &= 10^{6.498 - 2909.39/T(K) - 0.02379T(K)} \\
 &= 10^{6.498 - 2909.39/288\text{ K} - 0.02379 \times 288\text{ K}} = 3.50 \times 10^{-11} \\
 \alpha_1 &= \frac{1}{(1.0 \times 10^{-7.2}) / 3.79 \times 10^{-7} + 1 + 3.5 \times 10^{-11} / (1.0 \times 10^{-7.2})} \\
 &= 0.86 \\
 C_T &= \frac{[\text{HCO}_3^-]}{\alpha_1} = \frac{(240\text{ mg/L}) [1/(100\text{ g/mol})] (1\text{g}/10^3\text{ mg})}{0.86} \\
 &= 2.79 \times 10^{-3}\text{ mol/L}
 \end{aligned}$$

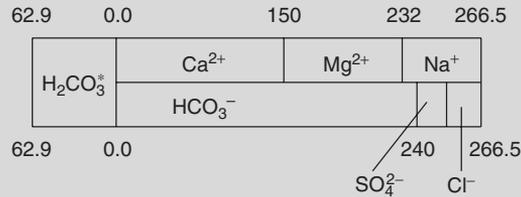

c. The carbonic acid concentration can be determined as

$$\begin{aligned}
 [\text{H}_2\text{CO}_3^*] &= C_T - [\text{HCO}_3^-] + [\text{CO}_3^{2-}] \\
 &= 2.79 \times 10^{-3} - 2.4 \times 10^{-3} - 0 \\
 &= (3.9 \times 10^{-4}\text{ mol/L})(100\text{ g/mol})(10^3\text{ mg/g}) \\
 &= 39.0\text{ mg/L as CaCO}_3
 \end{aligned}$$

d. A summary of the chemical constituents in terms of  $\text{CaCO}_3$  is shown in the following table:

Chemical Constituent	Concentration		Molecular Equivalent		mg/L as	
	mg/L	Equivalents	Weight	Weight	meq/L	CaCO <sub>3</sub>
H <sub>2</sub> CO <sub>3</sub> *	39	2	62.0	31.0	1.26	62.9
Cations						
Ca <sup>2+</sup>	60	2	40.0	20.0	3.00	150
Mg <sup>2+</sup>	20	2	24.4	12.2	1.64	82
Na <sup>+</sup>	15.9	1	23.0	23.0	0.69	34.5
Total					5.33	266.5
Anions						
Alk as CaCO <sub>3</sub>	240	2	100	50.0	4.8	240
SO <sub>4</sub> <sup>2-</sup>	12	2	96.0	48	0.25	12.5
Cl <sup>-</sup>	10	1	35.5	35.5	0.28	14
Total					5.33	266.5

2. Construct a bar diagram of the raw water that includes the chemical constituents (as  $\text{CaCO}_3$ ) that are important for softening (see step 2 in Example 20-6 for a discussion of the development of the bar diagram).

3. Determine the total hardness, carbonate hardness, and noncarbonate hardness.
- The total hardness can be calculated from the summary table as the sum of the calcium and magnesium ions as  $\text{CaCO}_3$  or taken directly from the bar chart:

$$\begin{aligned}\text{Total hardness} &= (150 + 82) \text{ mg/L as CaCO}_3 \\ &= 232 \text{ mg/L as CaCO}_3\end{aligned}$$

- The carbonate hardness is the same as the total hardness because there is no noncarbonate hardness present:

$$\text{Carbonate hardness} = 232 \text{ mg/L as CaCO}_3$$

- In this case the noncarbonate hardness is zero.

4. Calculate the lime, soda ash, and carbon dioxide dosages required for excess lime softening.
- From Table 20-11 for excess lime treatment, the following expression can be used to calculate the lime dose:

$$\begin{aligned}\text{CaO required} &= \text{carbonic acid concentration} + \text{calcium hardness} \\ &\quad + \text{magnesium hardness} + \text{excess lime dose} \\ &= [(62.9 + 240 + 82 + 30) \text{ mg CaCO}_3/\text{L}] \\ &\quad \times (28 \text{ mg CaO}/50 \text{ mg CaCO}_3) \\ &= 232 \text{ mg/L} \\ &= (232 \text{ mg CaO/L})(1 \text{ kg}/10^6 \text{ mg})(50 \times 10^6 \text{ L/d}) \\ &= 11,600 \text{ kg/d}\end{aligned}$$

- Because all the hardness is in the carbonate form, no soda ash dose is required.

- c. The carbon dioxide requirement for selective calcium removal is equal to the estimated carbonate alkalinity of the softened water plus two times the excess lime dose and the estimated residual magnesium hardness of the softened water or as given by the expression

CO<sub>2</sub> required

= estimated carbonate alkalinity of softened water

+ 2 × excess lime dose

+ estimated residual magnesium hardness of softened water

- d. Carbonate alkalinity of the softened water is calculated as

Estimated carbonate alkalinity of softened water

= source water alkalinity – source water total hardness

– excess lime dose

+ estimated residual calcium hardness of softened water

= (240 – 232 – 30 + 30) mg CaCO<sub>3</sub>/L = 8 mg CaCO<sub>3</sub>/L

- e. Consequently, the CO<sub>2</sub> dosage requirement is calculated as

CO<sub>2</sub> required

= [(8 + 2 × 30 + 20) mg CaCO<sub>3</sub>/L](22 mg CO<sub>2</sub>/50 mg CaCO<sub>3</sub>)

= 39 mg CO<sub>2</sub>/L

= (39 mg CO<sub>2</sub>/L)(1 kg/10<sup>6</sup> mg)(50 × 10<sup>6</sup> L/d) = 1,950 kg/d

- f. The CaCO<sub>3</sub> solids precipitated can be calculated from the table where it will be equal to the sum of the H<sub>2</sub>CO<sub>3</sub>\* precipitated as CaCO<sub>3</sub>, 2 times the calcium carbonate hardness precipitated as CaCO<sub>3</sub> (see Eq. 20-20), 2 times the magnesium hardness precipitated, precipitation of the excess lime added, and minus the solubility of CaCO<sub>3</sub>:

CaCO<sub>3</sub> solids produced

= [(62.9 + 2 × 150 + 2 × 82 – 30) mg CaCO<sub>3</sub>/L]

(1 kg/10<sup>6</sup> mg)(50 × 10<sup>6</sup> L/d)

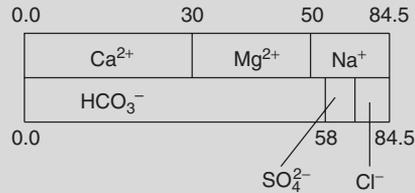

= 24,845 kg/d

5. Calculate the total, carbonate, and noncarbonate hardness present in finished waters. The carbonate hardness will be the sum of the

soluble calcium and the magnesium carbonate hardness and the noncarbonate hardness is equal to zero. Therefore, the total hardness is equal to the total carbonate hardness:

$$\text{Total carbonate hardness} = (30 + 20) = 50 \text{ mg/L as CaCO}_3$$

6. The final bar diagram of the finished water in terms of  $\text{CaCO}_3$  is given below.

## 20-5 Nitrate

The principal sources of nitrogen are from (1) nitrogenous compounds produced by plant and animals, (2) the mining of sodium nitrate for use in fertilizers, and (3) the atmosphere. The most oxidized form of nitrogen is nitrate ( $\text{NO}_3^-$ ). In the United States, the average dietary intake of nitrate is about 75 to 100 mg/d, of which approximately 80 to 90 percent comes from vegetables. Vegetables with high nitrate levels are lettuce, beets, celery, and spinach. It is interesting that people on a vegetarian diet may consume as much as 250 mg/d of nitrate. Accordingly, drinking water accounts for only 5 to 10 percent of nitrates consumed. However, if the nitrate levels in the water are five times the MCL (10 mg/L), water may supply a person about half the daily diet requirements.

Although nitrate occurs naturally in drinking water sources, elevated levels usually come from human activity such as municipal and industrial wastes, unmanaged solid waste landfills, onsite wastewater systems, runoff or groundwater from manured and fertilized agricultural lands, stormwater drainage, and animal feed lots. Because nitrates are extremely soluble in water, they can easily seep through the soil and into drinking water supplies. Surface waters such as lakes, reservoirs, and rivers are also susceptible to nitrate contamination from these sources. Nitrate concentrations in surface and groundwaters may be increasing worldwide (Nixon, 1992; Spalding and Exner, 1993).

Nitrate is of primary concern for infants younger than 6 months of age. Infants are very susceptible to methemoglobinemia, a condition known as “blue baby syndrome.” High nitrate levels that are reduced in the stomach and/or the saliva of an infant to nitrite cause blue baby syndrome. Nitrite

### Occurrence and Importance in Water Supplies

in the blood combines with hemoglobin to form methemoglobin, which reduces the capability of the blood to transport oxygen throughout the body. This results in the skin of a baby turning blue and can be fatal. The present MCL in the United States is 10 mg/L as nitrate and Canada has established a maximum acceptable concentration (MAC) of 10 mg NO<sub>3</sub><sup>-</sup> – N/L. The European Union recommends a level of 11.3 mg NO<sub>3</sub><sup>-</sup>/L.

## Treatment Strategies

Because nitrate is a stable, highly soluble ion, it is difficult to remove by conventional coagulation and adsorption processes. Present technologies for nitrate removal from water supplies include chemical and biological denitrification, reverse osmosis, electrodialysis, and ion exchange.

### CHEMICAL DENITRIFICATION

Chemical denitrification involves the reduction of nitrate to nitrogen gas using metals such as iron and aluminum. This process was evaluated and found to be very expensive due to the high metal dosages and other costs associated with the process (Murphy, 1991; Sorg, 1978a,b).

### BIOLOGICAL DENITRIFICATION

Biological denitrification takes place in an anoxic environment where nitrate is converted to nitrogen gas through the following series of steps:

To provide an anoxic environment, the DO concentration in the water must be less than about 0.1 mg/L. Both heterotrophic and autotrophic bacteria can be used to denitrify water. Heterotrophic bacteria require an organic carbon source to be used as an electron acceptor for the denitrification reaction. For drinking water, the microorganisms can utilize NOM if the concentration is high enough and the form of NOM is amenable to biodegradation. In most cases, it is necessary to add in an organic source such as methanol, ethanol, or acetic acid. The carbon-to-nitrogen ratios required for methanol, ethanol, and acetic acid are reported to be 0.93, 1.05, and 1.32, respectively (Mateju et al., 1992).

Autotrophic bacteria are also capable of denitrification. Bacteria such as *Thiobacillus denitrificans* can use hydrogen or reduced sulfur species as substrate and carbon dioxide or bicarbonate as carbon sources for cell synthesis. Autotrophic bacteria require a minimum sulfur-to-nitrogen ratio of 4.3 when using thiosulfate and a minimum hydrogen-to-nitrogen ratio of 0.38 when using hydrogen as the substrate. Autotrophic bacteria have also been used in in situ denitrification in groundwater (Gayle et al., 1989).

#### *Attached and suspended growth*

Pilot studies have been performed to evaluate the feasibility and performance of several biological denitrification processes. The results from a number of biological denitrification pilot- and some full-scale studies that were designed to evaluate the biological denitrification process are reported

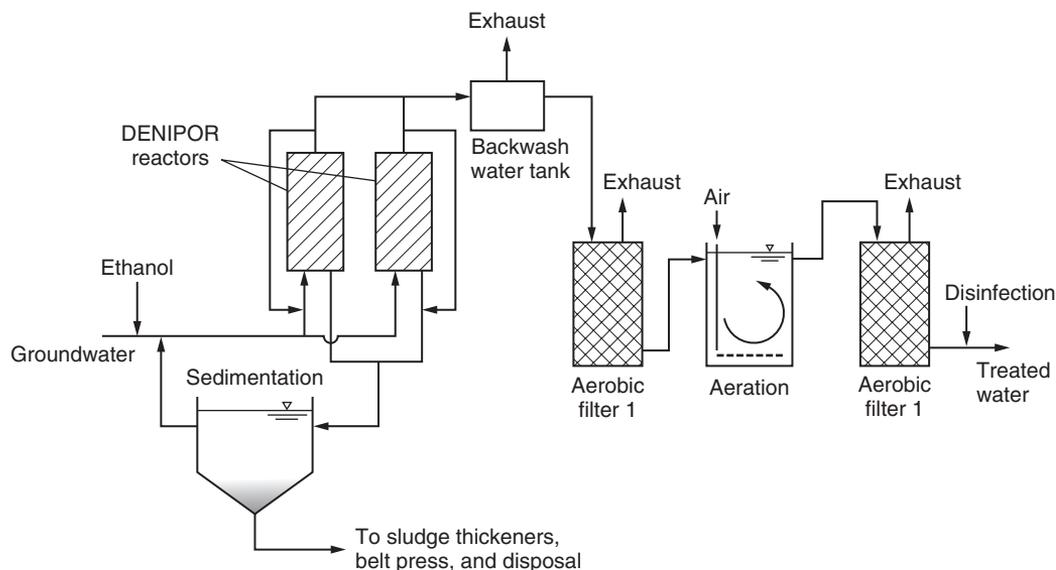

**Table 20-12**

Summary of several reported biological denitrification studies

Study	Reactor Type(s)	Water Source	Performance	Comments
1	1. Packed bed 2. Suspended growth  3. Fluidized sand bed (heterotrophic)	Thames water with methanol added	Reported denitrification rate 1. 12 g N/m <sup>3</sup> · h 2. 12–160 g N/m <sup>3</sup> · h 3. 160 g N/m <sup>3</sup> · h	Fluidized-bed reactor reduced nitrate by 45 mg/L at 2°C using upflow velocity of 12 m/h
2	Packed sand bed (heterotrophic)	Groundwater with sucrose added	With initial nitrate concentration of 22.6 mg/L, 100% removal was obtained with carbon-to-nitrogen ratio of 2.0	Vacuum used to remove trapped nitrogen gas in packed column
3	Static bed upflow reactor with spherical support medium (heterotrophic)	Groundwater with acetic acid added	With initial nitrate concentration of 100 mg/L, 100% removal was obtained with carbon-to-nitrogen ratio of 1.5	Retention time 9 h, effluent high in suspended solids and turbidity
4	Fluidized sand bed (heterotrophic)	Groundwater with methanol added	With initial nitrate concentration of 75 mg/L, 100% removal was observed for EBCT of 15 min	Flow rate 0.95 ML/d (0.25 mgd), reactor loading was 9.0 kg NO <sub>3</sub> <sup>-</sup> /m <sup>3</sup> d, methanol added 20–25% higher than stoichiometric requirement
5	DENITROPUR process, fixed-bed reactor (heterotrophic)	Groundwater with hydrogen added	With initial nitrate concentration of 75 mg/L, 99% removal observed	Flow rate 2.4 ML/d (0.63 mgd) with loading rate of 0.12 kg N/m <sup>3</sup> · d
6	DENIPOR process, fixed-bed reactor with polystyrene medium (autotrophic)	Groundwater with ethanol and phosphate added	Removal rate of 95% reported	Process loading rate 0.7–1.0 kg N/m <sup>3</sup> · d

in Table 20-12. Two processes developed in Germany are the DENIPOR and DENITROPUR processes. A schematic of the DENIPOR process used for full-scale microbiological denitrification in Mönchengladbach, Germany, is shown on Fig. 20-13. As shown, buoyant polystyrene spherical beads are used to support the biomass in the fixed-bed reactors. A periodic downward flushing is used to remove excess biofilm that can cause plugging.

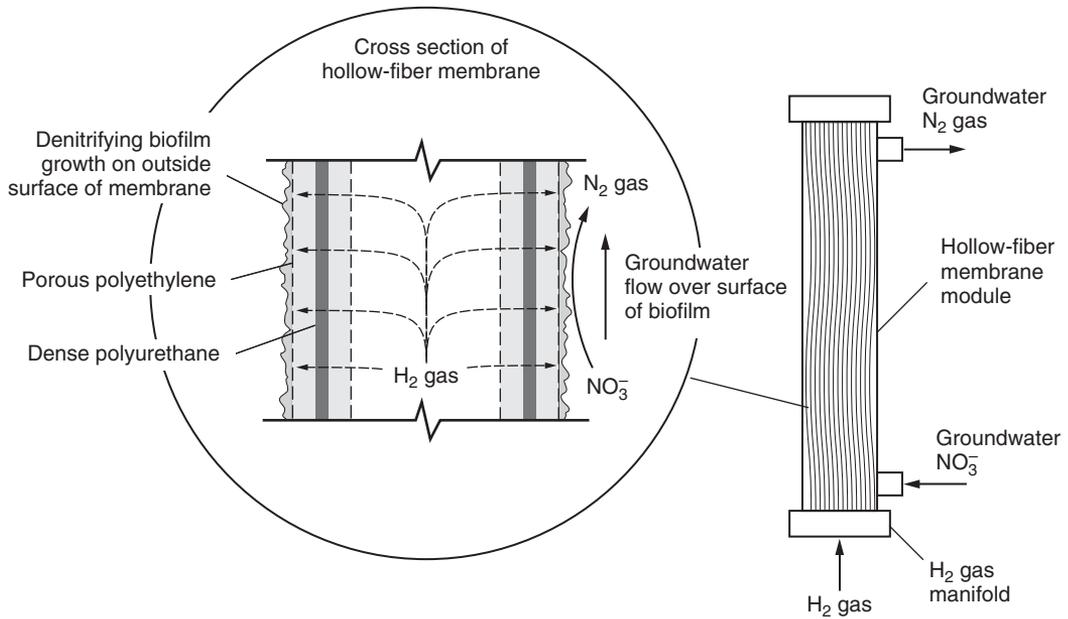

**Figure 20-13**  
Schematic of DINIPOR process for biological denitrification.

The water from the denitrification reactors is treated further through two aerobic filters. The advantages of this process are (1) an organic substrate is not needed and (2) as the biomass production is low the sludge production is also low (a sludge production rate of only 0.2 kg organic matter/kg N was observed). The disadvantage of this process is that the kinetics of autotrophic bacteria is much slower than heterotrophic bacteria.

#### *Hollow-fiber membrane bioreactor*

An emerging autotrophic biological process for denitrification is called the hollow-fiber membrane bioreactor (HFMB) process, as shown on Fig. 20-14 (Lee and Rittmann, 1999). The HFMB process consists of membrane modules supporting several confined hollow-fiber membranes that contain a thin film of autotrophic bacteria on the outer portion of the hollow-fiber membranes. The inside of the confined hollow-fiber membranes contains hydrogen gas that diffuses outward in the radial direction through the membrane, providing dissolved hydrogen gas to the biofilm and creating a hydrogen atmosphere surrounding the biofilm. Biological denitrification is carried out by the autotrophic biofilm as  $\text{NO}_3^-$  is used as a terminal electron acceptor for respiration while hydrogen is used as the electron donor under anoxic conditions.

Results of pilot plant studies show the HFMB process is effective for the removal of nitrate from groundwater and is summarized in Table 20-13 (Falk and Ergas, 2002). Removal efficiencies of greater than 90 percent can be achieved with the HFMB process.

**Figure 20-14**  
Schematic of bench-scale hollow-fiber membrane bioreactor process. (Adapted from Lee and Rittmann, 1999.)

**Table 20-13**  
Performance data from studies evaluating HFMB process

Parameter	Unit	Study <sup>a</sup>			
		Falk and Ergas (2002)		Lee and Rittmann, 2002	
		Influent	Effluent	Influent	Effluent
Nitrate	mg $NO_3^-$ -N/L	76	28	12.5	<1

**REVERSE OSMOSIS**

Reverse osmosis and electrodialysis can be used to reduce nitrate levels in drinking water but is primarily used to treat high total dissolved solids and salt water. The cost of RO for treatment of nitrate only is much more expensive than the ion exchange process. Reverse osmosis is usually cost effective for nitrate removal if there are other water quality issues such as high TDS concentrations. Electrodialysis is a process that involves passing electric current through a series of semipermeable membranes to remove nitrate and other ions. The electrodialysis process provides about the same removal as reverse osmosis but is limited to treating soft waters, is expensive, and requires full-time monitoring.

**ION EXCHANGE**

Ion exchange is an effective treatment process for removal of nitrate. As discussed in Chap. 16, SBA exchange resins are used to remove anions. Typically major anions present in water supplies are sulfate, bicarbonate, and chloride. When nitrate is present in the water, these ions along with nitrate will be removed on SBA resins. The preference for anion exchange onto standard type 1 and type 2 SBA resins is sulfate > nitrate > bicarbonate > chloride. Because sulfate is preferred over nitrate, the impact of sulfate on nitrate exchange is very important and needs to be considered (see Chap. 16). For both type 1 and type 2 polystyrene resins and polyacrylic SBA resins, the quantity of nitrate removed in a given exchange cycle will depend upon the sulfate concentration, TDS, and nitrate concentration.

*Resin types*

There are also nitrate-specific resins that are specifically designed for nitrate removal. Nitrate-selective resins are usually used when chromatographic peaking in standard resins may impact the process performance (Clifford, 1999). Chromatographic peaking occurs when the more preferred sulfate ion migrates through the resin bed displacing the nitrate and concentrating it toward the end of the bed. When sulfate migrates to the end of the bed, it displaces the concentrated nitrate off the resin, resulting in a higher concentration of nitrate in the effluent than in the influent.

When treating a typical groundwater, the ion exchange effluent nitrate concentration can reach as high as 130 percent of the influent concentration. Consequently, resins used to treat nitrate are designed such that nitrate is preferred over sulfate. Some commercially available nitrate-selective resins are described in Table 20-14. Nitrate-selective resins are similar to standard type 1 resins but have ethyl, propyl, or butyl groups substituted for the methyl group on the trimethyl amine functionality  $[RN(CH_3)_3]$ . These substitutions separate the charged exchange sites along the backbone of the resins far enough apart so that the sulfate ion, which requires two charged sites close to each other, will not readily exchange. The nitrate-selective resins also have a higher hydrophobicity than the standard SBA

**Table 20-14**

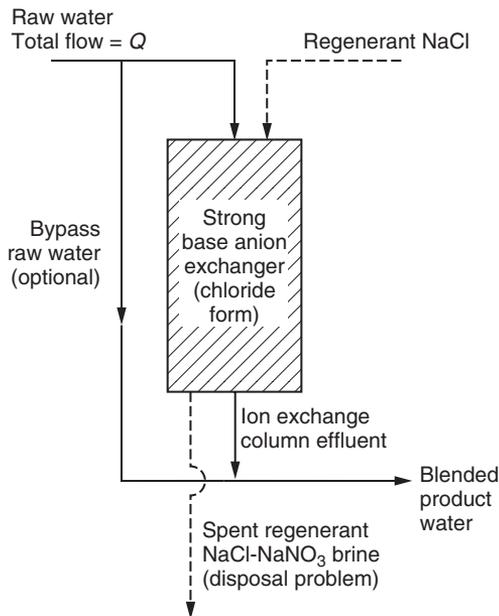

Summary of commercially available SBA nitrate-selective resins

Resin	Functional Groups	Ionic Form	Total Volume Capacity Minimum, meq/mL	Shipping Weight (approx.), kg/m <sup>3</sup>	Water Retention, %
Purolite A520E	Quaternary ammonium	Cl <sup>-</sup>	1.0	684	52–56
SR-6 Sybron	Trimethyl amine	Cl <sup>-</sup>	0.85	668	42–45
Amberlite-996, Rohm & Haas	Trimethyl amine	Cl <sup>-</sup>	1.0	—	50–56

resins. Nitrate-selective resins are also required when brine reuse by denitrification is implemented when the sulfate concentration in the feed water is greater than 200 mg/L (Liu and Clifford, 1996). Nitrate-selective resins and their technical information can be obtained from several manufacturers (e.g., Purolite, London, England; Rohm and Haas, Philadelphia, PA; and Sybron/Bayer Corporation, Pittsburgh, PA).

#### *Ion exchange process*

A typical ion exchange process for nitrate removal is shown on Fig. 20-15. Strong-base anion resins are usually in the chloride form so that NaCl can

**Figure 20-15**  
Schematic of typical ion exchange process using NaCl regeneration.

be used for regeneration of the resin. The fixed beds operate in the down-flow mode and co-current regeneration is usually used to reduce leakage of nitrate. An optional bypass of the water is sometimes used so that, when blended with the ion exchange process water, the nitrate concentration in the water is around 7 to 8 mg/L and is below the MCL. Depending on the water quality, nitrate breakthrough typically occurs around 100 to 500 BV. For example, field experiments showed that for an influent nitrate concentration of 21.5 mg/L and sulfate concentrations of 43 and 310 mg/L the nitrate breakthrough decreased from 400 to 180 BV (Clifford, 1999). Consequently, pilot studies are usually carried out to evaluate the breakthrough performance for a particular raw-water source.

#### *Regeneration*

Two types of regeneration techniques, partial and complete, can be used. However, for economic reasons, partial regeneration is used because significant leakage can be tolerated up to 10 mg/L of nitrate. For partial regeneration, it is important to completely mix the resin after each regeneration cycle to ensure leakage is not excessive. Performance for two full-scale plants using partial regeneration with NaCl is presented in Table 20-15. Both plants are used to treat 3.8 ML/d (1 mgd) using NaCl for resin regeneration. The water treated in the McFarland, California, plant contains 15 mg/L  $\text{NO}_3^-$ , 100 mg/L  $\text{SO}_4^{2-}$ , 90 mg/L  $\text{Cl}^-$ , and 100 mg/L  $\text{HCO}_3^-$ . In the plant in Binic, France, the surface water is pretreated with coagulation, sedimentation, and filtration ahead of the ion exchange process. The raw water treated in the Binic, France, plant contains 10 to 23 mg/L  $\text{NO}_3^-$ , 50 mg/L  $\text{SO}_4^{2-}$ , 50 mg/L  $\text{Cl}^-$ , and 85 mg/L  $\text{HCO}_3^-$ . This water is also

**Table 20-15**  
Full-scale nitrate ion exchange plant performance

Description	Unit	McFarland, CA	Binic, France
Source water	—	Well water	Surface water
Polystyrene–DVB SBA Type I resin	—	Duolite A101D	Dowex SBRP
Regenerant concentration	N (%)	1.0 (6%)	—
Resin capacity, meq/L	meq/L	1.3	1.2

NaCl consumption for 3.8 ML/d blended product water	kg/d	1130	1150

Source: Clifford and Liu (1995).

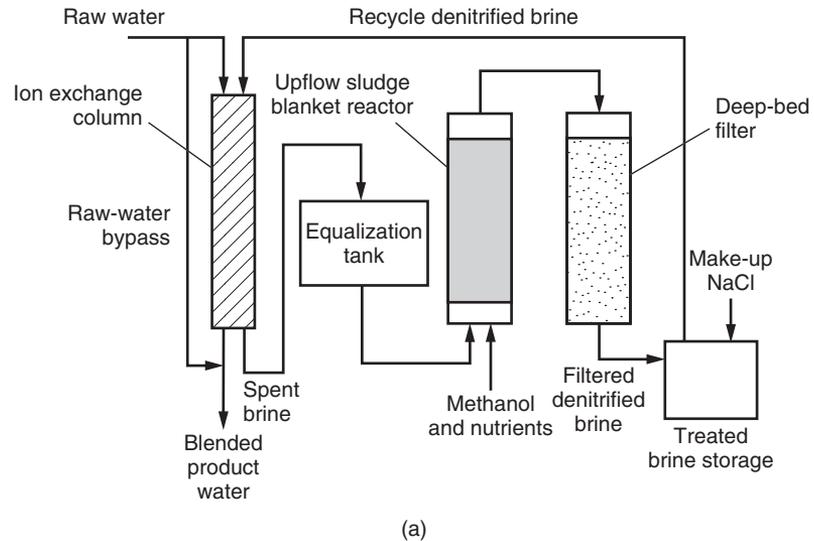

high in TOC and the resin is replaced every 3 years due to organic fouling. Because the Binic plant had lower TDS and sulfate concentrations than the McFarland plant, it could treat up to 135 more BVs. It should also be noted that the Binic plant was unable to utilize a bypass stream and, thus, required higher salt usage than the McFarland plant. If the Binic plant were allowed to have a leakage of 7.9 mg/L nitrate, then the salt consumption in that plant would have only been 530 kg/d (Clifford and Liu, 1995).

#### *Brine disposal*

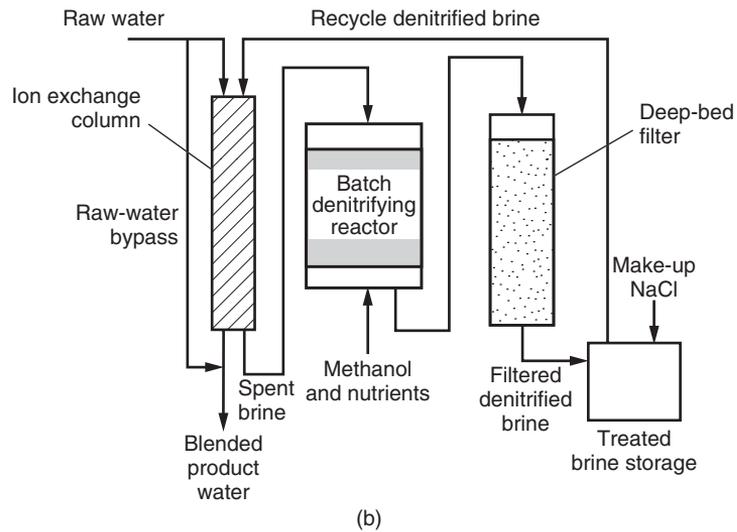

Nitrate-containing brine cannot be directly discharged into lakes and rivers due to its high salinity and nitrate, which causes eutrophication. For ion exchange plants near the coastal regions, ocean disposal may be an alternative if the conveyance system is available. For both the cities of McFarland, California, and Binic, France, the brine is disposed of in the sanitary sewer system as the brine waste is only a small portion of the total wastewater sent to the treatment plant and the biological treatment is not impacted. However, the McFarland plant, which uses aerated lagoons, discharges the water for irrigation of cotton crops. Unfortunately, salt concentrations are beginning to accumulate in the soil. While the exchange process is a cost-effective treatment process for nitrate removal from water, the issues of brine disposal must be carefully considered.

Recent studies have focused on brine treatment by denitrification and brine reuse to reduce the cost and problems associated with salt usage and brine disposal. The two processes shown on Fig. 20-16 are the biological denitrification of brine wastes using an upflow sludge blanket (USB) reactor (Hoek and Klapwijk, 1987, 1988) and a sequencing batch reactor (SBR) process (Liu and Clifford, 1996). The USB reactor is used to denitrify the spent nitrate-containing brine. An equalization tank is used to provide a constant nitrate influent in the USB and filtration is required for the denitrified brine before reuse. An advantage of the SBR process is that regeneration of an ion exchange column is also a batch process so the SBR process can also act as an equalization tank. Based on the results of bench and pilot studies for a methanol-to-nitrate ratio of 2.2, the nitrate removal efficiency is above 95 percent per batch. With the use of nitrate-selective resins, the brine has been reused over 38 times without significant sulfate buildup problems in the brine. With the SBR process there were no significant problems associated with resin performance. Compared to the conventional partial-regeneration process, with reuse of the denitrified brine it was possible to treat 70 percent more water per run, use 23 percent less salt, and produce 60 percent less wastewater (Clifford and Liu, 1995). While this process shows much promise, it has yet to be tested as a full-scale application.

A comparison of the various nitrate removal processes is presented in Table 20-16, including (1) conventional ion exchange, (2) direct biological

(a)

(b)

**Figure 20-16**

Dutch and American nitrate removal processes that incorporate biological denitrification into ion exchange process for spent-brine treatment: (a) Dutch ion exchange process with biological denitrification using upflow sludge blanket reactor (adapted from van der Hoek and Klapwijk, 1987) and (b) American ion exchange process with biological denitrification using sequencing batch reactor (adapted from Clifford and Liu, 1995).

denitrification, and (3) ion exchange with biological denitrification and reuse of the brine (Clifford and Liu, 1995). Both ion exchange and biological denitrification have been operated on a full-scale level, and the combined ion exchange and spent-brine denitrification process has only been tested on the pilot scale. If the nitrate-laden brine can be disposed of in a safe and cost-effective way, then the chloride ion exchange process may be the simplest and most cost-effective process. However, if there are problems with brine disposal, then direct biological denitrification or ion exchange with biological denitrification and brine reuse may be required.

**Table 20-16**  
Comparison of nitrate removal techniques

Parameter	Ion Exchange	Direct Biological Heterotrophic Denitrification	Ion Exchange with Biological Denitrification and Brine Reuse
Raw-water quality (typically groundwater)	High TDS and sulfate reduce resin capacity for $\text{NO}_3^-$	Not influenced by water quality	Same as ion exchange
Treated-water quality	Increased chloride and corrosivity, variable anion concentrations	Posttreatment required to increase DO and eliminate TOC, $\text{NO}_2^-$ , and turbidity	Same as ion exchange
Posttreatment required	Usually none	Biological oxidation, filtration, disinfection	Filtration of brine and possible disinfection required
Process complexity	Simple	Complex	Complex
Process control	Run length based on cumulative flow	Must control rate of ethanol and nutrient addition	Same as ion exchange plus addition of ethanol and nutrients <sup>a</sup>
Monitoring of treated water	$\text{NO}_3^-$	$\text{NO}_3^-$ , $\text{NO}_2^-$ , TOC, and bacteria	$\text{NO}_3^-$ brine conductivity
Startup and shutdown	Operates on demand	Weeks to months required for startup; maintain viable denitrifying organisms	Maintain viable denitrifying organisms
Waste disposal	Large volume of brine containing $\text{NO}_3^-$ and excess NaCl	Small volume of biomass sludge <sup>b</sup>	Small amount of nitrate-free brine and biomass sludge <sup>b</sup>

<sup>a</sup>For batch denitrification of brine, only batch addition of substrate and nutrients is required.

<sup>b</sup>Nitrate is converted to nitrogen gas by bacteria that grow slowly and produce a small amount of biomass for disposal.

## 20-6 Radionuclides

Natural radionuclides are the most common source of radioactivity in the environment. Natural radionuclides are formed from the dissolution of rock formations containing uranium ore and gases released from deep in the Earth's crust. The principal source of natural radionuclides is uranium ore ( $\text{U}_3\text{O}_8$ ), and its abundance in the Earth's crust is only about 1 part per  $10^{12}$  parts. The anthropogenic radionuclides come from sources such

as nuclear power plants used to supply electrical energy, medical facilities that provide nuclear medicines and x-ray services, academic and research facilities using nuclear materials for research, commercial products such as televisions and smoke detectors, and nuclear weapons for national defense.

### **Occurrence and Importance in Water Supplies**

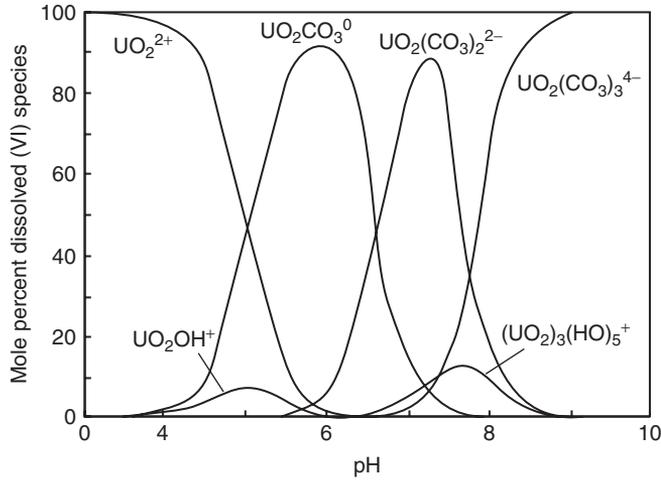

Most drinking water sources contain very low levels of radioactive nuclei, or radionuclides, which is not usually a public health concern. However, there are some groundwater sources, primarily areas of the Midwest and western United States, with radionuclide concentrations that exceed present drinking water standards. Presently, radionuclide contamination of drinking water has not been a concern for large water utilities, but for small water utilities using groundwater in some areas of the country treatment is required. Use of radionuclide materials by industry may become greater due to increases in energy demand and possible medical applications, and the increase in demand may impact some water utilities. In addition, the present threat of terrorist activities related to the use of nuclear material in the United States and abroad may also be a future source of contamination in water supplies.

### **Chemistry and Removal**

The most common radionuclide of concern in water treatment are radium-226, radon-222, radium-228, uranium-234, which are ionic decay products of uranium-238 and thorium-232. With respect to aqueous systems, radium-226 and radium-228 exist in natural groundwaters primarily as divalent cations. Radon-222 is a gaseous radioactive element that can exist as 25 different isotopes. Radon-222 is highly volatile and has a Henry's law constant of 1.69 ( $L_{\text{Water}}/L_{\text{Air}}$ ) at 20°C. Uranium has four oxidation states, U(III), U(IV), U(V), and U(VI). The oxidation states U(III) and U(V) are unstable in both air and water, U(IV) is stable in air, and U(VI) is stable in water. In aqueous solution, uranium exists as uranyl ion and readily complexes primarily with carbonate and hydroxide, as shown on Fig. 20-17. In the pH range of most natural waters, the uranyl ion complexes primarily with the carbonate and bicarbonate anions to form uranyl carbonate complexes. At pH values between 5.0 and 6.5, the primary species is  $\text{UO}_2\text{CO}_3^0$ , and between pH values of 6.5 and about 7.5 the primary species is  $\text{UO}_2(\text{CO}_3)_2^{2-}$ . Small uranyl hydroxide complexes [ $\text{UO}_2\text{OH}^+$  and  $(\text{UO}_2)_3(\text{OH})_5^+$ ] are also formed as shown on Fig. 20-17.

### **Treatment Methods**

Several conventional water treatment technologies are capable of removing radionuclides. The U.S. EPA's best available technology (BAT) for radon-222 removal is aeration; for combined radium-226 and radium-228 it is coagulation–filtration; for radium-226 and radium-228 separately it is ion exchange, reverse osmosis, or lime softening; and for uranium it is ion exchange. Performance data for various processes used to remove radionuclides are reported in Table 20-17. The highest removal efficiencies

**Figure 20-17**  
Distribution of uranium species in water.

**Table 20-17**

Summary of technology and performance of processes for removing radionuclides from drinking water

Method	Removal Efficiency, %		
	Radon	Radium	Uranium
Activated alumina			90
Aeration, packed tower	To 99+		
Aeration, diffused bubble	To 99+		
Aeration, spray	70–95+		
Coagulation–filtration			80–98
GAC adsorption–decay	62–99+		
Electrodialysis		90	
Greensand		25–50	
Hydrous manganese oxide filter		90	
Ion exchange		81–99	90–100
Lime softening		80–92	85–99
Reverse osmosis		90–95+	90–99

<sup>a</sup>The highest removal efficiencies for some technologies are associated with point-of-entry and point-of-use devices.

Source: Adapted from Lowery and Lowery (1988).

observed are for point-of-entry (POE) and point-of-use (POU) treatment systems. Water treatment processes for radionuclides are further discussed in the following sections.

#### AERATION

Radon-222 gas has a very high Henry's law constant and is very amenable to aeration. As discussed in Chap. 14, aeration methods such as spray, bubble,

and packed-tower systems are very effective methods for removing radon-222 from water. In packed towers, reported radon-222 removal efficiencies have been as high as 98 percent using an air-to-water ratio of only 8 : 1 (Dixon et al., 1991). Using higher air-to-water ratios can achieve removals greater than 99 percent. Design procedures discussed in Chap. 14 can be used to design aeration devices to remove radon-222.

#### **ION EXCHANGE**

Strong-acid cation resins in the sodium form and weak acid cation (WAC) resins in the hydrogen form can be used to remove radium-226 and radium-228 from aqueous systems. For normal sodium ion exchange softening, both radium isotopes can be removed completely. The advantage of using WAC resins is that they are easier to regenerate and require less regenerant per unit volume treated than SAC resins. However, the disadvantages of using WACs are that they swell during exhaustion, acid-resistant materials are required to prevent corrosion when using HCl as a regenerant solution, noncarbonate hardness is not removed, it will be necessary to strip the CO<sub>2</sub> from the treated water, and pH adjustment is needed (Faust and Aly, 1998).

For combined radium and uranium removal, a mixed bed containing SBA and SAC resins can be used. A mixture of 10 percent SBA and 90 percent SAC resins in a small fixed bed was able to treat water containing 25 pCi/L radium and 120 µg/L uranium to less than 1 pCi/L radium and 20 µg/L uranium (Clifford and Zhang, 1994). Potassium chloride was found to be a better regenerant than sodium chloride for radium removal. Design concepts and procedures discussed in Chap. 16 can be used to provide design guidance for ion exchange systems. With respect to disposal of contaminated brines, present practice is disposal to municipal sanitary sewers.

#### **COAGULATION-FILTRATION**

Conventional coagulation-filtration plants can be effective in removing uranium from drinking water supplies. Based on laboratory studies using jar tests, it has been found that uranium can be removed effectively using iron and aluminum coagulants (Lee and Bondietti, 1983; Lee et al., 1982).

The full-scale Moffat CO water treatment plant has an influent uranium concentration of 15 µg/L, and 75 percent removal was achieved at a raw-water pH of 7.5 using alum, lime, and polymer (Hanson, 1987; Lee et al., 1982). However, there was wide variation in the percent removals. For the same water treated at the Moffat plant, Hanson (1987) also reported that the alum plant in Arvada, Colorado, which uses the microfloc system, was able to achieve removals of 18 to 90 percent, and an average efficiency of 67±15 percent. High removals have also been observed using chemical clarification and dissolved air flotation.

**LIME SOFTENING**

In the same jar test study described above, Lee et al. (1982) showed the addition of lime (50 to 250 mg/L) raised the pH to 10.6 to 11.5 and obtained uranium removals of 85 to 90 percent. The impact of pH between 10.6 and 11.5 did not impact the removals. Jar tests were also performed with various doses of lime and magnesium carbonate ( $\text{MgCO}_3$ ). At pH values between 9.8 and 10.6  $\text{MgCO}_3$  dosages reduced the effectiveness of lime softening on uranium removal. However, at pH values greater than 10.6, uranium removal increased with increasing  $\text{MgCO}_3$  dosages. The critical pH value was determined to be 10.6. Above this value the addition of  $\text{MgCO}_3$  with lime increased uranium removals to 93 to 99 percent. Further experiments showed that magnesium hydroxide precipitate plays an important role in the removal of uranium.

**REVERSE OSMOSIS**

Reverse osmosis provides excellent removal of radium and uranium isotopes. Operating results for several membranes used to remove natural uranium from a groundwater in Florida with an influent concentration of 300  $\mu\text{g/L}$  are displayed in Table 20-18. Removal efficiencies of 98 percent and greater were observed for each membrane. High removal efficiencies were also reported for radium-226. These results have been confirmed on similar waters containing uranium and radium (Sorg, 1988).

**ADSORPTION**

A promising adsorbent for the removal of radium is hydrous manganese oxides (HMOs), which has been successfully used in bench and pilot studies. The HMOs are preformed by the addition of potassium permanganate ( $\text{KMnO}_4$ ), which brings about the oxidation of manganese sulfate ( $\text{MnSO}_4$ ). Radium will adsorb onto the preformed HMOs and be removed by filtration. For conventional water treatment plants, this process can be incorporated

**Table 20-18**Radionuclide removal using membranes<sup>a</sup>

Radionuclide	Feed Concentration Range	Contaminant Removal, %			
		Dow CTA, HF	DuPont ARAMIDHF	Filmtec TFC, SW	Hydranautics MCA, SW

easily into the process flow stream without significant plant modifications if radium removal is required. Periodic acid wash of the sand filters may be required to remove excess  $\text{MnO}_2$ . Preformed HMO was successfully used to remove radium from drinking water (Valentine et al., 1990).

## 20-7 Pharmaceuticals and Personal Care Products

---

Increasing interconnectedness between receiving waters for treated wastewater and source waters for potable water systems has created concern about whether trace contaminants can pass through wastewater treatment systems and enter the water supply. Many recent investigations have found evidence of low concentrations of pharmaceuticals and personal care products (PPCPs) and endocrine disrupting compounds (EDCs) in the source water for many communities throughout the United States and other developed nations. PPCPs are not currently regulated drinking water contaminants in the United States, but there is broad concern about their presence in drinking water supplies.

Pharmaceuticals include antibiotics, analgesics [painkillers such as aspirin, ibuprofen (e.g., Advil), acetaminophen (e.g., Tylenol)], lipid regulators (e.g., atorvastatin, the active ingredient in Lipitor), mood regulators (e.g., fluoxetine, the active ingredient in Prozac), antiepileptics (e.g., carbamazepine, the active ingredient in many epilepsy and bipolar disorder medications), and many other medications. Personal care products can include cosmetics and fragrances, acne medication, insect repellants, lotions, detergents, and other products. Ingested pharmaceuticals can be excreted with human waste and enter the wastewater system. Additional pharmaceuticals can enter the wastewater system because of the common practice of flushing unused medication down the toilet. Personal care products can be washed from the skin and hair during washing or showering. Discharge from wastewater treatment plants (WWTPs) have been shown to be a major source of many PPCPs (Wintgrens et al., 2004; Snyder et al., 2003) in the environment. Untreated animal waste, manufacturing residues, pesticides, and agricultural runoff are other sources of PPCPs (Kolpin et al., 2002).

Endocrine disrupting chemicals are chemicals that have the capability to interfere with the function of the human endocrine system (either stimulating or repressing hormonal function). EDCs can interfere with female sex hormones (estrogenic EDCs), male sex hormones (androgenic EDCs), or hormones that control metabolism and many other systems in the body (thyroidal EDCs). EDCs include natural hormones excreted from humans, ingested hormones such as estrogens subsequently excreted from females after use of birth-control pills, or synthetic compounds that mimic the function of hormones, such as bisphenol A.

## Occurrence and Significance in Water Supplies

PPCPs have been detected in wastewater in the United States since the 1960s and 1970s, and recent studies have detected them in a significant number of surface waters and even in treated drinking water supplies (Halling-Sorensen et al., 1998; Kolpin et al., 2002; Barnes et al., 2008; Focazio et al., 2008; Benotti et al., 2009). Analytical technologies have improved to the extent that the detection limit for many PPCPs is in the range of 5 to 10 ng/L, and these analytical capabilities have led to increased incidence of detection. In most cases, the concentrations of PPCPs and EDCs detected in source waters are below 1 µg/L. These concentrations are orders of magnitude below the therapeutic doses of many medications, which are typically tens to hundreds of milligrams per day. Example 20-8 demonstrates a comparison between level of exposure between concentrations found in water supplies and in therapeutic doses.

### Example 20-8 Comparison of therapeutic and environmental exposures to pharmaceuticals

A single adult tablet of a pain medication contains 200 mg of ibuprofen. Compare the amount of ibuprofen consumed in one tablet to the amount consumed in drinking water in (1) one day and (2) over a lifetime, if the drinking water contains 1 µg/L of ibuprofen.

#### Solution

1. Daily exposure. A typical human consumes about 2 L of water per day. Comparing one day of drinking water consumption to one tablet is

$$\frac{200 \text{ mg} (10^3 \text{ } \mu\text{g}/\text{mg})}{(1 \text{ } \mu\text{g}/\text{L}) (2 \text{ L})} = 100,000 = 10^5$$

One tablet of pain medication contains 100,000 times more ibuprofen than the amount consumed by drinking water for 1 day.

2. Lifetime exposure. The average life expectancy in several countries is just over 80 years. Consumption of water containing 1 µg/L of ibuprofen for 80 years would expose a person to:

$$(1 \text{ } \mu\text{g}/\text{L}) (2 \text{ L}/\text{d}) (365 \text{ d}/\text{yr}) (80 \text{ yr}) (10^{-3} \text{ mg}/\mu\text{g}) = 58.4 \text{ mg}$$

$$\frac{58.4 \text{ mg}}{200 \text{ mg}} \times 100 = 29\%$$

The amount of ibuprofen consumed in drinking water over a lifetime is less than 30 percent of the amount in one tablet.

Example 20-8 demonstrates that environmental exposure to PPCPs can be low compared to exposure for medical purposes. Nevertheless, exposure to PPCPs and EDCs through drinking water remains an area of potential concern. Concern because of the increased incidence of detection that has been caused by improvements in analytical technologies has already been noted. Other possible reasons for recent concern about PPCPs and EDCs in water supplies include (1) increased interest in indirect potable reuse and increased awareness of the interconnections between wastewater discharge and water supplies, (2) the possibility of synergistic effects from exposure to trace concentrations of multiple PPCPs, and (3) the possibility that trace amounts of antibiotics in the environment may lead to the formation of resistant strains of bacteria.

Regardless of the public's concern regarding PPCPs and EDCs, it is important for the water treatment and regulatory communities to assess the concentration at which PPCPs and EDCs may pose health threats to consumers. An AWWARF study (Bruce et al., 2010) evaluated the toxicological relevance of PPCPs and indicated, for the compounds evaluated, the concentrations found in drinking water supplies were significantly below the concentrations considered to be significant from a toxicological perspective. Additional studies are ongoing to assess the human health significance of PPCPs and EDCs in drinking water.

## **Chemical Properties**

Separation of constituents from water or wastewater is accomplished by exploiting differences in physical, chemical, and biological properties between the contaminants and water. These properties include molecular weight, solubility, charge, polarity, volatility, chemical reactivity, biodegradability, and others. Often, groups of compounds with similar properties can be removed by a single treatment process that exploits a specific property. However, there are thousands of different drugs and chemical compounds in use today that can, and do, end up in water with a correspondingly large variation in their physical, chemical, and biological properties (Dalton, 2004). The variability in properties means that these compounds will respond differently to different treatment techniques, so no treatment process will be effective for all PPCPs and EDCs.

Many PPCPs are organic compounds with relatively low molecular weight (< 1000 Da). However, they have differences in charge, polarity, volatility, and other properties that will make generalized treatment strategies more difficult. In addition, many pharmaceuticals are designed with specific properties to enhance their function as pharmacological agents that may interfere with treatment objectives. For instance, PPCPs may be designed with high chemical stability, high water solubility, low biodegradability, and low adsorbancy to nonpolar adsorbants, which may make treatment more difficult.

Despite the wide range of chemical properties that may be expressed by PPCPs and EDCs, there are several treatment strategies that work well for many compounds. The most practical for the widest range of compounds are advanced oxidation, reverse osmosis, and adsorption onto activated carbon. The application of these treatment processes to PPCPs is described in the following sections.

#### **ADVANCED OXIDATION**

Oxidation and advanced oxidation processes (AOPs) achieve removal by chemical destruction. Advanced oxidation processes use combinations of chemical oxidants or combine a chemical oxidant with UV radiation to increase the rate of oxidation through generation of highly reactive free radicals such as the hydroxyl radical ( $\text{OH}\cdot$ ). Common AOPs include ozone/hydrogen peroxide, UV/ozone (UV/ $\text{O}_3$ ), and UV/hydrogen peroxide (UV/ $\text{H}_2\text{O}_2$ ). Advanced oxidation is discussed in more detail in Chap. 18.

Most conventional chemical oxidation processes are not very effective at removing many PPCPs at the doses used for disinfection (Snyder et al., 2008; Okuda et al., 2008). The same is generally true for UV light oxidation. UV irradiation alone achieves limited degradation of many PPCPs, particularly at doses used for disinfection (Kim et al., 2007, 2008; Canonica et al., 2008; Kruithof et al., 2007). However, doses at least 5 to 10 times higher than the typical doses for disinfection can achieve better removal of some PPCPs (Snyder et al., 2003; Kruithof et al., 2007).

Ozone, ozone-based, and UV-based AOPs can effectively degrade most PPCPs. Ozonation by itself can reduce both the concentration and number of compounds detected after treatment (Snyder et al., 2006; Andreozzi et al., 2004; Vieno et al., 2007). Okuda et al. (2008) found that ozone coupled with a biological activated carbon process reduced all residual pharmaceuticals to below quantification limits. As with other uses of ozonation, the formation of bromate is a consideration when using ozone for PPCP removal. In addition, ozonation of PPCPs may require longer contact times and/or higher doses than that used for disinfection (Andreozzi et al., 2004; Ternes et al., 2003). The combination of hydrogen peroxide and UV light has also been shown to be highly effective at degrading many PPCPs (Pereira et al., 2007a, 2007b; Chen et al., 2007).

Because of the differences in chemical properties, some compounds are slowly oxidized or poorly degraded by advanced oxidation processes. Cyclophosphamide, 2-quinoxaline carboxylic acid (2-QCA) and N,N-diethyl-m-toluavin (DEET) were poorly removed in one study (Kim et al., 2008). Other studies have found that clofibric acid (Westerhoff et al., 2005; Ternes et al., 2003) and ciprofloxacin (Vieno et al., 2007) are difficult to remove by advanced oxidation processes.

An important consideration in the use of advanced oxidation for PPCP removal is that the reaction products are almost certainly not fully mineralized to  $H_2O$  and  $CO_2$ . While an oxidation process may destroy the parent compound, it may produce degradation products with unknown biological activity. A subsequent process, such as biofiltration following ozone, may be appropriate to remove the oxidation products. Biofiltration is discussed in Sec. 11-8 of Chap. 11.

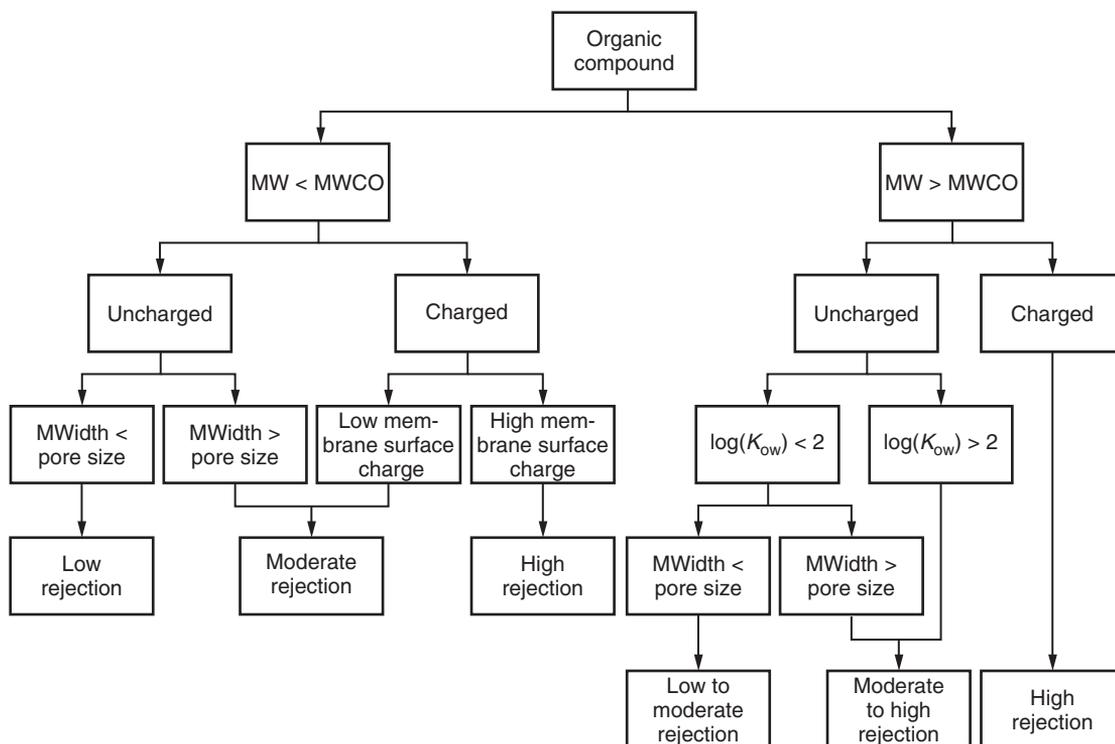

#### REVERSE OSMOSIS

Reverse osmosis is a membrane-based treatment process that separates contaminants from water by forcing water through the membrane under pressure. Dissolved contaminants are separated from the water as the water passes through the membrane. RO can effectively remove most PPCPs; removal efficiencies depend on properties of the feed water, membranes, and compounds to be removed. Reverse osmosis is discussed in Chap 17.

Many studies that have evaluated reverse osmosis for PPCP removal have found that RO can achieve excellent removal for most compounds (Snyder et al., 2003, 2007; Drewes et al., 2006). However, a number of factors can affect the level of removal. The most important parameters include the molecular weight or size, polarity, hydrophobicity, and charge of the compound, the membrane's surface charge and molecular weight cut-off (MWCO), and the fractional water recovery (Bellona et al., 2004; Kimura et al., 2003; Verliefde et al., 2007). The relationship between compound physicochemical properties and removal efficiency are qualitatively summarized in Fig. 20-18 (Drewes et al., 2006). Important compound properties reflected in this diagram are MWCO, charge, and hydrophobicity. As shown on the right side of Fig. 20-18, when the MWCO of the membrane is smaller than the MW of the compound, high rejection can be achieved for charged and hydrophobic [ $\log(K_{ow}) > 2$ ] compounds, and lower rejection might be observed for small, neutral, hydrophilic compounds depending on the shape of the molecule. A number of researchers have shown that NF membranes do not achieve as good a rejection of PPCPs as tighter RO membranes (Xu et al., 2005; Yoon et al., 2002).

An operating parameter that can have a significant effect on PPCP removal is the feed water recovery. As noted in Chap. 17, osmotic pressure, concentration polarization, and the solubility of sparingly soluble salts can limit the recovery of water from an RO system. Higher recovery increases permeate volume but decreases its quality. Verliefde et al. (2007) showed that at a recovery of 10 percent, an NF membrane was able to remove >75 percent of all target compounds with most achieving >90 percent removal and a few compounds being removed at >99 percent. At 80 percent recovery, the same compounds were removed less effectively with one compound dropping to ~10 percent removal.

PPCP removal can be maximized by selecting membranes with a lower MWCO (i.e., seawater RO in lieu of brackish water RO membranes).

**Figure 20-18**

Rejection diagram for microconstituents using membrane processes as functions of both solute and membrane properties. (Adapted from Drewes et al., 2006.)

Membranes with a lower MWCO, however, typically operate at lower water flux rates. As a result, it would be necessary to increase the size of the system or increase the feed pressure, which increases capital and operating costs.

As a treatment process, reverse osmosis has several negative aspects. These include (1) high loss of product water because of low recovery, (2) high energy consumption, (3) large volume waste stream, which increases disposal costs. These negative aspects should be considered when comparing reverse osmosis to other treatment processes for PPCP treatment.

#### ADSORPTION ONTO ACTIVATED CARBON

Activated carbon is an effective adsorbent that is used for removing many dissolved compounds from water. Granular activated carbon (GAC) and powdered activated carbon (PAC) have both been evaluated for their effectiveness in removing PPCPs and found to be effective for many PPCPs.

The compounds most effectively removed by activated carbon include the more nonpolar, more hydrophobic, lower MW, uncharged, and lower solubility compounds. Lower MW compounds are more efficiently removed because of increased accessibility to inner pores of the carbon. The pH is

also important for PPCPs that are weak acids because the pH affects the charge of the species.

Adsorption capacity affects the use of PAC and GAC differently. For PAC, a dose of carbon is added to the water and adsorption occurs until the capacity is reached, with the remaining pollutant staying in the water. Westerhoff et al. (2005) showed that protonated bases are well removed by PAC. Compounds with low  $K_{ow}$  values and deprotonated acid functional groups were the most difficult to remove. Increased removal efficiency for many compounds can be achieved by increasing the PAC dose and/or the contact time (Snyder et al., 2007; Baumgarten et al., 2007; Westerhoff et al., 2005).

For GAC, pollutants adsorb to the carbon bed and the pollutant concentration in the effluent can be unmeasurable until the capacity (measured as bed volumes) is reached, at which time the pollutant passes through the bed and the influent concentration of the pollutant is measured in the effluent. Studies have concluded that hydrophilic compounds break through the column sooner than the hydrophobic compounds (Snyder et al., 2007; Vieno et al., 2007). Vieno et al. (2007) found that the hydrophobic compound carbamazepine could be effectively removed by GAC even after treatment of >70,000 bed volumes of water, but that the more hydrophilic compounds could pass GAC treatment after only 2000 to 3000 bed volumes of water.

Once the adsorption capacity is reached, the media must be replaced or regenerated to restore removal effectiveness. Snyder et al. (2007) identified a facility with onsite and regular regeneration as having minimal breakthrough of organic contaminants and improved removal efficiency of selected PPCPs. In contrast, the study found little removal of trace organics in a facility with high levels of TOC that did not provide regular replacement/regeneration.

One parameter that affects both GAC and PAC is the NOM concentration (measured as DOC) in the feed water (Snyder et al., 2007). The presence of NOM can reduce the removal efficiency of PPCPs due to competition for adsorption sites. The NOM can block the pores within the activated carbon structure, leaving less opportunity for the PPCPs to be adsorbed. The quantity and characteristics of DOC in the feed water is an important parameter that can influence removal efficiencies for activated carbon (Westerhoff et al., 2005).

Studies have found that combined use of GAC or PAC with membrane processes is highly effective at removing PPCPs. One of the reported advantages is that this combination of processes effectively removes both DOC and DBPs. Verliefe et al. (2007) reported the combination of NF and GAC can provide a robust dual barrier for the removal of organic PPCPs. This is attributed to the NF membrane's ability to effectively remove high-molecular weight polar solutes, while activated carbon is more effective at removing nonpolar solutes. Similarly, use of RO to remove NOM would reduce the competition between NOM and PPCPs in a subsequent activated carbon process.

## Problems and Discussion Topics

---

- 20-1 A 100 ML/d raw-water source containing 10-mg/L ferrous iron is oxidized to ferric hydroxide. Calculate the quantity of oxygen required, alkalinity consumed as  $\text{CaCO}_3$  and quantity of sludge produced as ferric hydroxide.
- 20-2 A water supply containing a soluble  $\text{Fe}^{2+}$  concentration of 8.0 mg/L is to be oxidized by aeration to a concentration of 0.5 mg/L. The raw-water pH is 6.0, the temperature is  $12^\circ\text{C}$ , and it is assumed that  $P_{\text{O}_2}$  is in equilibrium with the atmosphere. Based on the results of laboratory studies, the pseudo-first-order rate constant for the oxygenation of  $\text{Fe}^{2+}$  is  $0.17 \text{ min}^{-1}$ . For steady-state operation and a flow rate of 40 ML/d (10.5 mgd), calculate and compare the minimum hydraulic detention time and reactor volume for the oxidation of  $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$  for plug flow and complete mixed flow reactors.
- 20-3 A 500-ML/d (132-mgd) flow of groundwater contains 2 mg/L of Mn(II) ion after aeration. A 5.0-mg/L ( $3.16 \times 10^{-5} \text{ mol/L}$ ) dose of potassium permanganate ( $\text{KMnO}_4$ ) is added to oxidize Mn(II) ion ( $\text{Mn}^{2+}$ ) to a concentration of 0.1 mg/L. The groundwater pH is 6.5, the temperature is  $15^\circ\text{C}$ , and it is assumed that 5 mg/L ( $5.75 \times 10^{-5} \text{ mol/L}$ ) of manganese dioxide ( $\text{MnO}_2$ ) is in equilibrium with 0.1 mg/L of  $\text{Mn}^{2+}$ . For steady-state operation in a CMFR and plug flow reactor, calculate and compare the minimum hydraulic detention times for the oxidation of  $\text{Mn}^{2+}$  to  $\text{MnO}_2$ .
- 20-4 A 20-ML/d flow of groundwater contains 5 mg/L of ferrous iron ( $\text{Fe}^{2+}$ ). Calculate the quantity of chlorine required to oxidize ferrous to ferric hydroxide, alkalinity consumed, and the quantity of sludge produced.
- 20-5 A groundwater contains 8 mg/L of ferrous iron ( $\text{Fe}^{2+}$ ) and 2 mg/L of Mn(II) ion ( $\text{Mn}^{2+}$ ). Potassium permanganate ( $\text{KMnO}_4$ ) is used to oxidize ferrous iron and Mn(II). If the well pumping rate is 9.81 ML/d (1500 gpm), calculate the quantity of potassium permanganate required, alkalinity consumed, and quantity of sludge produced.
- 20-6 The results of a mineral analysis of a raw water are as follows:  $\text{H}_2\text{CO}_3^* = 72 \text{ mg/L}$ ,  $\text{Ca}^{2+} = 100 \text{ mg/L}$ ,  $\text{Mg}^{2+} = 15 \text{ mg/L}$ ,  $\text{Na}^+ = 20 \text{ mg/L}$ ,  $\text{Alk}(\text{HCO}_3^-) = 220 \text{ mg/L as CaCO}_3$ ,  $\text{SO}_4^{2-} = 60 \text{ mg/L}$ ,  $\text{Cl}^- = 5.15 \text{ mg/L}$ . If 50 ML/d of water from this source is to be softened to reduce the hardness, calculate the total, carbonate, and noncarbonate hardness present in the raw and finished waters; the kg/d of lime, soda ash, and  $\text{CO}_2$  needed for selective calcium softening; and the kg/d of  $\text{CaCO}_3$  solids produced. Draw bar diagrams

- of the raw and softened water. Assume the residual hardness in the softened water is 30 mg/L as  $\text{CaCO}_3$ .
- 20-7 If the water in Problem 20-6 had an alkalinity of 100 mg/L as  $\text{CaCO}_3$  and an  $\text{SO}_4^{2-}$  concentration of 151 mg/L, calculate the total, carbonate, and noncarbonate hardness present in the raw and finished waters; the kg/d of lime, soda ash, and  $\text{CO}_2$  needed for selective calcium softening; and the kg/d of  $\text{CaCO}_3$  solids produced. Draw bar diagrams of the raw and softened water.
- 20-8 A two-state excess lime-softening plant is designed to treat 57 ML/d (15 mgd) of a groundwater that contains the following constituents:  $\text{Ca}^{2+} = 80$  mg/L,  $\text{Mg}^{2+} = 48.8$  mg/L,  $\text{Na}^+ = 23$  mg/L, Alk ( $\text{HCO}_3^-$ ) = 270 mg/L as  $\text{CaCO}_3$ ,  $\text{SO}_4^{2-} = 125$  mg/L, and  $\text{Cl}^- = 35$  mg/L. The water is to be softened by excess lime treatment. The average raw-water temperature and pH were found to be  $10^\circ\text{C}$  and 7.0, respectively. Draw a meq/L bar diagram, and determine the lime and soda ash dosages necessary in kg/d needed for softening. Assume that the soda ash is pure sodium carbonate and the lime is 85 percent  $\text{CaO}$  by weight. Also, calculate the kg/d of precipitated solids produced. Draw a meq/L bar graph of the water after the first stage of softening that includes the excess lime. Assume the practical limit of hardness removal for  $\text{CaCO}_3$  is 30 mg/L, and that of  $\text{Mg}(\text{OH})_2$  is 10 mg/L as  $\text{CaCO}_3$ . Determine the kg/d of  $\text{CO}_2$  required. Draw a meq/L bar diagram for the softened water after the second stage.
- 20-9 A 10-ML/d raw-water source is to be softened by two-stage lime softening to reduce the hardness. The results of a mineral analysis of the raw water are as follows:  $\text{Ca}^{2+} = 112$  mg/L,  $\text{Mg}^{2+} = 20$  mg/L,  $\text{Na}^+ = 11$  mg/L, Alk( $\text{HCO}_3^-$ ) = 260 mg/L as  $\text{CaCO}_3$ ,  $\text{SO}_4^{2-} = 80.6$  mg/L,  $\text{Cl}^- = 38.0$  mg/L. Calculate the total, carbonate, noncarbonate hardness present in the raw finished waters; the kg/d of lime, soda ash, and  $\text{CO}_2$  needed for selective calcium softening; and the kg/d of  $\text{CaCO}_3$  solids produced. Assume the residual calcium hardness in the softened water is 30 mg/L as  $\text{CaCO}_3$ . Draw the initial and final bar diagrams of the raw and softened water. The average raw-water temperature and pH were found to be  $15^\circ\text{C}$  and 7.2, respectively.
- 20-10 A 50-ML/d raw-water source is to be softened using excess lime treatment to reduce the hardness. The results of a mineral analysis of the raw water are as follows:  $\text{Ca}^{2+} = 70$  mg/L,  $\text{Mg}^{2+} = 15.9$  mg/L,  $\text{Na}^+ = 23$  mg/L, Alk( $\text{HCO}_3^-$ ) = 250 mg/L as  $\text{CaCO}_3$  and  $\text{SO}_4^{2-} = 38.4$  mg/L. Calculate the total, carbonate, and noncarbonate hardness present in the raw finished waters; the kg/d of lime, soda ash, and  $\text{CO}_2$  needed for selective calcium softening;

- and the kg/d of  $\text{CaCO}_3$  solids produced. Assume the residual calcium hardness in the softened water is 30 mg/L as  $\text{CaCO}_3$ . Draw bar diagrams of the raw and softened water.
- 20-11 For the groundwater given in Problem 20-10, determine the lime dose required for softening by split treatment assuming the magnesium concentration in the finished water does not exceed 40 mg/L as  $\text{CaCO}_3$  and the total hardness does not exceed 155 mg/L as  $\text{CaCO}_3$ . Determine the final hardness of the finished water.
- 20-12 A 200-ML/d (53 mgd) raw-water source is to be softened using excess lime treatment to reduce the hardness. The results of a mineral analysis of the raw water are as follows:  $\text{H}_2\text{CO}_3^* = 65.1$ ,  $\text{Ca}^{2+} = 80$  mg/L,  $\text{Mg}^{2+} = 19.5$  mg/L,  $\text{Na}^+ = 23$  mg/L,  $\text{Alk}(\text{HCO}_3^-) = 280$  mg/L as  $\text{CaCO}_3$ ,  $\text{SO}_4^{2-} = 28.8$  mg/L, and  $\text{Cl}^- = 14.2$  mg/L. Calculate the total, carbonate, and noncarbonate hardness present in the raw and finished waters; the kg/d of lime, soda ash, and  $\text{CO}_2$  needed for selective calcium softening; and the kg/d of  $\text{CaCO}_3$  solids produced. Assume the residual calcium hardness in the softened water is 30 mg/L as  $\text{CaCO}_3$ . Draw bar diagrams of the raw and softened water.
- 20-13 Consider the precipitation softening by split-stream treatment of the raw water in Problem 20-12. Assume that only 75 percent of the water is treated by excess lime treatment and the other 25 percent bypasses the first stage and is mixed in the second stage. Compute the kg/d of chemicals required and the hardness of the water.

## Terminology for Residuals Management

---

<b>Term</b>	<b>Definition</b>
Brine, ion exchange	Waste resulting from the regeneration of ion exchange resins including concentrated brine (high salinity solutions) and washwater.
Brine, sorbent	Waste resulting from the regeneration and conditioning of solid sorbents including activated aluminum and granular ferric hydroxide.
Chemical conditioning	Addition of chemicals to improve the dewaterability of treatment plant sludges.
Conditioning	Techniques and processes used improve the physical properties of the sludge so that it will dewater more easily.
Concentrate reverse osmosis	High salinity solution produced by the concentration of salts removed from brackish or saline waters during treatment.
Crystallization	Process of converting thickened concentrate and brine into mineral crystals that can be dewatered with a centrifuge or belt press.
Deep-well injection	Process of discharging membrane concentrate or ion exchange brine by injection into deep brackish or saline aquifers.
Dewatering	Process of removing excess water from sludge.
Flotation	Process of using air to float coagulated particles for thickening and removal.
Freezing	Freezing of sludge to enhance its dewaterability.
Heat treatment	Process of using heat to condition sludge for subsequent processing.
Leachate	Liquid underflow (percolate) from sand and other types of drying beds.
Membrane washwater	Waste stream resulting from the backwashing of the membranes.
Return flows	Flows returned to the plant influent or to separate treatment facilities resulting from operations such as centrifugal thickening of sludge (centrate), belt press thickening (filtrate or pressate), and plate and frame thickening of sludge (filtrate).
Residuals	Liquid, semisolid, solid, and gaseous phase by-products removed during the water treatment process, along with any transport water that is removed.

Term	Definition
Residuals management	Planning, designing, and operating of facilities to reuse and/or dispose of water treatment residuals.
Sorbent	Any material used to remove constituents from solution by sorption such as activated aluminum and granular ferric hydroxide.
Sorbent, spent	Sorbents that have lost significant adsorptive capacity and cannot be reactivated effectively.
Sterilization	Total destruction of disease-causing and other organisms.
Storage lagoons	Lined earthen basin used to store various sludges before processing.
Supernatant flow	Clear water decanted off residual solids resulting from the gravity and flotation thickening of sludge.
Underflows	See <i>Return flows</i> .
Waste washwater	Water from the backwashing of granular medium filters, other packed beds.

In most water treatment processes the objective is to remove certain materials from the water, to purify it. These materials are referred to as *residuals* and consist of the liquid-, solid-, semisolid, and gaseous-phase by-products removed during the water treatment process along with any transport water that is removed with them. These residuals include the turbidity-causing materials in raw water, organic and inorganic solids, algae, bacteria, viruses, colloids, precipitated from the raw water and those added in treatment, and dissolved salts. *Sludge* is the term used to refer to the solid, or liquid–solid, portion of some types of water plant residuals such as the underflow from sedimentation basins. In addition, some solid materials used to remove specific contaminants by sorption can become a *solid waste* when they can no longer be regenerated cost effectively or their removal (sorption) capacity has been reached when operated in a single-pass mode.

*Residuals management* is a term used to describe the planning, design, and operation of facilities to reuse or dispose of water treatment residuals. From a technical standpoint the objective in residuals management is usually to minimize the amount of material that must ultimately be disposed of by (1) recovering recyclable materials and (2) reducing the water content of the residuals. In most cases, the cost of transporting and ultimately disposing of the residuals makes up the major fraction of residuals management costs, and the most economical solution is to reduce the quantity of material for ultimate disposal. Other considerations include minimizing environmental impacts and meeting discharge requirements established by regulatory agencies.

Residuals management can have an important impact on the design and operation of many water treatment plants. For existing plants, residuals management systems may limit overall plant capacity if not designed and operated properly. Frequently, residuals are stored temporarily in the process train before removal for treatment, recycle, and/or disposal. Residual removal must be optimized for the process train and coordinated with the residuals management systems to maintain water quality.

Given the many issues associated with and the importance of residuals management, the purpose of this chapter is to (1) define the nature of the problem, including the sources of residuals; (2) review the physical and chemical properties used to characterize water treatment plant residuals; (3) consider the residuals and their properties, produced by the principal treatment processes; (4) review options available for the management of residual liquid streams; (5) review the options available for the management of residual concentrates and brines; (6) review the options available for the management of residual sludges; and (7) review options available for the ultimate reuse and/or disposal of residuals after processing.

## 21-1 Defining the Problem

---

The problem of residuals management can be quantified with respect to (1) the quantities and costs of handling residuals, (2) the constituents of concern, and (3) the environmental and regulatory constraints any engineered solution must meet. Before considering these topics, it is appropriate to consider the sources of residuals in water treatment processes.

The principal residuals generated from the treatment of water can be classified as (1) sludges from water treatment processes, (2) liquid wastes from water treatment processes, (3) liquid wastes resulting from processes used to thicken process sludges and to treat liquid wastes, and (4) gaseous wastes from specialized water treatment processes. The sources of these residuals and a brief description are presented in Table 21-1. The specific types of sludges and liquid waste streams will depend on the type of treatment train as illustrated on Fig. 21-1.

As much as 3 to 5 percent of the volume of the raw water entering a conventional water treatment plant may end up as solid, semisolid, and liquid residuals. The bulk of that volume will be the filter waste washwater, which typically contains less than 10 percent of the removed solids in a conventional treatment plant. Underflow from sedimentation basins typically contain on the order of 0.1 to 0.3 percent of the plant flow but contain most of the removed solids. In a direct or in-line filtration plant, however, all solids removal is accomplished in the filters. Typical values

### Sources of Residuals

### Magnitude of the Problem

**Table 21-1**

Sources of semisolid, solid, liquid, and gaseous residuals from the treatment of water

Source of Residual	Description
<b>Treatment Process Semisolid and Solid Residuals</b>	
Chemical precipitation with alum and iron	Sludges resulting from the chemical precipitation of surface waters that may contain clay, silt, colloidal material, and microorganisms with coagulant chemicals and polymers.
Coarse screens	Coarse screens prevent the entry of debris and fish into the intake structure. The coarse solids retained on the screens include rags, stringy material, and large wood pieces.
Flotation	Float, which in time thickens to sludge, resulting from the flotation process. Sludge, which settles, is removed periodically in small plants and continuously in large plants.
Presedimentation	Sludge resulting from presedimentation to remove gross amounts of sediment prior to conventional treatment.
Slow sand filter scrapings	Semisolid material resulting from the scraping of the surface of slow sand filters.
Spent sorbents	Solid material used to sorb constituents from solution such as hardness, arsenic, fluoride, phosphorus, and selected organic constituents, which have lost significant adsorptive capacity and/or cannot be reactivated effectively.
Traveling screens	Traveling screens are used to prevent grit, sand, and small rocks that have come through the intake from continuing into the treatment facility. Screenings include grit, sand, and small rocks.
Water softening	Lime sludge resulting from the removal of calcium and magnesium from hard waters during precipitation softening.
<b>Treatment Process Liquid Wastes</b>	
Brines and waste washwater from solid sorbents	Brine and rinse water from the reactivation of sorbents, principally ion exchange, along with waste washwater used to clean the beds.
Electrodialysis concentrate (brine)	The water that contains the dissolved constituents removed by the electrodialysis membranes used for softening and desalination.
Filter waste washwater	Waste washwater from backwashing filters to remove residual solids. Waste washwater is high in turbidity and may contain pathogenic organisms such as <i>Giardia</i> and <i>Cryptosporidium</i> .
Filter-to-waste water	Water used to condition filters after backwashing that has particles and turbidity above regulatory action levels.
Ion exchange brines and washwater	Brine and rinse water from the reactivation of ion exchange resins whose exchange capacity has been exhausted. Brines from resins used for softening typically containing sodium, chloride, and hardness ions; they are high in TDS, but low in suspended solids.
Membrane concentrate	The water that contains the dissolved constituents removed by reverse osmosis membranes.

**Table 21-1** (Continued)

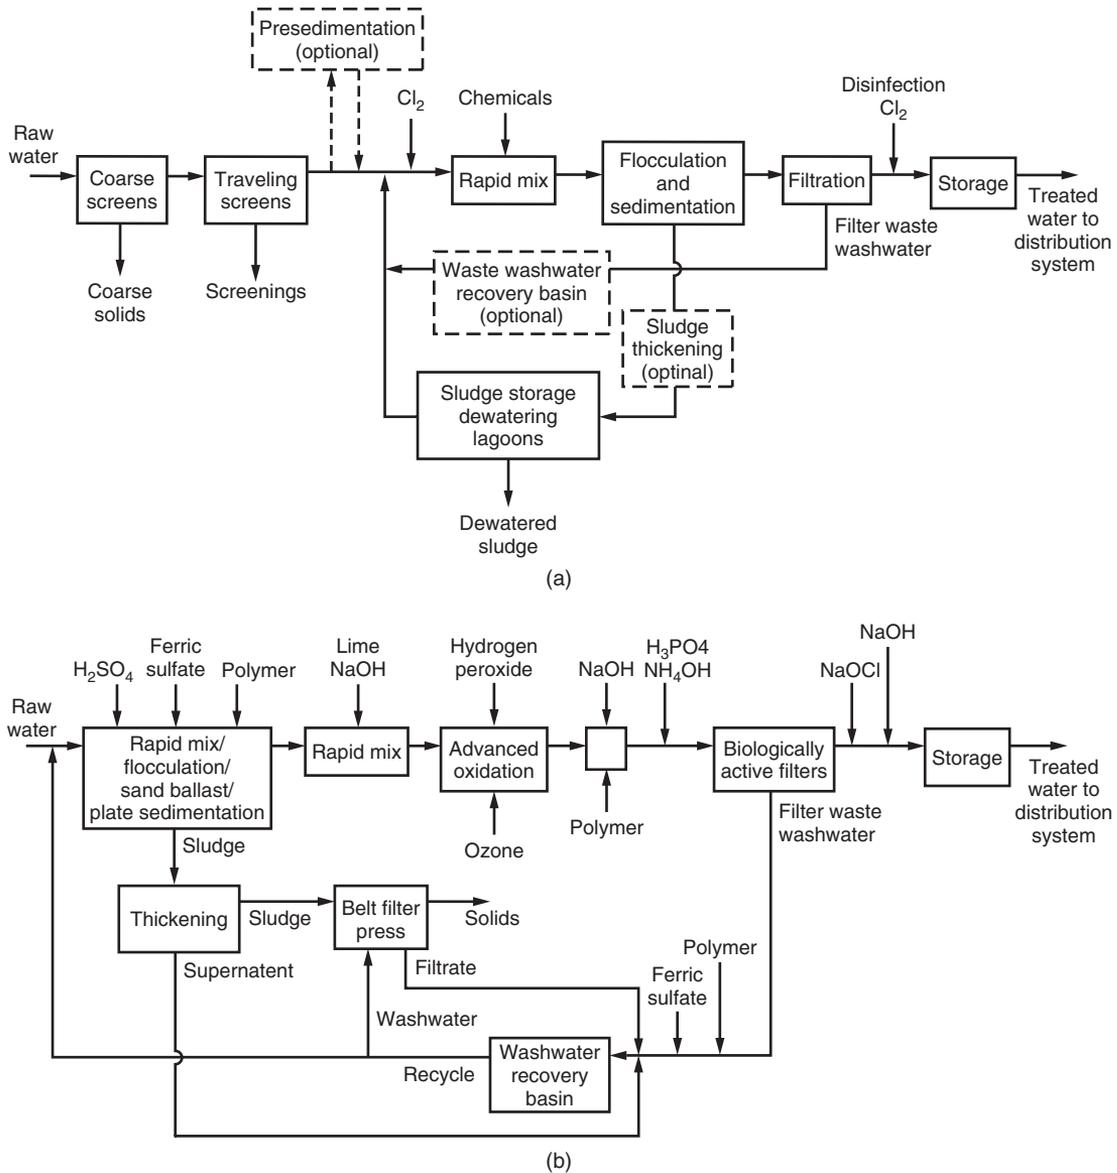

Source of Residual	Description
Membrane (micro- and ultrafiltration) washwater	Waste washwater from backwashing membranes to remove accumulated solids.
Slow sand filter washwater	Washwater high in turbidity that may contain pathogenic organisms such as <i>Giardia</i> and <i>Cryptosporidium</i> resulting from the cleaning of slow sand filter scrapings. (Note in many facilities the scraped sand is not washed for reuse on the filter beds but is used for other purposes.)
<b>Thickening/Dewatering Process Liquid Wastes</b>	
Centrate	Liquid resulting from centrifugal thickening of sludge.
Drying bed decant and underflow	Decant (supernatant) liquid from the surface and underflow (percolate) from sand and other types of drying beds.
Filtrate	Liquid resulting from plate and frame thickening of sludge.
Filtrate (pressate)	Liquid resulting from belt press thickening of sludge.
Supernatant flow	Clear water decanted off residual solids resulting from the gravity and flotation thickening of sludge.
<b>Treatment Process Gaseous Wastes</b>	
Stripping towers (not discussed in this chapter)	Off-gas from stripping operations contains contaminants that may need to be removed before gas can be discharged.

for the quantities of residuals produced by various treatment processes are summarized in Table 21-2. The costs of handling these residuals are dependent on the type of handling provided and the nature of the residuals. In general, the major portion of the cost with residuals management is associated with transport and ultimate disposal.

Residual constituents of concern contained in the sludges and liquid wastes from treatment processes and thickening operations may include the following:

- Pathogenic microorganisms
- Giardia* cysts and *Cryptosporidium* oocysts
- Turbidity/particles
- Disinfection by-products (DBPs)
- Precursors in the formation of DBPs (natural organic matter)
- Total organic carbon (TOC)
- Assimilative organic carbon (AOC)

### Constituents of Concern

**Figure 21-1**

Typical water treatment process flow diagrams: (a) small plant with sludge storage lagoons. Future options include the addition of a waste washwater recovery basin and sludge thickening before discharge to sludge lagoons; (b) large plant with mechanically intensive sludge-processing facilities.

**Table 21-2**

Typical production of residuals in water treatment facilities as percent of plant flow

Type of Residual	Percent of Plant Flow	
	Range	Typical
Alum coagulation sludge	0.08–0.3	0.1
Direct filtration backwash water	4–8	
Filter backwash water	2–5	2 <sup>a</sup> , 3 <sup>b</sup>
Flotation sludge (from reactor surface)	0.01–0.1	0.06
Flotation sludge (from reactor bottom)	0.001–0.04	
Ion exchange brine	1.5–10	5–8
Iron coagulation sludge	0.08–0.3	0.1
Lime-softening sludge	0.3–6	4
Microfiltration backwash water	2–8	6
Reverse osmosis concentrate	10–50	20–30

<sup>a</sup>During warm months.

<sup>b</sup>During cold months.

- Taste- and odor-causing compounds
- Synthetic organic compounds (SOCs)
- Manganese and iron
- Arsenic or other toxic compounds
- Radioactive materials
- Dissolved solids/salt

A variety of other compounds may also be of concern depending on the source of the water. Where liquid wastes and return flows from dewatering and thickening operations are recycled, these flows must, as noted previously, be returned to the headworks of the process train. However, concern over the presence of one or more of the above constituents has led, in some cases, to the use of separate treatment facilities for these liquid wastes. The use of separate treatment facilities is considered in Sec. 21-9.

In the past, treatment plant residuals were often discharged to nearby streams, stored in lagoons, or spread on land with little or no processing, which created both negative aesthetic and environmental impacts. Aesthetic impacts include discoloration or increased turbidity in receiving waters and buildup of sludge deposits in waterways and occupying large land areas with lagoons. Impacts on the biota are, for sludges and waste washwaters, related primarily to the impact(s) on fish from increased water turbidity, pH, and hardness. Redissolved iron and aluminum may also pose a problem. In the cases of brine, there may be toxic effects caused by the high salt concentrations, especially in localized areas around the discharge. Most

## Environmental Constraints

sludges, if spread on land to any depth, will prevent or inhibit plant growth; however, if mixed adequately into the soil, sludge may have little or no impact on plant growth. Lime sludges may have beneficial impacts on the soil, if used in appropriate amounts.

### **Regulatory Constraints**

Regulatory constraints on residuals disposal have become increasingly severe in recent years. Prior to the late 1960s there was little concern for disposal of water treatment residuals. In most cases residuals were returned to the nearest receiving water, usually the source of the water supply. In the late 1960s some states began considering these residuals as pollutants and began establishing treatment or discharge standards for them.

The 1972 Federal Water Pollution Control Act classified water treatment plant residuals as pollutants and categorized them as industrial waste. As such, they are now required to meet standards for best practicable control technology (BPT) currently available and best available technology (BAT) economically achievable. There has also been legislation, both federal and state, to control toxic and hazardous substances. Such regulations, while protecting public and environmental health, can severely limit the available residuals management options and add to the cost of disposal.

## **21-2 Physical, Chemical, and Biological Properties of Residuals**

---

An understanding of the physical, chemical, and biological properties of the residuals produced by treatment processes is fundamental to determining appropriate management techniques and to design facilities to implement those techniques. The physical, chemical, and biological properties used to characterize water treatment plant residuals are reviewed in this section. Additional information on the individual residuals is presented in the following sections dealing with coagulation sludges, lime sludges, filter waste washwater, and softening and demineralization concentrates.

### **Physical Properties**

The physical properties of water treatment plant residuals are important for sizing and design of residuals management facilities. The physical properties used most commonly to characterize residuals are summarized in Table 21-3. Total solids is one of the most important physical parameters. Sludge density is dependent on the moisture content, varying from the density of water ( $1000 \text{ kg/m}^3$ ) for sludges below about 1 percent to  $1100 \text{ kg/m}^3$  for a 15 percent sludge and higher for relatively dry sludges. A reasonable estimate of the wet density of inorganic sludges, typical of alum or iron salts, can be made by assuming the dry density of the solids is about  $2300 \text{ kg/m}^3$  (see Example 2-1).

**Table 21-3**

Physical, chemical, and biological properties used to characterize water treatment plant residuals

Parameter	Unit of Expression	Description
Physical		
Total solids	%	Measure of total mass of material that must be handled on dry basis as percent of combined mass of solute and material
Dry density	kg/m <sup>3</sup>	Measure of mass per unit volume on dry basis
Wet density	kg/m <sup>3</sup>	Measure of mass per unit volume on wet basis
Specific gravity of dry solids	Unitless	Mass relative to mass of water
Specific resistance	m/kg	Measure of rate at which sludge can be dewatered (see Eq. 21-6)
Dynamic viscosity	N · s/m <sup>2</sup>	Measure of resistance to tangential or shear stress
Initial settling velocity	mm/s	Initial settling rate of a water–solids suspension
Chemical		
BOD	mg/L	Estimate of readily biodegradable organic content
COD	mg/L	Measure of oxygen equivalent of organic matter determined by chemical oxidation
pH	Unitless	Measure of effective acidity or alkalinity of solution
Alum content	% or mg/L	Derived from addition of coagulating chemical
Calcium, magnesium content	% or mg/L	Derived from addition of lime for water softening
Iron content	% or mg/L	Derived from addition of coagulating chemical
Silica and inert material	% or mg/L	Material present in surface water supplies
Trace constituents	μg/L or ng/L	Detection of specific constituents of concern
Biological		
Bacteria	no./100 mL	Variable depending on source of water and season
Protozoan cysts and oocysts	no./100 mL	Variable depending on source of water and season
Helminths	no./100 mL	Variable depending on source of water and season
Viruses	no./100 mL	Variable depending on source of water and season

**SPECIFIC GRAVITY OF SLUDGE**

The volume of sludge depends primarily on its water content and only slightly on the character of the solid matter. For example, a 5 percent sludge contains 95 percent water by weight. If the solid matter is composed of fixed (mineral) solids and volatile (organic) solids, the specific gravity of all the solid matter can be computed as

$$\frac{W_s}{S_s \rho_w} = \frac{W_f}{S_f \rho_w} + \frac{W_v}{S_v \rho_w} \quad (21-1)$$

where  $W_s$  = weight of total dry solids, kg  
 $S_s$  = specific gravity of total solids, unitless

$\rho_w$  = density of water, kg/m<sup>3</sup>

$W_f$  = weight of fixed solids (mineral matter), kg

$S_f$  = specific gravity of fixed solids, unitless

$W_v$  = weight of volatile solids, kg

$S_v$  = specific gravity of volatile solids, unitless

Thus, if 90 percent by weight of the solid matter in a sludge containing 95 percent water is composed of fixed mineral solids with a specific gravity of 2.5 and 10 percent is composed of volatile solids with a specific gravity of 1.0, then the specific gravity of all solids,  $S_s$ , would be equal to 2.17, computed using Eq. 21-1:

$$\frac{1}{S_s} = \frac{0.90}{2.5} + \frac{0.10}{1.0} = 0.46$$

$$S_s = \frac{1.0}{0.46} = 2.17$$

If the specific gravity of the water is taken to be 1.00, the specific gravity of the sludge,  $S_{sl}$ , is 1.03, as follows:

$$\frac{1}{S_{sl}} = \frac{0.05}{2.17} + \frac{0.95}{1.00} = 0.97$$

$$S_{sl} = \frac{1.0}{0.97} = 1.03$$

#### DENSITY OF SLUDGE

The density of wet sludge, which is a mixture of solid matter and water, can be determined using the following expression:

$$\text{Density of wet sludge, } \rho_{sl} = \rho_w S_{sl} \quad (21-2)$$

where  $\rho_{sl}$  = density of sludge, kg/m<sup>3</sup>

$\rho_w$  = density of water, kg/m<sup>3</sup>

$S_{sl}$  = specific gravity of the sludge, unitless

#### VOLUME OF SLUDGE

The volume of a wet sludge may be computed with the following expression:

$$V = \frac{W_s}{\rho_w S_{sl} P_s} \quad (21-3)$$

where  $V$  = volume of wet sludge, m<sup>3</sup>

$W_s$  = weight of total dry solids, kg

$\rho_w$  = density of water, kg/m<sup>3</sup>

$S_{sl}$  = specific gravity of sludge, unitless

$P_s$  = percent solids expressed as a decimal

For approximate sludge volume calculations for a given solids content, it is simple to remember that the volume varies inversely with the percent of solid matter contained in the sludge, as given by

$$\frac{V_1}{V_2} = \frac{P_2}{P_1} \quad (\text{approximate}) \quad (21-4)$$

where  $V_1, V_2$  = sludge volumes  
 $P_1, P_2$  = percent solid matter

Application of the above relationships is illustrated in Examples 21-1 and 21-2.

### Example 21-1 Estimating density and volume of alum sludge

Determine the density and liquid volume of 1000 kg of dry alum sludge with the following characteristics:

Item	Unit	Value
Solids	%	15
Volatile matter	%	6
Specific gravity of fixed solids	Unitless	2.65
Specific gravity of volatile solids	Unitless	1.0
Temperature	°C	20

#### Solution

1. Compute the specific gravity of all the solids in the sludge using Eq. 21-1:

$$\frac{1}{S_s} = \frac{0.94}{2.65} + \frac{0.06}{1.0} = 0.41$$

$$S_s = \frac{1.0}{0.41} = 2.44$$

2. Compute the specific gravity of the wet alum sludge:

$$\frac{1}{S_{sl}} = \frac{0.15}{2.44} + \frac{0.85}{1.00} = 0.91$$

$$S_{sl} = \frac{1.0}{0.91} = 1.10$$

3. Compute the density of the wet alum sludge using Eq. 21-2:

$$\text{Density of wet sludge, } \rho_{sl} = \rho_w S_{sl}$$

The density of water at 15°C from App. C = 998.2 kg/m<sup>3</sup>.

$$\text{Density of wet sludge, } \rho_{sl} = (998.2 \text{ kg/m}^3)(1.10) = 1098 \text{ kg/m}^3$$

4. Compute the volume of wet sludge at 20°C using Eq. 21-2. The density of water at 15°C from App. C = 998.2 kg/m<sup>3</sup>.

$$V = \frac{W_s}{\rho_w S_{s1} P_s}$$

$$= \frac{1000 \text{ kg}}{(998.2 \text{ kg/m}^3)(1.10)(0.15)} = 6.07 \text{ m}^3$$

#### SPECIFIC RESISTANCE

Specific resistance, dynamic viscosity, initial settling velocity, and other physical properties are dependent on solids concentrations and the relative proportions of coagulant and other materials in the sludge. Specific resistance is a measure of the rate at which a sludge can be dewatered. Although developed for the vacuum filtration process, specific resistance has been found to be a useful parameter for assessing the dewaterability of sludges by gravity settling, centrifugation, belt filtration, plate and frame pressure filtration, and sand beds.

The concept of specific resistance is derived from the basic theory of filtration as developed by Carmen (1933, 1934) and extended by Coackley and Jones (1956) for conditions of streamline flow by the application of Poiseuille's and Darcy's law. The basic filtration equation is

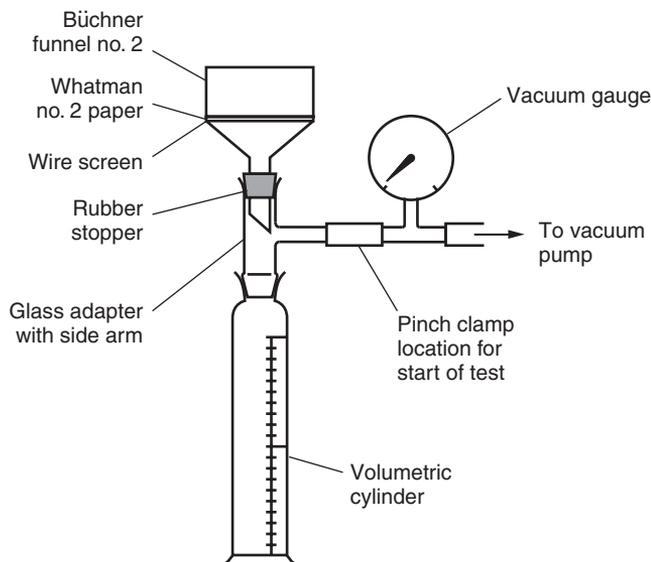

$$\frac{dV}{dt} = \frac{PA^2}{\mu (rWV + R_m A)} \quad (21-5)$$

where  $V$  = volume of filtrate, m<sup>3</sup>  
 $t$  = time, s  
 $P$  = pressure  
 $A$  = area, m<sup>2</sup>  
 $\mu$  = viscosity of filtrate, N · s/m<sup>2</sup>  
 $r$  = specific resistance of sludge cake, m/kg  
 $W$  = mass of dry solids per unit volume of filtrate, kg/m<sup>3</sup>  
 $V$  = volume, m<sup>3</sup>  
 $R_m$  = resistance of filter medium, m<sup>-1</sup>

For constant pressure, integration of Eq. 21-5 yields

$$\frac{t}{V} = \frac{\mu r W V}{2PA^2} + \frac{\mu R_m}{PA} \quad (21-6)$$

The specific resistance of a sludge can be determined from laboratory data on the time for a given volume of water to be filtered, obtained using a Buchner funnel (see Fig. 21-2) or other filters specifically designed for the

**Figure 21-2**  
Buchner funnel test apparatus used for  
determination of specific resistance of sludge.

purpose. If the measured data are plotted in terms of  $t/V$  versus  $V$ , then the specific resistance can be determined from the slope of the line:

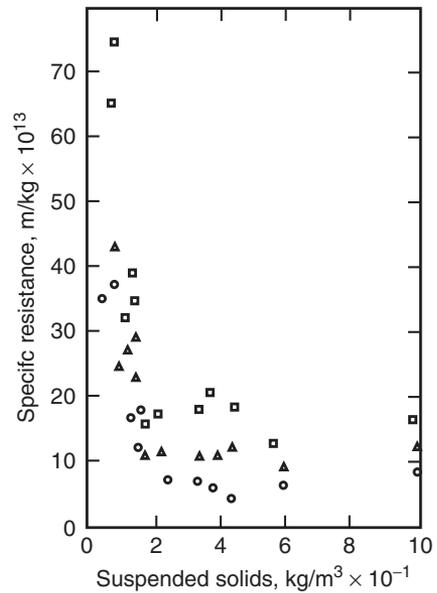

$$r = \frac{2PA^2m}{\mu W} \quad (21-7)$$

where  $m = \text{slope of line}$

Typical specific resistance values for various sludges range from  $5 \times 10^{10}$  to  $100 \times 10^{10}$  m/kg. Sludges with specific resistance values below  $10 \times 10^{10}$  m/kg are considered to be readily dewaterable. Sludges with values greater than  $100 \times 10^{10}$  m/kg are considered to be difficult to dewater. Specific resistance is sometimes expressed in units of seconds squared per gram, which is not dimensionally correct for use in Eq. 21-7. To compare values expressed in meters per kilogram to values expressed in seconds squared per gram, the values in meters per kilogram must be divided by the gravitational constant ( $9.81 \text{ m/s}^2$ ) and converted from grams to kilograms ( $10^3 \text{ g/kg}$ ). Typically, specific resistance increases at solids concentrations below about 2 percent but is relatively constant above that concentration, as shown on Fig. 21-3. Shear strength and viscosity increase as solids concentrations increase, as shown on Figs. 21-4 and 21-5.

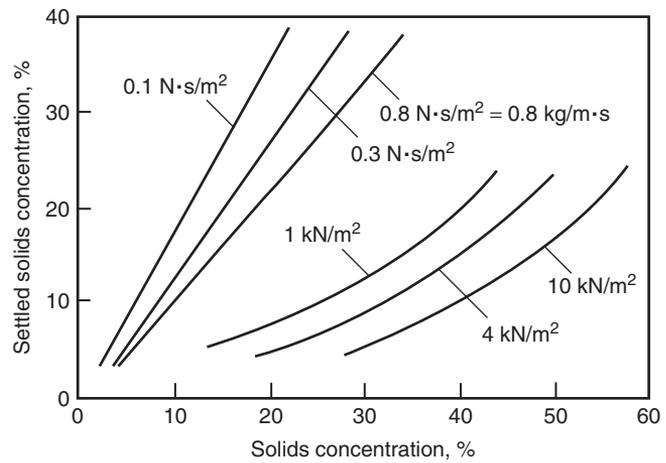

#### OTHER PHYSICAL PROPERTIES

The variation in physical properties among sludges of various compositions is due to the physical structure of the sludge. A coagulation sludge is made up of the suspended material in the raw water, metal hydroxides added during coagulation treatment, and a large amount of bound and entrapped

**Figure 21-3**

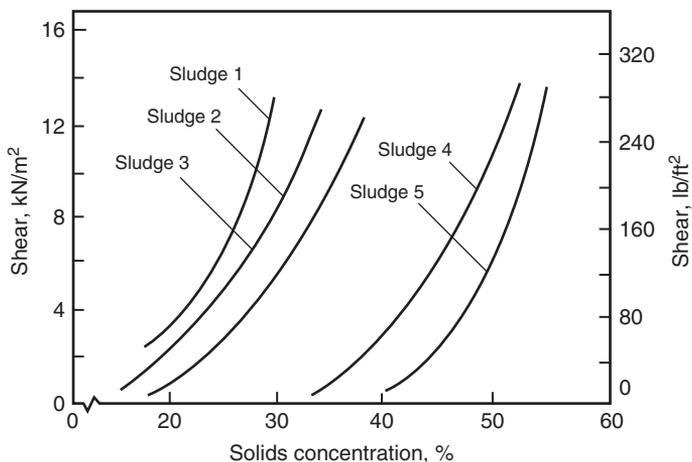

Relationship between suspended solids and specific resistance of alum sludges. (Adapted from Hawkins et al., 1974.)

**Figure 21-4**

Variation in sludge physical properties. (Adapted from Novak and Calkins, 1975.)

water in a loose structure. The suspended materials are clay and sediment particles, color-causing colloids, algae, and other similar materials. Clays and sediments are structurally solid and have a specific gravity of around 2.6; the other materials are agglomerations of individual metal hydroxide molecules with various ions and water molecules all loosely held together by electrostatic bonds. Metal hydroxides become attached to the suspended materials by electrostatic bonds and also physically entrap suspended materials as well as water molecules. In the coagulation–flocculation process the

**Figure 21-5**

Effect of concentration on shear of five different sludges as they are dried. (Adapted from Novak and Calkins, 1975.) Because of the wide variation between the five different plants, generalized information such as presented in this graph should be used with caution.

suspended particles and metal hydroxides are brought together to form the flocs that then settle and make sludges. When the individual flocs come in contact with each other in the sludge, they become loosely bound by the same electrostatic forces that hold the individual flocs together.

The extent of the bonding depends on the extent of the contact between the flocs, which is limited by the entrapped water that separates the flocs. As more water is removed by draining, pressure, or other means, the particles contact more and the sludge becomes increasingly solid. Because the metal hydroxides have water molecules in their structure, direct particle contact is more difficult than for other suspended materials that do not have water in their structure. Therefore, sludges with high proportions of metal hydroxides are not as dewatered easily as are sludges that have higher proportions of other materials unless the sludge is conditioned with large amounts of lime or an appropriate polymer dose. The polymer molecules form bridges between floc particles and improve the bond between particles. If polymers are added to coagulation sludges, either as sludge conditioners or as a part of the coagulation process, the sludge produced will have a more solid structure.

The chemical properties of residual sludges are related directly to the chemical content of the raw water and the coagulant chemicals. Important chemical characteristics are summarized in Table 21-3. The BOD, COD, TOC, and related organic content are representative of the dissolved and suspended organic materials and algae removed from the water. The inorganic solids are derived from the coagulant chemicals and the clay and sediments removed from the raw water. The pH and dissolved solids in the liquid portion of the sludge are about the same as those in the water being treated. In a complete chemical analysis of an alum sludge, as reported by Schmitt and Hall (1975), a total of 72 elements were detected.

## Chemical Properties

The major elements found were (in order of decreasing predominance by weight) silicon, aluminum, iron, titanium, calcium, potassium, magnesium, and manganese.

### **Biological Properties**

Water treatment plant residuals may contain a variety of microorganisms, depending on the source, the quality of the raw water, the treatment process employed (e.g., prechlorination), and the time of year. Coagulation sludges, filter waste washwater, and membrane concentrates will contain bacteria, protozoan cysts and oocysts, and viruses removed during treatment. It is not possible to generalize on the number of microorganisms that may be present per unit mass or volume for the reasons cited above.

## 21-3 Alum and Iron Coagulation Sludges

---

Coagulation sludges are produced by the coagulation and settling of natural turbidity by added coagulant chemicals. In water treatment plants, coagulation sludges are collected in the sedimentation basins and on the filters. The amount and properties of the sludge collected in the basins and the filters depends upon the water quality, type and dose of coagulant used, efficiency of operation, plant design, and other factors. For typical plants using alum as the coagulant, between 60 and 90 percent of the total residuals will be collected in the sedimentation basins with the remainder in the filters. The residuals collected on the filters are removed from the filters during backwashing and, if the waste washwater is recovered, are removed from the waste washwater by settling.

Sludge from the sedimentation basins may be removed continuously or, more commonly, on an intermittent basis. Sludge removal may be accomplished using various mechanical devices (see Chap. 10) or by draining and manually washing down the basin. If basins are manually cleaned, the frequency may be once every 3 months or more. Mechanical cleaning equipment is usually designed to operate between once a week and once every few hours or continuously. Sludge removal frequency is decided based on balancing the competing interests of maintaining water quality in the process train, available sludge storage in the process train, the ability of the residuals management system to accept additional inflows, and disposal costs.

Filters are typically backwashed every 24 to 72 h, resulting in a relatively large volume of waste washwater produced in a short time. However, some proprietary filter types (such as automatic backwash filters) may backwash as frequently as every 2 to 6 h. Waste washwater recovery facilities must be designed to accept high, intermittent flows.

Coagulation sludges are grouped according to the type of primary coagulant employed. The principal types of coagulant employed are

(1) hydrolyzing metal salts of alum and iron, (2) prehydrolyzed metal salts such as polyaluminum chloride (PACl) and polyiron chloride (PICl), and (3) synthetic organic polymers.

Typical overall values for the quantities of coagulant sludge produced were summarized previously in Table 21-2. For design purposes, the amount of sludge anticipated at a plant can be estimated based on the quality of the raw water and the type of chemical treatment. The suspended solids fraction of the sludge may be safely assumed to be equal to the suspended solids of the raw water, or, if total suspended solids (TSS) data are not available, it may be estimated from turbidity data. It is important to note, however, that there is great variability in the TSS/turbidity ratio depending on the organic content of the water source. The ratio for most water sources will vary between 1 and 2, with a typical value being about 1.4. For turbidities less than 10 NTU the ratio is nearly equal to 1.

### Estimating Quantities of Coagulant Sludges

#### PRECIPITATION REACTIONS

Typical precipitation reactions for alum and iron when used as coagulants, as shown in Eqs. 9-11 to 9-13 in Chap. 9, are as follows:

For alum or iron sludges, the precipitates are largely aluminum and iron hydroxide, respectively, and the quantity precipitated can be calculated from the stoichiometry. Using Eq. 21-8, it can be calculated that a total of 0.26 kg of sludge on a dry-solids basis will be produced for each kilogram of alum [ $\text{Al}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}$ ] added [e.g.,  $78 \text{ g/mol Al}(\text{OH})_3 \times (2 \text{ mol/mol}) / (594 \text{ g/mol alum})$ ]. The corresponding values for ferric coagulants are 0.53 kg sludge/kg ferric sulfate [ $\text{Fe}_2(\text{SO}_4)_3$ ] added, and 0.66 kg sludge/kg ferric chloride ( $\text{FeCl}_3$ ) added. Typical values that can be used to estimate the quantity of alum and iron sludges are given in Table 21-4.

Prehydrolyzed PACl [ $\text{Al}_n\text{Cl}_{(3n-m)}(\text{OH})_m$ ] is supplied in solution form containing varying amounts of aluminum. The amount of sludge produced can be estimated using the relationship

$$\text{mgAl}(\text{OH})_3/\text{mg PACl added} = (\text{mg PACl/L}) (\% \text{Al in PACl}/100) \\ [\text{mg Al}(\text{OH})_3/\text{mgAl}] \quad (21-11)$$

Typical values that can be used to estimate the quantity of PACl sludge are given in Table 21-4.

For polymer sludges or sludges with polymer used as coagulant aid, the amount of polymer added should also be included in the calculation of the total amount of sludge produced. Other coagulant aids, such as bentonite

**Table 21-4**

Typical values that can be used to estimate quantities of sludge resulting from addition of coagulating chemicals and polymers, turbidity removal, and softening in water treatment processes

Process	Unit	Range	Typical Value
Coagulation			
Alum, $\text{Al}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}$	kg dry sludge/kg coagulant	0.2–0.33 <sup>a</sup>	0.26
Ferric sulfate, $\text{Fe}_2(\text{SO}_4)_3$	kg dry sludge/kg coagulant	0.5–0.53 <sup>a</sup>	0.53
Ferric chloride, $\text{FeCl}_3$	kg dry sludge/kg coagulant	0.6–0.66 <sup>a</sup>	0.66
PACl	kg dry sludge/kg PACl	$(0.0372\text{--}0.0489) \times \text{Al} (\%)$	$(0.0489) \times (\text{Al}, \%)$
Polymer addition	kg dry sludge/kg coagulant	1	1
Turbidity removal	mg TSS/NTU removed	1.0–2	1.4
Softening			
$\text{Ca}^{2+b}$	kg dry sludge/kg $\text{Ca}^{2+}$ removed	2.0	2.0
$\text{Mg}^{2+c}$	kg dry sludge/kg $\text{Mg}^{2+}$ removed	2.6	2.6

<sup>a</sup>Value without bound water.

<sup>b</sup>Sludge is expressed as  $\text{CaCO}_3$ .

<sup>c</sup>Sludge is expressed as  $\text{Mg}(\text{OH})_2$ .

or activated silica, should also be considered in the calculation as well as any other chemicals or materials, such as activated carbon, that may be collected in the basins or filters.

#### ESTIMATING SLUDGE MASS

The total sludge mass and volume produced can be calculated as

$$\begin{aligned} \text{Total sludge} &= \text{sludge from chemical coagulant} \\ &+ \text{sludge from suspended solids} \\ &+ \text{sludge from other chemicals or materials} \end{aligned} \quad (21-12)$$

Application of Eq. 21-12 is illustrated in Example 21-2, following the discussion of the relationships for alum, ferric sulfate, and ferric chloride.

For example, for alum with 14 bound water:

$$M = [D_{\text{Al}} (0.26) + \text{TSS} + X] (10^{-3} \text{ kg/g}) \quad (21-13)$$

where  $M$  = total sludge produced,  $\text{kg/m}^3$

$D_{\text{Al}}$  = alum dose,  $\text{g/m}^3$

TSS = total dissolved solids,  $\text{g/m}^3$

$X$  = other coagulant aids added to enhance precipitation,  $\text{g/m}^3$

Similarly for ferric sulfate and ferric chloride without bound water:

$$M = [D_{\text{FeSO}_4} (0.53) + \text{TSS} + X] (10^{-3} \text{ kg/g}) \quad (21-14)$$

$$M = [D_{\text{FeCl}_3} (0.66) + \text{TSS} + X] (10^{-3} \text{ kg/g}) \quad (21-15)$$

where  $D_{\text{FeSO}_4}$  = ferric sulfate dose, g/m<sup>3</sup>  
 $D_{\text{FeCl}_3}$  = ferric chloride dose, g/m<sup>3</sup>

For the enhanced coagulation and precipitation process, which results in the production of additional sludge, the following relationship has been recommended by the U.S. EPA (1996):

$$M = [D_{\text{Al}} (0.36) + \text{TOC} + X] (10^{-3} \text{ kg/g}) \quad (21-16)$$

where TOC = total organic carbon, kg/m<sup>3</sup>

The additional sludge that is produced is accounted for primarily by the factor by which the alum dose is multiplied (0.36) versus the factor (0.26) used in Eq. 21-12.

### Example 21-2 Determination of quantity (mass and volume) of sludge from coagulant addition and the volume of sludge as percentage of the total flow

Determine the mass and volume of sludge produced from alum or PACl precipitation for the removal of turbidity. Assume the following conditions apply: (1) flow rate is 0.5 m<sup>3</sup>/s (11.4 mgd), (2) average raw-water turbidity is 25 NTU, and (3) average alum or PACl dose is 30 mg/L, the sludge solids concentration is 5 percent with a corresponding specific gravity of 1.05, and the temperature is 15°C. Assume the ratio between TSS and turbidity expressed as NTU is 1.4, the ratio of alum sludge produced per kilogram of alum added is 0.26 (see Table 21-4), and that 1 mg/L of a polymer will be used. Assume the PACl contains 13 percent Al by weight. See also Example 9-2 for calculation of stoichiometry of the sludge from the coagulant.

#### Solution

##### Part A Mass and volume of alum sludge

1. Determine the amount of dry sludge produced from the addition of alum:

Sludge from alum, kg/d

$$\begin{aligned} &= (0.5 \text{ m}^3/\text{s})(30 \text{ mg/L})(0.26)(86,400 \text{ s/d})(10^3 \text{ L/m}^3)(1 \text{ kg}/10^6 \text{ mg}) \\ &= 337 \text{ kg/d} \end{aligned}$$

2. Determine the amount of dry sludge produced from the removal of turbidity:

$$\begin{aligned} &\text{Sludge from turbidity, kg/d} \\ &= (0.5 \text{ m}^3/\text{s})(25 \text{ NTU})(1.4 \text{ g/m}^3 \cdot \text{NTU})(86,400 \text{ s/d})(1 \text{ kg}/10^3 \text{ g}) \\ &= 1512 \text{ kg/d} \end{aligned}$$

3. Determine the amount of dry sludge produced from the addition of a polymer:

$$\begin{aligned} &\text{Sludge from polymer addition} \\ &= (0.5 \text{ m}^3/\text{s})(1 \text{ mg/L})(86,400 \text{ s/d})(10^3 \text{ L/m}^3)(1 \text{ kg}/10^6 \text{ mg}) \\ &= 43 \text{ kg/d} \end{aligned}$$

4. Determine the total amount of sludge produced using Eq. 21-12:

$$\text{Total sludge} = (337 + 1512 + 43) \text{ kg/d} = 1892 \text{ kg/d}$$

5. Estimate the volume of the sludge using the mass determined in step 4 and the given sludge characteristics using Eq. 21-3. The density of water at 15°C from App. C = 999.1 kg/m<sup>3</sup>.

$$\text{Sludge volume} = \frac{1892 \text{ kg/d}}{(999.1 \text{ kg/m}^3)(0.05)(1.05)} = 36.1 \text{ m}^3/\text{d}$$

6. Estimate the volume of the sludge as a percent of the total flow:

$$\begin{aligned} &\text{Sludge volume, \% of total flow} \\ &= [(36.1 \text{ m}^3/\text{d})/(0.5 \text{ m}^3/\text{s})(86,400 \text{ s/d})] \times 100 \\ &= 0.08\% \end{aligned}$$

### **Part B Mass and Volume of PACI sludge**

7. Determine the amount of dry sludge produced from the addition of PACI using the typical value given in Table 21-4:

$$\begin{aligned} &\text{Sludge, kg/d} \\ &= (0.5 \text{ m}^3/\text{s})(30 \text{ mg/L})(0.0489)(13)(86,400 \text{ s/d}) \\ &\quad \times (10^3 \text{ L/m}^3)(1 \text{ kg}/10^6 \text{ mg}) \\ &= 824 \text{ kg/d} \end{aligned}$$

8. Determine the total amount of sludge produced using Eq. 21-12 and the data from Part A:

$$\text{Total sludge} = (824 + 1512 + 43) \text{ kg/d} = 2379 \text{ kg/d}$$

9. Estimate the volume of the sludge using the mass determined in step 3 and the given sludge characteristics using Eq. 21-3.

$$\text{Sludge volume} = \frac{2379 \text{ kg/d}}{(999.1 \text{ kg/m}^3)(0.05)(1.05)} = 45.4 \text{ m}^3/\text{d}$$

10. Estimate the volume of the sludge as a percent of the total flow:

$$\begin{aligned} \text{Sludge volume, \% of total flow} \\ &= [(45.4 \text{ m}^3/\text{d}) / (0.5 \text{ m}^3/\text{s})(86,400 \text{ s/d})] \times 100 \\ &= 0.11\% \end{aligned}$$

The physical properties of alum and iron sludges are summarized in Table 21-5. The solids concentrations and physical properties are the most important properties for sizing and design of residuals management facilities. Solids concentrations depend on the design and operation of the sedimentation basins in addition to the type of sludge and its composition.

### Physical Properties of Coagulant Sludges

**Table 21-5**

Typical physical properties and chemical constituents of alum and iron sludges from chemical precipitation

Item	Unit	Type of Sludge	
		Alum	Iron
Physical properties			
Volume	% water treated	0.05–0.15	0.06–0.15
Total solids	%	0.1–4	0.25–3.5
Dry density	kg/m <sup>3</sup>	1200–1500	1200–1800
Wet density	kg/m <sup>3</sup>	1025–1100	1050–1200
Specific resistance <sup>a</sup>	m/kg	10–50 × 10 <sup>11</sup>	40–150 × 10 <sup>11</sup>
Viscosity at 20°C	N · s/m <sup>2</sup>	2–4 × 10 <sup>-3</sup>	2–4 × 10 <sup>-3</sup>
Initial settling velocity	M/h	2.2–5.5	1–5
Chemical constituents			
BOD	mg/L	30–300	30–300
COD	mg/L	30–5000	30–5000
pH	Unitless	6–8	6–8
Solids			
Al <sub>2</sub> O <sub>3</sub> · 5.5H <sub>2</sub> O	%	15–40	
Fe	%		4–21
Silicates and inert materials	%	35–70	35–70
Organics	%	10–25	5–15

<sup>a</sup>Values of specific resistance reported in literature in units of s<sup>2</sup>/g must be multiplied by 9.81 × 10<sup>3</sup> [(s<sup>2</sup>/g)(9.81 m/s<sup>2</sup>)(10<sup>3</sup> g/kg) = m/kg] to obtain units of m/kg.

For example, alum sludge from an upflow clarifier would typically be drawn off at a concentration of 0.1 to 0.3 percent solids, compared to sludge from a horizontal-flow basin at 0.2 to 1.0 percent or more. Sludge may thicken to 4 to 6 percent solids if it is allowed to accumulate for a month or longer in a horizontal-flow sedimentation basin. Sludges that have relatively high proportions of alum or iron coagulant, as would result from treating low-turbidity water, will have lower solids concentrations than will those with relatively higher proportions of turbidity or silt. Coagulation of waters having substantial algae concentrations will also result in light, low-solids-concentration sludges. The addition of polymers generally tends to produce higher solids concentrations.

As coagulation sludges are dewatered and dried, there is a gradual transformation from a liquid to a semisolid to a solid. For the purposes of designing residuals management facilities, it is important to know when that transformation occurs as it will determine the type of equipment required to handle the sludge. As a liquid, the sludge can be pumped, piped, and transported in tank trucks, while as a semisolid or solid it must be shoveled and transported on a conveyor or in open trucks.

Unfortunately, the transition is not sharply defined and the transition point is not the same for all sludges. Coagulation sludges that have high proportions of gelatinous aluminum or iron hydroxides will act as liquids at higher solids concentrations than will those that contain more clay and sediments. These sludges are also thixotropic; that is, on standing they will seem to solidify, but when disturbed with a sudden jolt will revert to a liquid state. The minimum concentration at which sludge can be considered a solid is about 16 percent solids.

### **Chemical Properties of Coagulant Sludges**

The chemical characteristics of coagulant sludges are directly related to the chemical content of the raw water and the coagulant chemicals. Typical data on the chemical characteristics of coagulant sludges are given in Table 21-5.

## **21-4 Lime Precipitation Sludges**

---

Lime sludges are produced from the precipitation of calcium carbonate and magnesium hydroxide in the lime–soda softening process. Lime sludges may be essentially pure chemical sludges or they may include suspended materials from the raw water if turbidity removal is combined with softening. Similar sludges are produced in the magnesium carbonate softening process.

### **Estimating Quantities of Lime Sludges**

Typical quantities of lime sludge produced from water softening are reported in Table 21-2. For design purposes, the amount of sludge anticipated at a plant can be estimated based on the chemical treatment

and raw-water quality. The sludge is essentially composed of precipitated calcium carbonate and magnesium hydroxide, any turbidity or suspended solids that are removed during softening, and any insoluble impurities present in the treatment chemicals, such as lime grit. The suspended contribution can be estimated from turbidity data, as discussed above for coagulation sludges.

The amounts of precipitated calcium carbonate and magnesium hydroxide can be estimated directly from the anticipated calcium and magnesium removals. The pertinent precipitation reactions for lime softening are given in Chap. 20. Based on the reactions given in Chap. 20, the total lime sludge can be estimated with the following expression (Kawamura, 2000):

$$M = [(2.0 \text{ Ca}^{2+} + 2.58 \text{ Mg}^{2+}) + \text{TSS} + X](10^{-3} \text{ kg/g}) \quad (21-17)$$

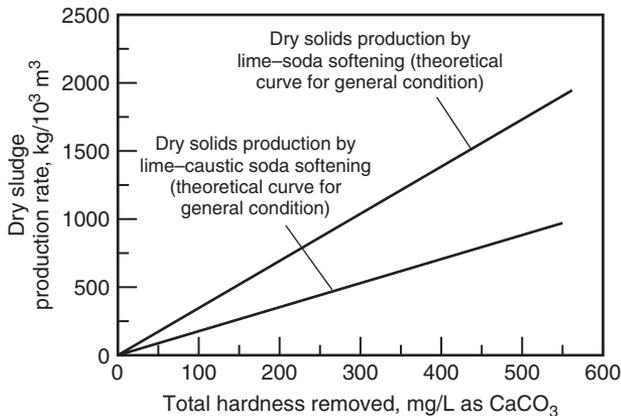

where

- $M$  = total sludge produced,  $\text{kg}/\text{m}^3$
- $\text{Ca}^{2+}$  = calcium removed,  $\text{g}/\text{m}^3$  as  $\text{CaCO}_3$
- $\text{Mg}^{2+}$  = magnesium removed,  $\text{g}/\text{m}^3$  as  $\text{CaCO}_3$
- TSS = total suspended solids,  $\text{g}/\text{m}^3$
- $X$  = other coagulant aids added to enhance precipitation,  $\text{g}/\text{m}^3$

Thus, the removal of 1.0 mg of calcium (expressed as  $\text{CaCO}_3$ ) results in 2.0 mg of  $\text{CaCO}_3$  in the sludge. Similarly, removal of 1.0 mg of magnesium (expressed as  $\text{CaCO}_3$ ) results in 2.58 mg of sludge [ $\text{CaCO}_3 + \text{Mg}(\text{OH})_2$ ]. A graphical means of estimating sludge production on the total hardness removed is given on Fig 21-6.

The physical properties of lime sludges, as reported in Table 21-6, are the most important factors in sizing treatment facilities. In larger plants, it is sometimes economical to recover lime from the sludge, in which case the chemical content of the sludge also becomes important. Solids

### Physical Properties of Lime Sludges

**Figure 21-6**  
Dry sludge production rate versus total hardness removed.

**Table 21-6**

Typical physical properties and chemical constituents of lime-softening sludge

Item	Unit	Range of Values
Physical properties		
Volume	% water treated	0.3–6
Total solids	%	2–15
Dry density	kg/m <sup>3</sup>	1100
Wet density	kg/m <sup>3</sup>	1920
Specific resistance	m/kg	12 × 10 <sup>10</sup>
Viscosity	N · s/m <sup>2</sup>	5–7 × 10 <sup>-3</sup>
Initial settling velocity	m/h	0.4–3.6
Chemical constituents		
BOD	mg/L	0–low
COD	mg/L	0–low
pH	Unitless	10.5–11.5
Total dissolved solids	%	2–15
Solids		
CaCO <sub>3</sub>	%	85–94
Mg(OH) <sub>2</sub>	%	0.5–8
Silicates and inert materials	%	2–6
Organics	%	5–8

concentrations are dependent on the treatment process and on the proportions of the various chemical precipitates in the sludge. Sludges high in CaCO<sub>3</sub> typically have higher solids concentrations than sludges with more Mg(OH)<sub>2</sub> because CaCO<sub>3</sub> is a fine-grained, dense precipitate while Mg(OH)<sub>2</sub> is a more gelatinous material. The typical treatment process utilizing either upflow or horizontal-flow sedimentation basins following chemical addition and reaction produces fine-grained precipitates similar in nature to mud or silt deposits.

### Chemical Properties of Lime Sludges

Lime sludges typically have a high pH (10.5 to 11.5) and are white, unless colored by turbidity, iron, or manganese. Generally, lime sludges are odorless, with little or no organic matter. Because of the high pH, lime sludges do not contain significant numbers of viable microorganisms. Typical chemical characteristics are summarized in Table 21-6. The specific chemical content of sludge from any given plant can be determined from the raw-water quality and the quantity of chemicals used.

## 21-5 Diatomaceous Earth Sludges

Sludges are produced during backwash of diatomaceous earth filters. Generally, the diatomaceous earth (DE) filter process is operated until the filter

cake contains about two parts of DE for each part of impurities removed from the water. As a result, the sludge characteristics are predominantly those of the DE. The volume of waste washwater will vary from 2 to 5 percent of the plant flow. The corresponding solids concentration will typically vary from 6000 to 8000 mg/L, comprised primarily of DE. The total dry sludge is equivalent to the DE added in the process plus the suspended materials removed in the filter. The dry density of DE is about 160 kg/m<sup>3</sup>.

## 21-6 Granular and Membrane Filter Waste Washwater

---

Waste washwater from the cleaning of granular or membrane filters is the most common type of liquid waste produced at water treatment plants.

It is difficult to estimate the quantity of waste washwater because it will depend on the raw-water quality, the degree and effectiveness of the treatment processes preceding the filtration step, the duration of the filter run, and the duration and type of backwash cycle employed. Based on the operating experience from a variety of water treatment plants, the quantity of waste washwater for both granular and membrane filters will typically comprise from 2 to 5 percent of the total amount of water processed. Some designers use 5 percent as a design value for the quantity of waste washwater. The volume of washwater to be handled depends on the frequency and duration of the backwash cycle. Because the backwash cycle from membrane filters is shorter and more frequent than that from granular filters, the volume of water to be handled from each backwash will be smaller.

Estimates of filter waste washwater quantities and frequencies may be obtained from pilot studies and filter design criteria. Pilot studies can be used to obtain critical information on backwashing rates and frequencies, which may be scaled up to address backwash duration at full scale. Using the information from pilot plant studies, the frequency, volume, and flow rate of waste washwater may be estimated.

Filter design criteria that are relevant to determining waste washwater frequency in granular filters are the unit filter run volume (UFRV) and the unit backwash volume (UBWV). These concepts are introduced in Chap. 11 and are used to determine the effective filtration rate ( $v_{\text{EFF}}$ ) and the recovery or production efficiency ( $\text{Rec} = v_{\text{EFF}}/v$ ) for a filter. The design criterion for production efficiency is typically 95 percent or greater. Typically, waste washwater quantities are 8 m<sup>3</sup>/m<sup>2</sup> (200 gal/ft<sup>2</sup>). To achieve a filter production efficiency of 95 percent, the UFRV would have to be at least 200 m<sup>3</sup>/m<sup>2</sup> (5000 gal/ft<sup>2</sup>) a run. At a filtration rate of 12.2 m/h (5 gpm/ft<sup>2</sup>), a filter run would have to last at least 1000 min between backwash cycles.

### Estimating Quantities of Filter Waste Washwater

The calculation for recovery in membrane filters is the same as for granular filters, but the terminology is different. Recovery ( $r$ ) is the ratio of net-to-gross water production over a filter run, which is the volume of water fed to the membrane over a filter run ( $V_F$ ) less the volume of water used during a backwash ( $V_{BW}$ ) quantity divided by  $V_F$ . Recovery in membrane filtration is typically 95 to 98 percent, which is comparable to granular filters.

Another liquid waste stream from granular filters occurs when a filter is initially brought online after backwashing and the initial filter effluent is wasted, called *filter to waste*. During this initial period of operation, the filter is clean and does not have the same ability to remove particles as it does when fully ripened. The initial flow from a clean filter is typically diverted from the filter effluent to reduce the chance of undesirable constituents passing through the filter outlet and on through the process train. Filter-to-waste flow typically occurs for 15 min to 1 h after a filter is backwashed, but the specific time a filter operates in a filter-to-waste mode is based on the filter effluent quality.

The filter-to-waste flow may be captured and recycled through the treatment plant headworks or, in some cases, directly upstream of the filters. Filter-to-waste water quality is different than both filter waste washwater and supernatant from dewatering processes so it may need to be separated from these other waste streams.

### **Physicochemical Properties of Waste Washwater**

The physicochemical properties of waste washwater are reported in Table 21-7. As reported in Table 21-7, the average total suspended solids concentration is typically on the order 100 to 1000 mg/L. Thus, the physical properties of waste washwater are similar to those for water. Because of the low concentration of solids and their settlability, waste washwater has historically been (1) returned directly to the headworks of the treatment plant when comprising less than 10 percent of the plant flow; (2) discharged to a flow equalization basin and then returned to the headworks of the treatment plant; (3) discharged to waste washwater recovery ponds, basins, or lagoons where it is allowed to settle for 24 h or more before being decanted and returned to the headworks of the treatment plant; or (4) discharged to surface waters with the appropriate National Pollutant Discharge Elimination System (NPDES) permit in place. The current trend for handling waste washwater is to have a separate treatment facility, especially in larger plants, because of concern over the presence and recycling of microorganisms, potential increases in the concentration of disinfection by-products, as well as other concerns such as taste and odor.

**Table 21-7**

Typical physical properties and chemical constituents of granular filter and membrane filter waste washwater

Item	Unit	Range of Values	
		Granular Filter	Microfiltration
Physical properties			
Volume	% water treated	1–5	2–8
Total solids	mg/L	100–1000	100–1000
Specific gravity	Unitless	1.00–1.025	1.00–1.025
Specific resistance	m/kg	$11–120 \times 10^{10}$	$11–120 \times 10^{10}$
Viscosity at 20°C	N · s/m <sup>2</sup>	$1–1.2 \times 10^{-3}$	$1–1.2 \times 10^{-3}$
Initial settling velocity	m/h	0.06–0.15	0.06–0.15
Chemical constituents			
BOD	mg/L	2–10	2–10
COD	mg/L	20–200	20–200
pH	Unitless	7.2–7.8	7.2–7.8

Organics	%	15–22	15–22

## 21-7 Reverse Osmosis Concentrate

Increasingly, greater use is being made of membrane processes for the treatment of water. As noted in Chap. 17, nanofiltration and reverse osmosis membranes are used for the removal of dissolved constituents from water. Nanofiltration is typically used for water softening, whereas reverse osmosis is used most commonly for demineralization of brackish water and seawater. In general, these processes produce wastes that are high in dissolved solids but low in suspended solids.

Typical quantities of concentrate produced in reverse osmosis were shown in Table 21-2. The quantity of concentrate produced depends on the operating characteristics of the membrane and the water and solute mass transfer coefficients.

The solvent (i.e., water) recovery rate  $r$  is defined as (Eq. 17-12, reprinted here)

$$r = \frac{Q_P}{Q_F} \quad (21-18)$$

**Estimating  
Quantities of  
Membrane  
Concentrate**

where  $Q_P$  = permeate stream flow,  $\text{m}^3/\text{s}$   
 $Q_F$  = feed stream flow,  $\text{m}^3/\text{s}$

The rate of rejection  $\text{Re}_j$ , which is used to describe the removal of the solute from the permeate, is calculated as (Eq. 17-1, reprinted here)

$$\text{Re}_j = \frac{C_F - C_P}{C_F} = \left(1 - \frac{C_P}{C_F}\right) \quad (21-19)$$

where  $C_F$  = concentration of solute in feed,  $\text{g}/\text{m}^3$   
 $C_P$  = concentration of solute in permeate,  $\text{g}/\text{m}^3$

To determine the quantity and concentration of the concentrate, equations for recovery and rejection are combined with mass balances for water and solute (Eqs. 17-13 and 17-14, reprinted here):

$$Q_F = Q_P + Q_C \quad (21-20)$$

$$Q_F C_F = Q_P C_P + Q_C C_C \quad (21-21)$$

where  $Q_C$  = concentrate stream flow,  $\text{m}^3/\text{s}$   
 $C_C$  = concentration in concentrate,  $\text{g}/\text{m}^3$

Combining Eqs. 21-20 and 21-18 results in the following expression for the concentrate stream flow rate:

$$Q_C = \frac{Q_P(1 - r)}{r} \quad (21-22)$$

The application of the above equations is illustrated in Example 21-3.

### Example 21-3 Estimating quantity and quality of waste stream from a reverse osmosis facility

Estimate the quantity and quality of the waste stream and the total quantity of water that must be processed from a reverse osmosis facility that is to produce  $4600 \text{ m}^3/\text{d}$  of demineralized water. Assume that the recovery and rejection rates are 86 and 92 percent, respectively, and that the concentration of total dissolved solids in the feed stream is  $2200 \text{ mg}/\text{L}$ .

#### Solution

1. Determine the flow rate of the concentrated waste stream and the total amount of water that must be processed.

- a. Determine the concentrate stream flow rate using Eq. 21-22:

$$Q_C = \frac{Q_P(1-r)}{r}$$

$$= \frac{(4600 \text{ m}^3/\text{d})(1-0.86)}{0.86} = 748.8 \text{ m}^3/\text{d}$$

- b. Determine the total amount of water that must be processed to produce 4600 m<sup>3</sup>/d of permeate. Using Eq. 21-20, the required amount of water is given as

$$Q_F = Q_P + Q_C = (4600 + 748.8) \text{ m}^3/\text{d} = 5348.8 \text{ m}^3/\text{d}$$

2. Determine the concentration of the permeate stream. The permeate concentration is obtained by writing Eq. 21-19 as follows:

$$C_P = C_F(1 - Rej) = (2200 \text{ mg/L})(1 - 0.92) = 176 \text{ mg/L}$$

3. Determine the concentration of the concentrated waste stream using Eq. 21-21:

$$C_C = \frac{Q_F C_F - Q_P C_P}{Q_C}$$

$$= \frac{(5348.8 \text{ m}^3/\text{d})(2200 \text{ mg/L}) - (4600 \text{ m}^3/\text{d})(176 \text{ mg/L})}{748.8 \text{ m}^3/\text{d}}$$

$$= 14,634 \text{ mg/L}$$

Concentrate may be clear or colored, with the specific gravity being dependent on the salt concentration but typically in the range of 1.02 to 1.035. Any residual suspended material present in the water to be treated would also be included in the waste concentrate. The detailed chemical content of a waste concentrate can be determined from a mass balance on the process and, as discussed above, depends on the quality of the water to be treated, the water and solute mass transfer coefficients (specific for the membrane), and the detailed design and operation of the system.

### Physicochemical Properties of Membrane Concentrate

## 21-8 Ion Exchange Brine

Ion exchange brines resulting from the softening of water are considered in this section. Specific quantities and characteristics of the brine from a particular softening plant will depend on the resin selected, the raw-water characteristics, and the operation of the regeneration process.

**Table 21-8**Typical chemical properties of ion exchange brine from softening<sup>a</sup>

Item	Unit	Range of Values
BOD	mg/L	30–300
COD	mg/L	30–5000
pH	Unitless	6–8
Total dissolved solids	mg/L	15,000–30,000
Solids		
Ca <sup>2+</sup>	mg/L	3000–6000
Mg <sup>2+</sup>	mg/L	1000–2000
Na <sup>+</sup>	mg/L	2000–5000
Cl <sup>-</sup>	mg/L	9000–22,000
SO <sub>4</sub> <sup>2-</sup>	%	5–15

<sup>a</sup>The volume of brine as a function of the water treated will vary from 1.5 to 10%.

### Estimating Quantities of Ion Exchange Brine

Typical quantities of brine produced in ion exchange were given previously in Table 21-2 and will vary from 1.5 to 10 percent of the plant flow. Quantities of brine required for regeneration are determined during design of an ion exchange facility, as discussed in Chap. 16. The brine to be disposed of is equal in volume to that used for regeneration, but instead of being entirely composed of water and regeneration salts, it will be a mixture of the excess sodium required to drive the regeneration process and the ions removed by the ion exchange process. In addition, there will be rinse water used to flush the brine out of the resin between the regeneration cycle and operation, and there may be waste washwater from an initial backwash cycle to remove any suspended materials collected by the bed. Depending on the design of the facilities, the various waste streams may be separated or combined. Ideally, the brine and the freshwater streams are segregated, as are less contaminated portions of the regenerant brine, so as to allow some brine recovery.

### Chemical Properties of Ion Exchange Brine

The chemical properties of typical ion exchange brines are summarized in Table 21-8. Physically, these waste brines are clear, with the specific gravity being dependent on the salt concentration but typically in the range of 1.02 to 1.035. If waste washwater is included, any suspended material present in the raw water would also be included in the waste. The detailed chemical content of a waste brine can be determined from a mass balance on the process and, as discussed above, depends on the raw-water quality and the detailed design and operation of the system.

## 21-9 Solid Sorbent Brines and Washwater

Brines and other liquid wastes resulting from the regeneration of sorption media are reviewed briefly in this section. At the present time a variety of

**Table 21-9**

Common solid sorbents used for the removal of specific constituents in water

Sorbent	Application
Activated carbon, granular (GAC)	Control of toxic organic compounds; barrier to occasional spikes of toxic organics in surface waters; control of taste and odor compounds; control of disinfection by-product precursors or DOC
Activated carbon, powdered (PAC)	Used primarily in the treatment of taste and odor compounds and the treatment of low concentrations of pesticides and other organic micropollutants
Ion exchange resins, mixed bed resins	Specific inorganic and organic constituents, organic compounds
Activated alumina (AA)	Used for the removal of fluoride, arsenic (see also Table 4-7)
Granular ferric oxide (GFO), granular ferric hydroxide (GFH)	Used for the removal of arsenic (III and V), phosphate, and metals such as chromium, selenium, antimony, and copper
Fibroid chemisorbents, various	Used for the removal of radionuclides, heavy metal ions, and organic contaminants from drinking water

sorption processes are used for the removal of specific constituents. The most common solid sorbents are listed in Table 21-9. The use of granular and powdered activated carbon is discussed in Chap. 15. Ion exchange is considered in Chap. 16. The other two commonly used sorbents are activated alumina (AA) for fluoride and arsenic removal and granular ferric hydroxide (GFH) for the removal of phosphorus and arsenic.

Use of fibroid chemisorbents is not common in the water industry. With the exception of ion exchange resins, discussed previously in Sec. 21-8, these sorbents are typically not regenerated but used in a single-pass mode until the adsorptive capacity has been reached and then disposed of. Once-through use is advantageous because there is no need for onsite storage regeneration chemicals and solid waste disposal issues are minimized. Where these sorbents are regenerated, the specific quantities and characteristics of the brine and wash waters will depend on the sorbent, the raw water characteristics, and the specific regeneration process selected. The management of brines is considered in Sec. 21-13; the disposal of solid sorbents is considered in Sec. 21-16.

The focus of the following discussion is on the use of AA and GFH solid sorbents. Typical quantities of brines and washwater will vary with each sorbent and the specific chemicals used in the regeneration process. For example, where AA is used for fluoride removal, three methods have been used for regeneration including (1) NaOH/H<sub>2</sub>SO<sub>4</sub>, (2) Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>, and H<sub>2</sub>SO<sub>4</sub>. If the NaOH/H<sub>2</sub>SO<sub>4</sub> method is used, the four-step process described in Table 21-10 is used.

**Estimating  
Quantities of  
Brines and  
Washwater from  
Sorption  
Processes**

**Table 21-10**Regeneration sequence for activated alumina using NaOH/H<sub>2</sub>SO<sub>4</sub>

Step	Description	Waste	Approximate volume, mL/100 g Al <sub>2</sub> O <sub>3</sub>
1	Backwash with raw water <sup>a</sup>	Washwater	<sup>a</sup>
2	Regeneration with 1% NaOH	Spent regenerant containing removed constituents	1000–1200
3	Rinse with raw water	Washwater	700–800
4	Neutralization with 0.05% H <sub>2</sub> SO <sub>4</sub>	Spent acid solution	1000–1200

<sup>a</sup>Backwash operation takes about 10 min to expand bed and remove accumulated solids before regeneration.

Source: Adapted from Tramfloc, Inc., Tempe, Arizona.

The quantities of brine and washwater must be determined by laboratory and pilot plant testing because of the variability of local operating conditions. Typically, the amount of backwash water will be about 2 to 4 percent of the total throughput, depending on the solids accumulation. When used for fluoride removal, on a once-through basis, a dilute aluminum sulfate solution [Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> · 18H<sub>2</sub>O] is used to contact the AA as a pretreatment step to enhance performance. This pretreatment step is not needed when the AA is regenerated as described above. In a similar manner, GFH can be regenerated using either NaOH or H<sub>2</sub>O<sub>2</sub>.

Depending on the operating conditions, NaOH concentrations between 0.1 to 1 M are required for regeneration following a backwash cycle to clean the bed. Minimum regenerant volumes are on the order of 4 to 6 bed volumes. The backwash rate is in the range from 20 to 30 m/h. Operationally, the GFH sorbent bed is backwashed every 2–6 weeks to remove accumulated solids and to prevent compaction of the filter bed.

### Chemical Properties of Brines and Washwater from Sorption Processes

The chemical properties of typical waste washwater and spent regenerant brines will depend on the specific chemicals used for regeneration. For the AA example given above, the regeneration process results in waste washwater, spent caustic brine solution containing a high concentration of the removed constituents, and a spent acid solution. Similarly, the brine resulting from the GFH regeneration is caustic with a high concentration of phosphorus. As discussed in the section on ion exchange brine, the detailed chemical content of brine solutions is estimated based on a mass balance on the process and will depend on the raw-water quality and the detailed design and operation of the system. Physically, the waste brines are clear, with the specific gravity typically in the range of 1.01 to 1.035. The management of these brines is considered in Sec. 21-13.

## 21-10 Management of Residual Liquid Streams

---

In addition to sludges, a number of residual liquid streams result from the treatment of water. As identified in Table 21-1, the principal liquid waste streams, excluding membrane concentrates and ion exchange brines, are filter waste washwater and filter-to-waste water for water treatment plants with granular filters and filter waste washwater for water treatment plants that use membrane filtration. Other waste streams are comprised of recycle flows from sludge-processing operations, including centrate, filtrate, pressate, supernatant flow, and leachate. The combined volume of these waste streams may approach 4 to 5 percent of the total water treated, depending on the processes employed. In the past, these streams were returned to the headworks, discharged to nearby water bodies, land applied, or discharged to wastewater collection systems. Because of new regulations, many of these past practices are no longer acceptable. As a result, the management of these liquid waste streams is a major issue in the design and operation of most water treatment plants.

As noted in the introduction to this chapter, the concerns with recycle flows are related to the constituents contained in them. The principal constituents of concern are listed in Sec. 21-1 and the options for dealing with these constituents are considered below.

Flow equalization is used to reduce the impact of the intermittent high-volume flows from backwashing operations (see Fig. 21-1b). By returning the waste washwater at a more constant rate, the impact on treatment process performance is minimized.

When the equalization basin also functions as a settling basin, the impact of the return flow is further mitigated (see Fig. 21-7). When the suspended material in the raw water has been effectively coagulated and flocculated prior to filtration, the solids in the waste washwater generally settle rapidly. To achieve a supernatant turbidity of about 5 NTU with this type of waste washwater, the equalization basin should provide a minimum detention time of 1 to 2 h. Coagulants and coagulant aids such as alum and cationic polymer may be added to improve the settling characteristics of the solids in the waste washwater.

Because of concern over the constituents in the return flows, separate treatment facilities are now used at some water treatment plants to process recycle flows. Treatment options include

- Flow equalization without or with chemical addition
- Lagoons without or with chemical addition
- Batch sedimentation without or with chemical addition

### Concerns with Recycle Waste Streams

### Flow Equalization Lagoons or Basins

### Treatment of Recycle Waste Streams

**Figure 21-7**

Typical waste washwater basins used for flow equalization and as settling basins.

- High-rate sedimentation without or with chemical addition and preflocculation
- Dissolved air flotation
- Granular filtration
- Membrane filtration
- Disinfection
- UV oxidation.

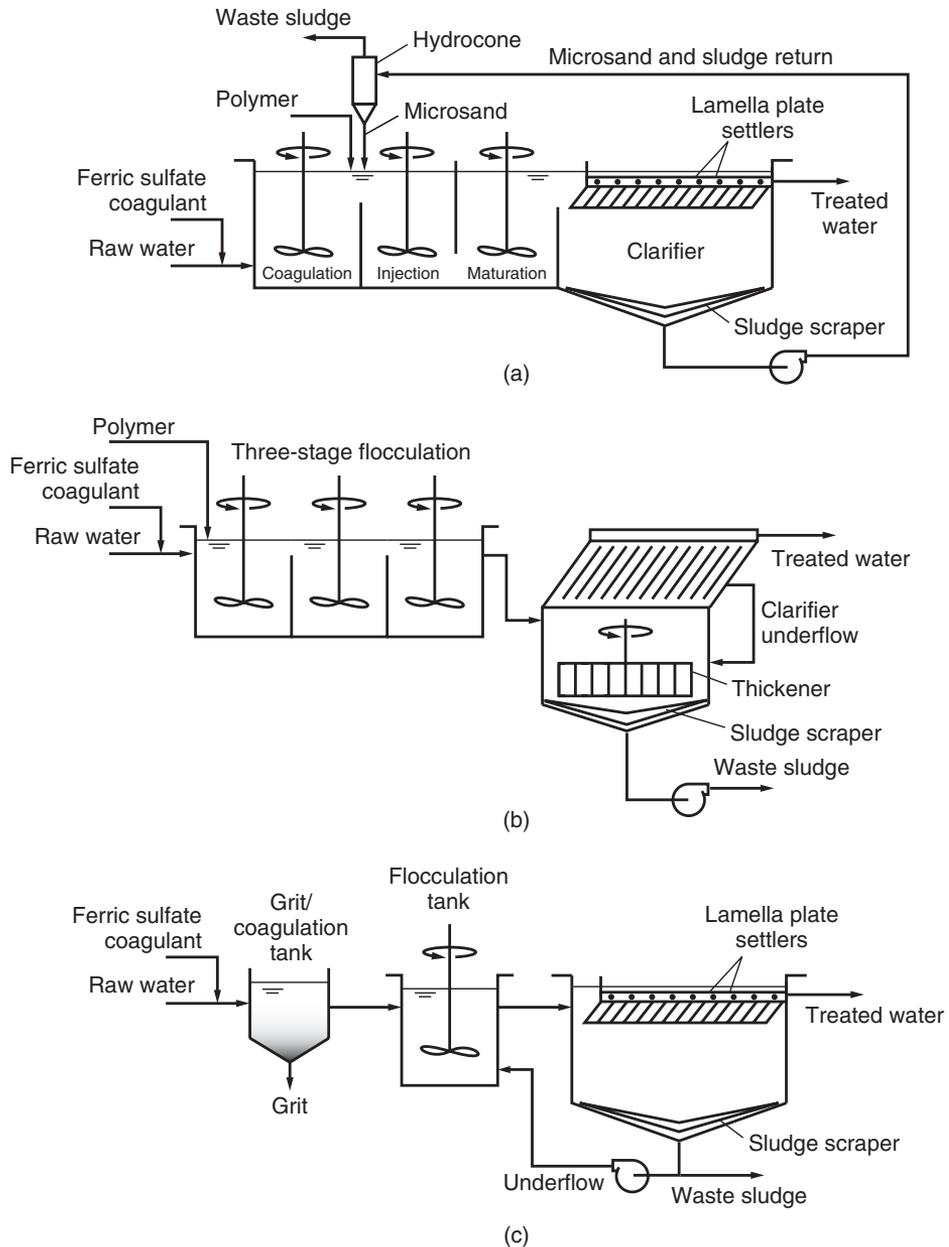

Because of the larger area required for waste washwater storage basins, the use of high-rate sedimentation (see Fig. 21-8) has become common in larger water treatment plants. The sludge resulting from the high-rate sedimentation process as well as from the treatment options identified above is typically combined with other plant sludges for further treatment. Some innovative applications of treatment processes for filter waste washwater are reviewed and discussed in Cornwell et al. (2010).

### **Disposal of Liquid Streams**

In some cases, residual liquid waste streams have been discharged to surface waters and/or to wastewater collection systems. The ability to use either of these options is site specific.

#### **DISPOSAL TO SURFACE WATERS**

Surface water discharges are regulated under the Clean Water Act through the National Pollutant Discharge Elimination System (NPDES). These laws consider water treatment and supply to be an industry, and, therefore, consider water treatment residuals, such as concentrate, an industrial waste. The NPDES permits can specify a variety of water quality requirements,

**Figure 21-8**

High-rate clarification processes: (a) ballasted flocculation, (b) lamella plate clarification and (c) dense sludge. (Adapted from Tchobanoglous et al., 2003.)

depending on classification of the receiving water body (e.g., potable water source, trout stream). State and local governments may impose additional restrictions on surface water discharges.

#### **DISCHARGE TO WASTEWATER COLLECTION SYSTEM**

The same laws that govern surface water discharge apply to wastewater collection system disposal. Pretreatment of the residual prior to discharge to the wastewater plant may be required because of state regulations or conditions imposed by the wastewater plant. In general, local pretreatment guidelines will cover the discharge from a water treatment plant to the wastewater collection system.

The capacity of the collection system or the wastewater treatment plant and the types of processes and operations at the wastewater facility may limit the amounts and type of liquids and/or solids that may be added to the wastewater system. The viability of sewer discharge is affected by the chemical characteristics of the residual stream, particularly with respect to whether high TDS, low dissolved oxygen, or high metals content may be toxic to the biological process at the wastewater plant.

Direct discharge to a wastewater collection system has a low capital cost and may also have a low operation and maintenance cost depending on monitoring requirements and sewer use fees. An advantage of this method is simpler permitting requirements. Discharge to a collection system is the easiest disposal method if a local wastewater treatment plant is willing to accept the waste, an issue that is often facilitated when a municipality operates both the water and wastewater systems.

A condition of discharge may be continuous monitoring of the organic strength and solids content of the residual flow. An attempt should be made to assess the impact of the residuals on the wastewater treatment facility prior to the selection of this alternative. It is possible that disposal of alum sludge may enhance phosphate removal at the wastewater treatment plant if any of the alum activity remains. Residual coagulant activity may also enhance primary sedimentation.

## **21-11 Management of Membrane Concentrates and Cleaning Solutions**

---

Concentrate is produced when nanofiltration (NF) and reverse osmosis (RO) membranes are utilized in the treatment process. As noted previously, these processes produce a concentrate that is high in TDS but low in suspended solids. Concerns that must be addressed in the management of membrane concentrates include (1) the volume of concentrate (typically 15 to 50 percent) and (2) environmental classification and regulations, as discussed in Chap. 17. The management of cleaning solutions is also an important consideration. The management of membrane concentrates and cleaning solutions is considered in the following discussion. Ion exchange

brines are considered in the following section. Additional details on the management of membrane concentrates may be found in Fox et al. (2009) and Mackey and Seacord (2008).

Because of the interest in the application of RO, a variety of methods have been developed to treat the concentrate streams to both recover water and reduce the quantity of waste that must be processed further (see also Chap. 17). Some of the proven treatment processes for RO concentrate are summarized in Table 21-11. Of the methods listed in Table 21-11 precipitation, as discussed in Chap. 12, is used most commonly.

### Concentrate Treatment Methods

Because the volume of the concentrate stream from membrane processes that must be disposed of is larger than the waste stream from virtually all other water treatment processes, a number of alternative processes have been developed to further thicken (concentrate) the concentrate. Included among the thickening methods that have been developed are (1) membrane concentration, (2) evaporation/distillation, (3) crystallization, (4) solar evaporation, and (5) crystallization.

### Methods of Thickening Concentrates

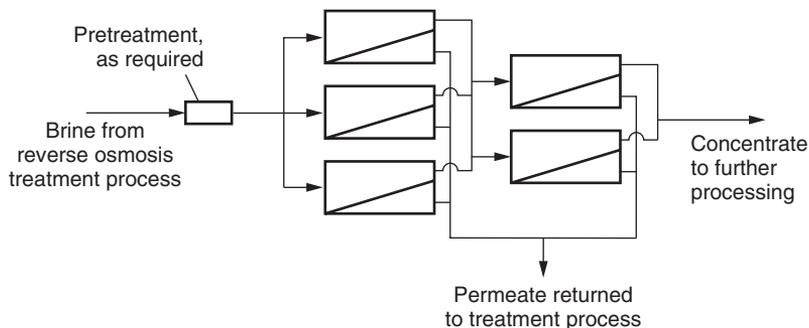

#### MEMBRANE CONCENTRATION

Two- and three-stage RO membrane concentration steps (see Fig. 21-9) have been used to increase the concentration of the brine to TDS values greater

**Table 21-11**

Treatment methods for RO concentrate

Treatment method	Description
Chemical precipitation	Precipitation to remove sparingly soluble salts and hardness. Precipitation has been used as a pretreatment step for conventional RO treatment to reduce scaling and for the pretreatment of brine before RO concentration to improve recovery. Reducing scaling is more critical in RO concentration operations because of enhanced scaling potential at high brine concentrations.
Electrodialysis reversal (EDR)	Use of a semipermeable ion exchange, ion selective, or electrodialysis membranes to separate the positively and negatively charged ions. Typically used as a pretreatment process.
High-efficiency reverse osmosis (HERO)	Involves specific pretreatment steps with RO to improve the recovery. Ions that cause scaling are removed and the pH is raised above 10 to limit the precipitation of silica on the membranes.
Natural treatment systems	Rely on naturally occurring physical, chemical, and biological processes to treat and assimilate the constituents in the brine. Free surface flow, subsurface flow, combined free and subsurface flow, and natural wetlands have been used and/or studied.

**Figure 21-9**  
Two-stage reverse osmosis process.

than 35,000 mg/L. The concentrated brine can then be processed further by crystallization and solar evaporation. Details concerning membrane concentrate may be found in Chap. 17.

#### EVAPORATION/DISTILLATION

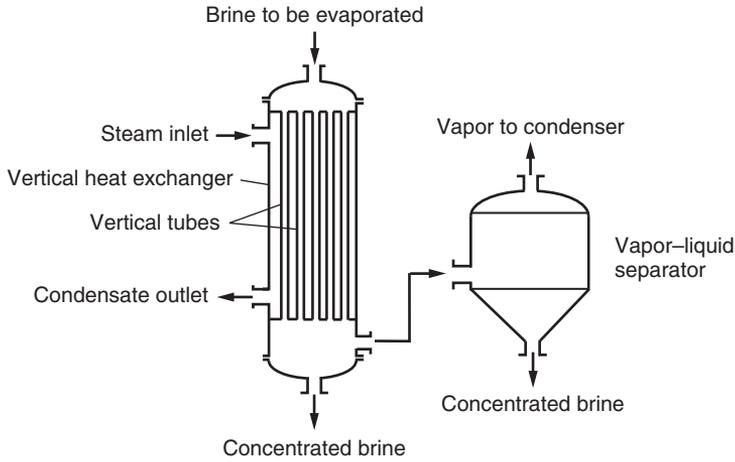

Residual concentrates and ion exchange brines (discussed in the following section) can be concentrated further by evaporation/distillation. Evaporation/distillation technologies that potentially could be used to concentrate residual brines include (1) boiling with submerged tube heating surface, (2) boiling with long-tube vertical evaporator, (3) flash evaporation, (4) forced circulation with vapor compression, (5) solar evaporation, (6) rotating-surface evaporation, (7) wiped-surface evaporation, (8) vapor reheating process, (9) direct heat transfer using an immiscible liquid, and (10) condensing-vapor heat transfer by vapor other than steam. Of these types of evaporation/distillation processes, multistage flash evaporation, multiple-effect evaporation, and vapor compression distillation appear most feasible for the processing of residual concentrates. A vertical-tube falling-film evaporator is illustrated on Fig. 21-10.

#### SOLAR EVAPORATION

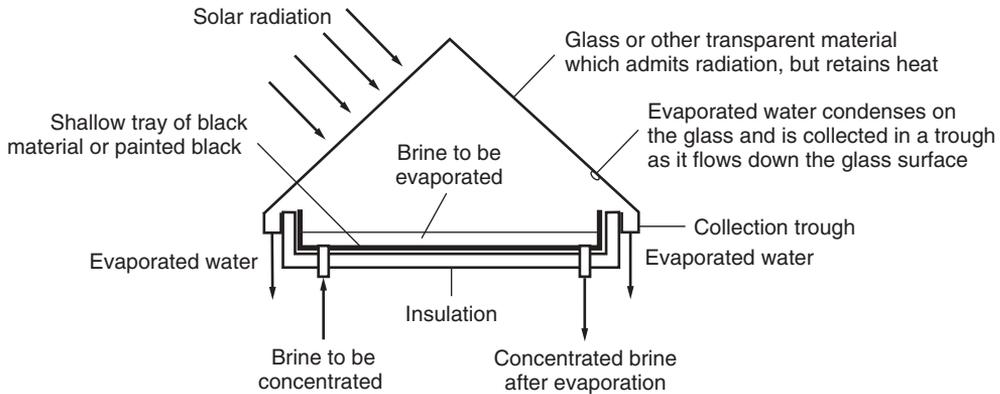

Where climatic conditions are favorable, the use of evaporation ponds may be feasible. Important factors that affect the performance of evaporation ponds include relative humidity, wind velocity, barometric pressure, water temperature, and the salt content of the brine. In some locations, glass-covered solar ponds similar to those used for desalination in many of the dry Mediterranean countries are used to further concentrate brines by evaporation (see Fig. 21-11).

#### CRYSTALLIZATION

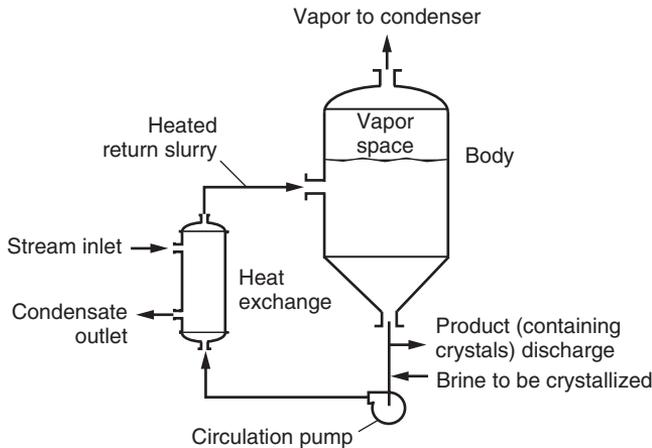

The crystallization process involves the conversion of thickened concentrate and brine into crystals that can be dewatered with a centrifuge or belt press. A typical brine crystallizer is illustrated on Fig. 21-12. The disposal of brine crystals is by landfilling.

**Figure 21-10**  
Schematic diagram of vertical-tube falling-film evaporator that can be used as a brine concentrator. Brine to be concentrated flows downward in a thin film along the inner walls of the vertical tubes and is partially evaporated. The evaporated vapor and concentrated brine flow into a vapor-liquid separator where the vapor is separated from the concentrated brine.

**Figure 21-11**  
Schematic of solar brine evaporator. Solar radiation absorbed on dark tray heats the brine to be evaporated.

**Figure 21-12**  
Schematic of forced circulation brine crystallizer. The heated return slurry causes the liquid in the body to boil. As the liquid boils and vapor is released, the concentration of the constituents in the liquid increases until supersaturation occurs and crystals form.

**Ultimate Disposal  
Methods for  
Membrane  
Concentrates**

Conventional methods used for the disposal of membrane concentrates include (1) disposal to surface waters, (2) discharge to wastewater collection systems, and (3) deep-well injection. Each of these methods is considered below.

**DISPOSAL TO SURFACE WATERS**

Despite complex regulatory requirements discussed previously in connection with the management of liquid waste streams, surface water discharge is often the most cost-effective disposal option for RO plants, especially for those plants located in coastal areas, where brackish or saline receiving waters are a viable discharge option. More than half of the plants in the United States now use this method of disposal. The advantage of a surface water disposal system is the relatively low capital and operation and maintenance costs. Disadvantages include the uncertainty of continued allowance of this practice in the future and the potential for creating a water pollution problem. Under the NPDES, extensive monitoring of the concentrate and the discharge water body is required.

*Water quality issues*

Surface water discharge is dependent on the quality of the concentrate. Nominally, the waste stream is comprised of inorganic solutes from the source water that have been concentrated. The degree of concentration is typically expressed as a concentration factor, which is estimated using a (worst-case) assumption of 100 percent rejection. With this approximation, the concentration factor (CF) is simply

$$CF = \frac{1}{1 - r} \quad (21-23)$$

where  $r$  = recovery rate expressed as a fraction

For instance, a low-pressure RO treating a brackish water (feed water TDS = 5000 mg/L) at a recovery of 85 percent produces a concentrate TDS of 33,300 mg/L, roughly the salinity of ocean water.

Thus, a coastal plant drawing water from a brackish aquifer and discharging concentrate to the ocean would appear to have little environmental impact. In addition to TDS, however, it is important to consider the toxicity of individual heavy metals, whose concentration is increased by the same factor. Additionally, many concentrate streams are anaerobic, which can be toxic to fish in the receiving water without sufficient dilution. Toxicity can initially be assessed by comparing predicted heavy-metal concentrations to regulated limits, but bioassays are often required before permits are issued. In many cases, economic considerations favor discharge to a brackish river or bay near the plant over an ocean outfall. However, the difference in salinity between the concentrate and the receiving water is more important in these locations.

*Design considerations*

Considerations for the design of a surface water disposal system include quality of the concentrate, pumping requirements, flow equalization, and outfall location and design. Outfall location is also an extremely important concern. The outfall should be located such that it discharges to a point of maximum dispersion. Similarly, the outfall should be designed to disperse the concentrate across the well-mixed zone of the water body. The location and design of the outfall significantly impact the pumping requirements. Consideration should be given to equalizing the residual flow to minimize pump and motor sizing and limit discharge of large residual slugs to the receiving water.

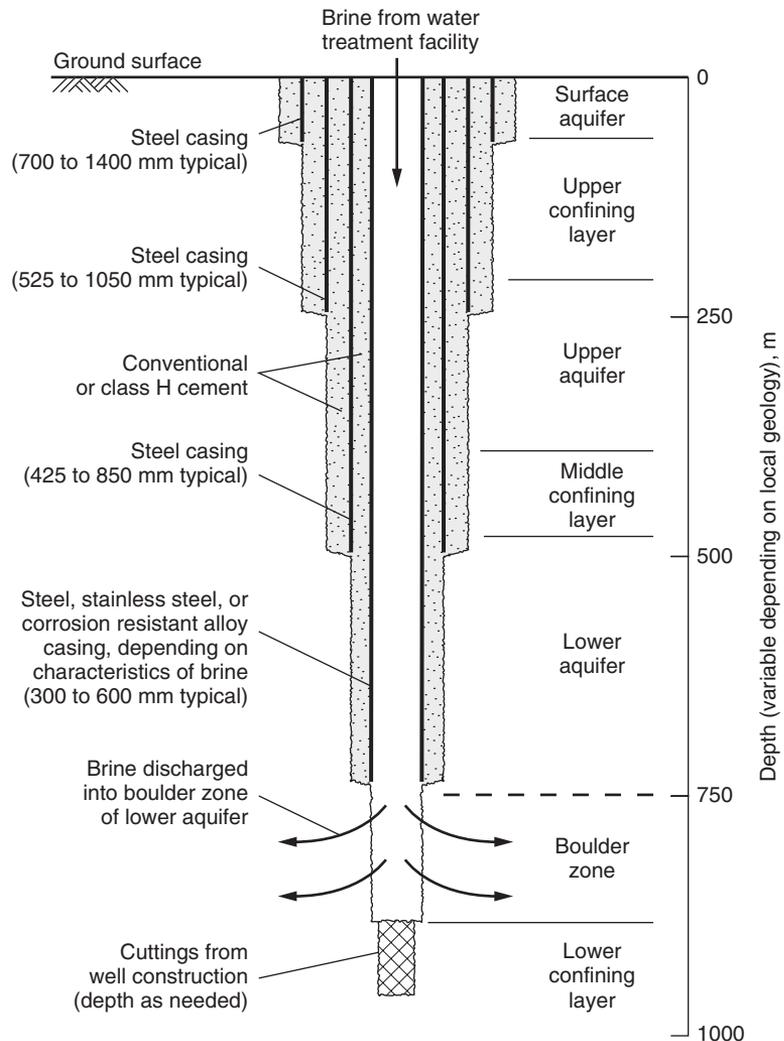

**DISCHARGE TO WASTEWATER COLLECTION SYSTEM**

As with the disposal of liquid streams, local pretreatment guidelines will cover the discharge of membrane concentrates to the wastewater collection system. In the case of RO plant residuals, which are primarily concentrated inorganic solutes, the biological process provides little treatment for the concentrate stream. In some situations it may be advantageous to discharge the concentrate to the wastewater plant effluent rather than the influent. Blending concentrate with wastewater effluent avoids toxicity issues in the wastewater process while still using the effluent to dilute the concentrate prior to discharge to a surface water. Dilution before discharge is a legitimate treatment strategy for a waste consisting primarily of concentrated inorganic solutes from a natural source water.

Design of a wastewater disposal system must provide for controlled discharges to eliminate the possibility of large slugs of residuals upsetting the wastewater treatment facility. Discharge should be coordinated with the wastewater treatment plant operators so that they may optimize the performance of their process units.

**DEEP-WELL INJECTION OF MEMBRANE CONCENTRATE**

Discharge of clear membrane concentrate and ion exchange brine by means of deep-well injection into a brackish or saline aquifer is regulated by federal and local environmental regulations and is dependent on the geology and groundwater hydrology of the area. Deep-well injection involves pumping the concentrate or brine stream into an injection well, typically thousands of meters deep. A typical injection well is shown on Fig. 21-13. The injection zone is typically a brackish or saline aquifer with no potential for use as a potable water supply, which is overlain by thick layers of impermeable rock that prevent contamination of shallower freshwater aquifers. Deep-well injection is used by about 10 percent of RO plants, although its use is becoming more common, particularly in Florida. Preference for deep-well disposal in Florida has arisen because of the existence of a reliable injection zone and public and regulatory resistance to surface water discharge.

**Figure 21-13**  
Schematic of typical well used to inject brine into subsurface aquifers.

Well construction is governed by regulations for deep-well injection of industrial wastes. Wells are constructed of three to four casings, with the space between each casing filled with cement grout. Each casing typically ends at a different depth. Depending on the local groundwater hydrology, there may be a significant potential for groundwater contamination and multiple casings are designed to prevent any leakage from one aquifer to the next (Cornwell and Roth, 2011). Deep-well injection systems tend to be fairly expensive due to well-drilling cost and maintenance costs. The high pressure at the bottom of the injection well and the saline solution tend to enhance the corrosion potential of the well screen and casing. Selection

of materials resistant to corrosion under those conditions may prolong the operating life of an injection facility.

Although the concentrate is by far the most voluminous waste stream, RO plants must also dispose of spent cleaning solutions. Frequently, the cleaning solutions are acidic or basic solutions with added detergents or surfactants. In many cases, the cleaning solution volume is so small compared to the concentrate stream that the cleaning solution is diluted into and disposed with the concentrate. In some cases, treatment of the cleaning solution may be required prior to disposal, but treatment may consist only of pH neutralization. Detergents and surfactants should be selected with disposal issues in mind.

### **Managemet of Cleaning Solutions**

## 21-12 Management of Ion Exchange Brines

---

The principal source of ion exchange brines is from the softening of hard waters. The characteristics of ion exchange brines were considered previously in Sec. 21-8. In general, large ion exchange water-softening plants have been located on or near coastal areas so that the resulting brines can be discharged to the ocean.

The management of brines will often involve some form of thickening before disposal. The thickening methods discussed previously in Sec. 21-11 in connection with management of membrane concentrates are also used for brines.

### **Processing of Brines**

The principal methods used for the disposal of brines involves discharge to brackish or saline receiving waters, deep-well injection, and in the case of small facilities to wastewater collection systems. The same considerations discussed previously in Sec. 21-11 for the ultimate disposal of membrane concentrate also apply to ion exchange brines.

### **Ultimate Disposal of Brines**

## 21-13 Management of Brines and Washwater from Sorption Processes

---

Because most solid sorbents are used on a single-pass (once-through) mode, the waste volumes are relatively small. Further, because the spent regenerant brine solutions contain contaminants of concern (e.g., arsenic, fluoride, etc.), ocean discharge and deep-well injection are not viable options for disposal as was the case with the ion exchange brines discussed in the previous section. The principal methods used to process wastes from the regeneration of AA and GFH are reported in Table 21-12. As reported

**Table 21-12**

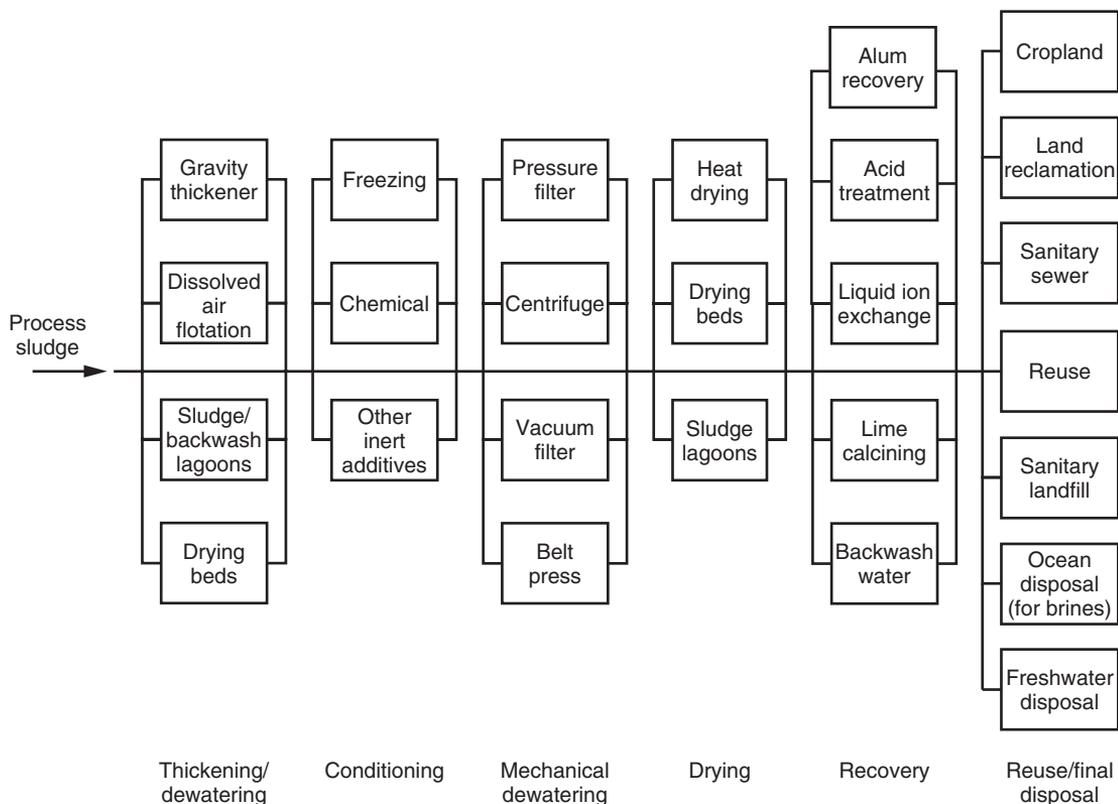

Management of sorbents used in water treatment or the removal of specific constituents

Sorbent	Source of Waste	Disposal Method
Activated alumina (AA)	Backwash water	Where allowed, the backwash water can be discharged to wastewater collection system, if not it must be processed with the regenerant and neutralization solutions.
	Spent regenerant	In arid regions, the spent regenerant is concentrated in evaporation ponds and ultimately disposed of to a hazardous waste processing facility, otherwise it must be disposed of to a hazardous waste facility.
	Washwater	Where allowed, the washwater can be discharged to a wastewater collection system, if the residual constituent concentration is low. If not, it must be processed with the regenerant and neutralization solutions.
	Spent acid	In arid regions, the spent acid brine solution is concentrated in evaporation ponds and ultimately disposed of to a hazardous waste processing facility; otherwise it must be disposed of to a hazardous waste facility.
	Pretreatment	Because of the relatively small volume the dilute alum sulfate pretreatment solution is discharged to the wastewater collection system.
Granular ferric hydroxide (GFH)	Backwash water to clean and restore bed porosity	Where allowed, the backwash water can be discharged to wastewater collection system. If not, it must be processed with the regenerant solution, if used.
	Spent regenerant	In arid regions, the spent regenerant solution is concentrated in evaporation ponds and ultimately disposed of to a hazardous waste processing facility; otherwise it must be disposed of to a hazardous waste facility.

in Table 21-12 there are basically two methods for the management of these waste solutions: (1) discharge to a wastewater collection system and (2) evaporation (in arid locations) and ultimate transfer to a hazardous processing facility.

## 21-14 Management of Residual Sludges

Based on an understanding of the characteristics of the residuals, development of a complete residuals process treatment train requires an understanding of the technologies that are available for processing the residuals. The major unit operations and processes that are employed for the management of residuals will be reviewed in this section. A generalized

**Figure 21-14**  
Unit operations and processes for management of water treatment plant sludges.

process diagram showing the various unit processes that may be used in residuals management and the sequence in which they may be assembled to form complete treatment systems are shown on Fig. 21-14. Some of the processes shown on Fig. 21-14 are omitted in the following discussion because either they are seldom used or insufficient data are available on their application.

A complete residuals management system is made up of one unit process from one or more of the process steps shown (e.g., thickening/dewatering, conditioning) and must include one of the unit processes from the final reuse and/or disposal step. Some typical residuals management processes are as follows:

- ❑ For alum sludge, gravity thickening, chemical conditioning, centrifugation, and final disposal to sanitary or monofill landfill
- ❑ For alum sludge, sludge lagoons, decant recovery and recycle, and final disposal to a sanitary or monofill landfill or wastewater collection system

- ❑ For lime sludge, gravity thickening, filter press dewatering, heat drying, lime calcining, and reuse
- ❑ For lime sludge, sludge lagoons, drying beds, cropland application, or monofill landfill
- ❑ For membrane concentrate, final disposal directly to brackish surface water, the ocean, deep-well injection, or wastewater collection system
- ❑ For ion exchange brines, membrane concentration, thermal brine concentration, and evaporation ponds

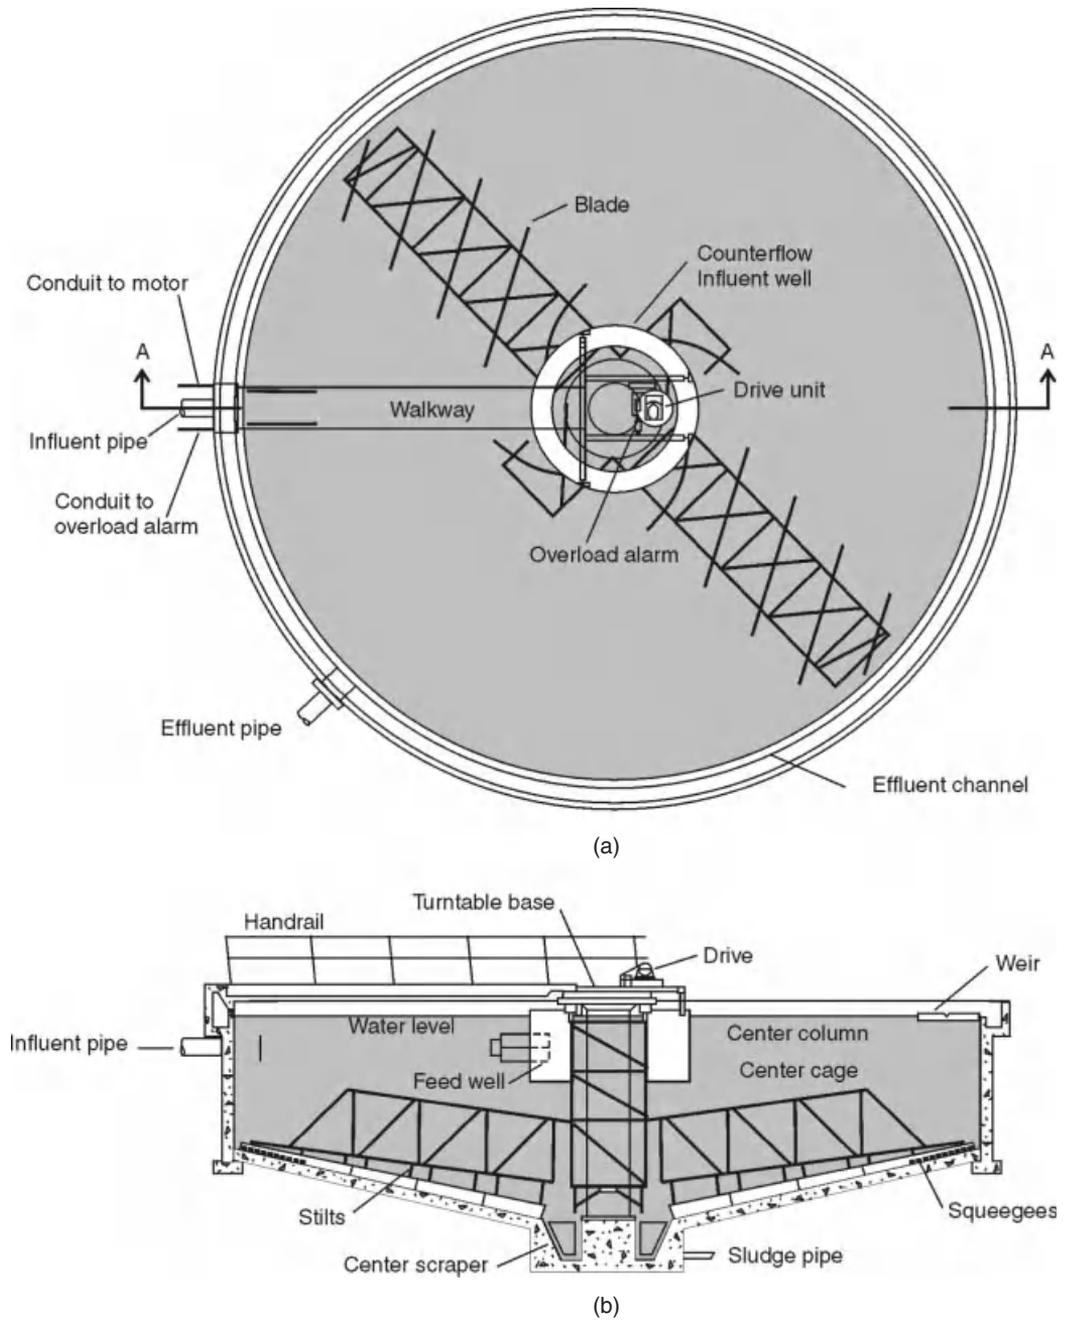

Unit operations that have proven to be the most successful and to have significant capabilities for dewatering sludges from water treatment plants are drying beds, vacuum filtration, pressure filter press, belt filter press, centrifugation, alum and lime recovery, and pellet flocculation. The above technologies are considered in the following discussion.

### **Thickening/ Dewatering**

Thickening to increase the solids content of sludge involves the removal of excess water by decanting and the concentration of the solids by settling. The decanted water is usually recovered unless the water contains objectionable tastes or odors or large numbers of algae or other microorganisms while the solids are processed further or disposed of. Gravity thickening is used most commonly as the first step in the residuals management process. The most common methods of gravity thickening for sludges are lagoon settling with a decantation operation and conventional gravity thickening in specifically designed reactors. For coagulation or softening sludges, the primary process involved is compaction thickening of the sludge, while for filter waste washwater the processes of settling and hindered settling are most important.

#### **MECHANICAL GRAVITY THICKENING**

Gravity thickening is typically accomplished in a circular tank designed and operated similarly to a solids-contact clarifier or sedimentation tank (see Fig. 21-15). Sludge is introduced into the tank and allowed to settle and compact. Gentle agitation of the sludge prior to settling creates channels in the sludge matrix for water to escape and promote densification of the solids. The thickened sludge is collected and withdrawn at the bottom of the tank. A properly designed and operated gravity thickening system can produce softening sludges in excess of the 2 to 6 percent associated with alum sludge, depending upon the calcium carbonate and magnesium hydroxide content in the sludge. Lime sludges that are predominantly calcium carbonate can be thickened to 30 percent solids and higher. Typical performance and design data on gravity thickening are presented in Table 21-13.

**Figure 21-15**

Typical mechanical gravity thickener for water treatment plant sludges: (a) plan view and (b) section through thickener.

**Table 21-13**

Typical performance and design data for gravity mechanical thickening of coagulant and lime sludges

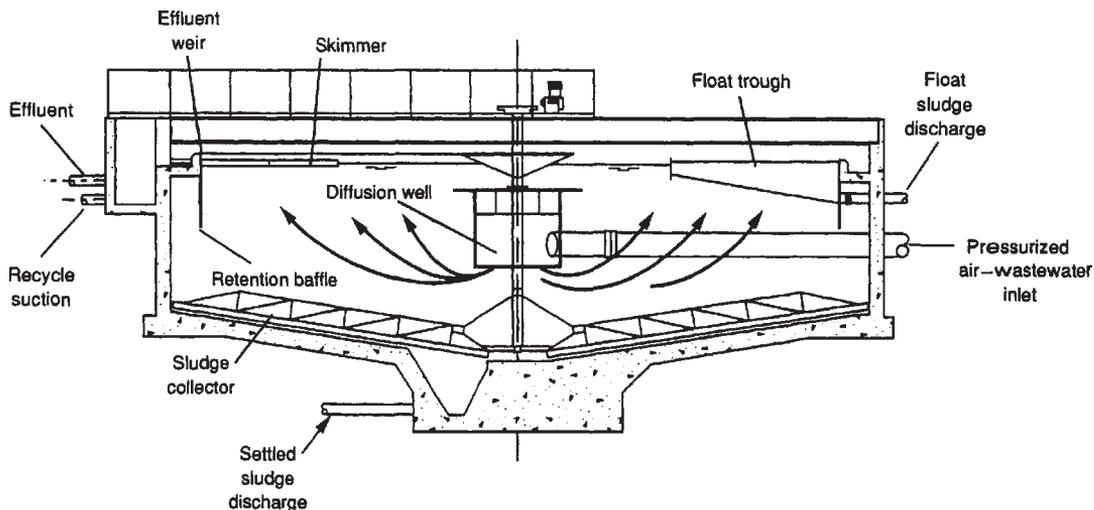

Parameter	Unit	Type of Sludge	
		Coagulant	Lime Softening
Feed solids	%	0.2–1	1–4
Thickened solids	%	2–3	>5
Solids recovery	%	80–90	80–90
Solids loading	kg/m <sup>2</sup> · d lb/ft <sup>2</sup> · d	20–80 4–16	100–200 20–40

#### FLOTATION THICKENING

Dissolved air flotation (DAF) thickening (see Fig. 21-16) involving both sedimentation and flotation has been used successfully for dewatering. Typical performance and design data on flotation thickening are presented in Table 21-14. In general, DAF thickening has been most successful with hydroxide sludges. The use of DAF for the treatment of return flows is also considered in Chap. 10.

#### SLUDGE LAGOONS

A nonmechanical means of handling water treatment plant sludges consists of dewatering in sludge lagoons or drying beds. If land is readily available and inexpensive, the use of sludge lagoons is a cost-effective means of

**Figure 21-16**

Section through typical flotation thickener for water treatment plant sludges (see also Fig. 10-22, Chap. 10).

**Table 21-14**

Typical performance and design data for dissolved air flotation thickening for coagulant and lime-softening sludges

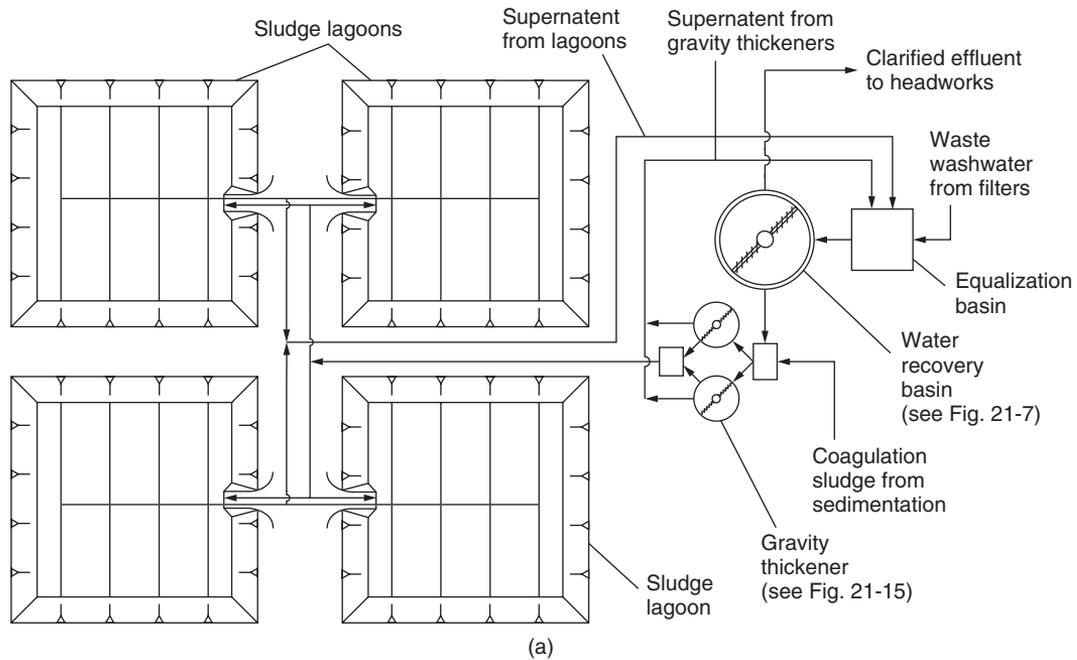

Parameter	Unit	Type of Sludge	
		Coagulant	Lime Softening
Feed solids	%	0.5–1	0.5–1
Thickened solids	%	3–5	3–5
Solids recovery	%	80–90	80–90
Solids loading	kg/m <sup>2</sup> · d	48–120	48–120
	lb/ft <sup>2</sup> · d	10–24	10–24
Volumetric loading	m <sup>3</sup> /m <sup>2</sup> · d	110–150	110–150
	gal/ft <sup>2</sup> · d	2800–3600	2800–3600

storing and thickening residuals. Lagoons are commonly lined earthen basins equipped with inlet control devices and overflow structures (see Fig. 21-17). Wastes with settleable solids are discharged into the lagoons from which the solids are separated by gravity sedimentation. Sludge lagoons can be classified by their mode of operation: permanent lagoons and dewatering lagoons. Permanent lagoons act as a final disposal site for settled water solids, whereas dewatering lagoons are cleaned periodically. Lime sludges have been dewatered to 50 percent solids concentration by the sludge lagoon handling method.

Lime-softening sludges dewater more readily than alum sludges. In addition, most softening plant sludges will air dry well in lagoons; therefore, it is important to design the lagoon so that the sludge does not remain submerged after initial filling, as lime sludge does not compact well when under water. Typically, sludge lagoons for lime wastes should be such that they can be filled and allowed to dry before being refilled. Typical values to which lime sludges can be dewatered (in percent solids concentration) vary from 30 to more than 50 percent. It should be noted that the final solids concentrations obtained by the various dewatering methods will vary depending on the type of sludge and sludge conditioning employed.

A common approach used at many water treatment plants in the United States is to use lagoons not only as thickeners (with continuous decanting) but also as drying beds after a predetermined filling period. Three months of filling and an average drying cycle of 3 months are the most common design parameters used. The required lagoon area can be determined using a sludge loading rate of 40 and 80 kg dry solids/m<sup>2</sup> of lagoon area (8.2 to 16.4 lb/ft<sup>2</sup>) for wet and dry regions, respectively.

For example, based on a loading rate of 80 kg/m<sup>2</sup>, the effective area of lagoons required to handle alum sludge from the 0.5-m<sup>3</sup>/s (11.4-mgd) water treatment plant of Example 21-2, Part A, can be approximated as follows. Assuming a total of four lagoons and an average of 100 days filling

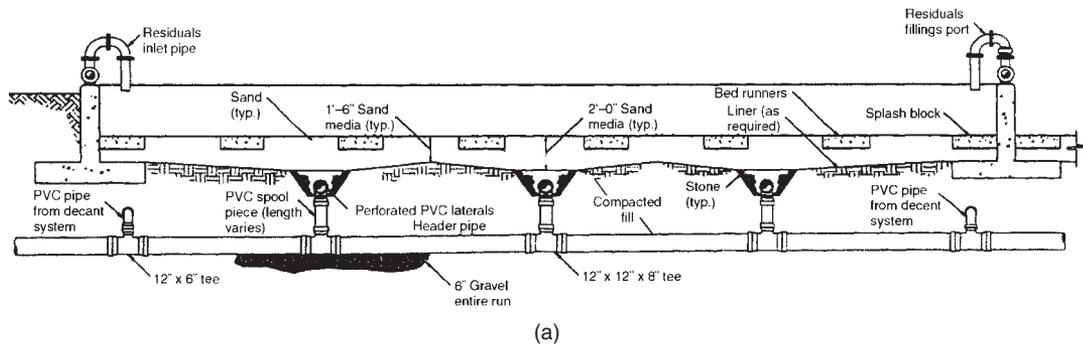

**Figure 21-17**

Typical sludge storage lagoons: (a) schematic (adapted from Qasim et al., 2000) and (b) view of large sludge lagoon.

cycle (detention) per lagoon in a dry region, an effective lagoon area for each lagoon is given as

$$\text{Effective lagoon area} = \frac{(1892 \text{ kg/d})(100 \text{ d})}{80 \text{ kg/m}^2} = 2365 \text{ m}^2 = 0.24 \text{ ha}$$

The actual area required for a lagoon would be at least 1.5 times the area computed because of the additional area required for berms and access roads.

**Figure 21-18**

Typical sludge-drying beds for water treatment plant sludges: (a) section through sludge-drying bed and (b) view of sand-drying beds.

#### GRAVITY DEWATERING ON DRYING BEDS

Gravity dewatering involves placement of the sludge to be dewatered on a sand (see Fig. 21-18) or wedge wire filter surface and the subsequent drainage of water from the sludge through the filter material. The process will produce a relatively dry, solid sludge for further treatment or disposal. Gravity dewatering may be combined with other drying and dewatering operations to produce a sludge of any desired dryness. Gravity dewatering is applicable to dewatering of sludge discharged directly from sedimentation basins or following thickening.

#### *Bed area*

The size of the drying bed required is usually the factor that determines the feasibility of gravity dewatering at a given site. If land is readily available, gravity dewatering is the method of choice; otherwise a more sophisticated mechanical system will be required. Multiple drying beds must be sized to

allow spreading of a relatively thin layer of sludge 0.15 to 0.3 m (6 to 12 in.) and sufficient time between spreading cycles to permit drainage, drying, and removal of the sludge. At least three and preferably four or more beds should be provided to allow discharge of sludge to one bed while the other beds are draining, drying, and being cleaned.

#### *Underdrains and decanters*

An underdrain system or decanter system must be provided to remove water from the sludge if the drying beds are constructed in wet regions. Underdrains are used to collect the water drained from the sludge and decanters are used to collect the water off the top of the sludge. Underdrains are not required in most dry regions, but decanters are helpful in any type of climate. The underflow or decanted water can then be either recycled to the plant inlet, if the quality is good, or discharged. Underdrains typically consist of gravel and perforated clay or PVC (polyvinyl chloride) pipes.

#### *Cycle time, weather, and conditioning*

As indicated above when discussing bed area, cycle time includes time for filling the bed, sludge draining and drying, and cleaning the bed. The major portion of the cycle time is the drainage and drying time. Ideally, the time required for draining and drying should be determined by bench or pilot testing, with due consideration given to variations in climate and sludge characteristics. In the absence of actual testing, the engineer must estimate the extent to which the sludge will drain. The use of polymers to condition alum sludge can reduce draining time but will probably not substantially increase the drained solids concentration.

After draining is completed, further dewatering occurs by evaporation. The time required to reach the desired dryness can be calculated from evaporation/precipitation data. Once the sludge is drained, rainfall will drain through or be decanted from the surface of the bed, rather than rewetting the sludge. For conservative design the net evaporation rate (evaporation minus precipitation) should be used as a reference for sizing drying beds.

## **Conditioning**

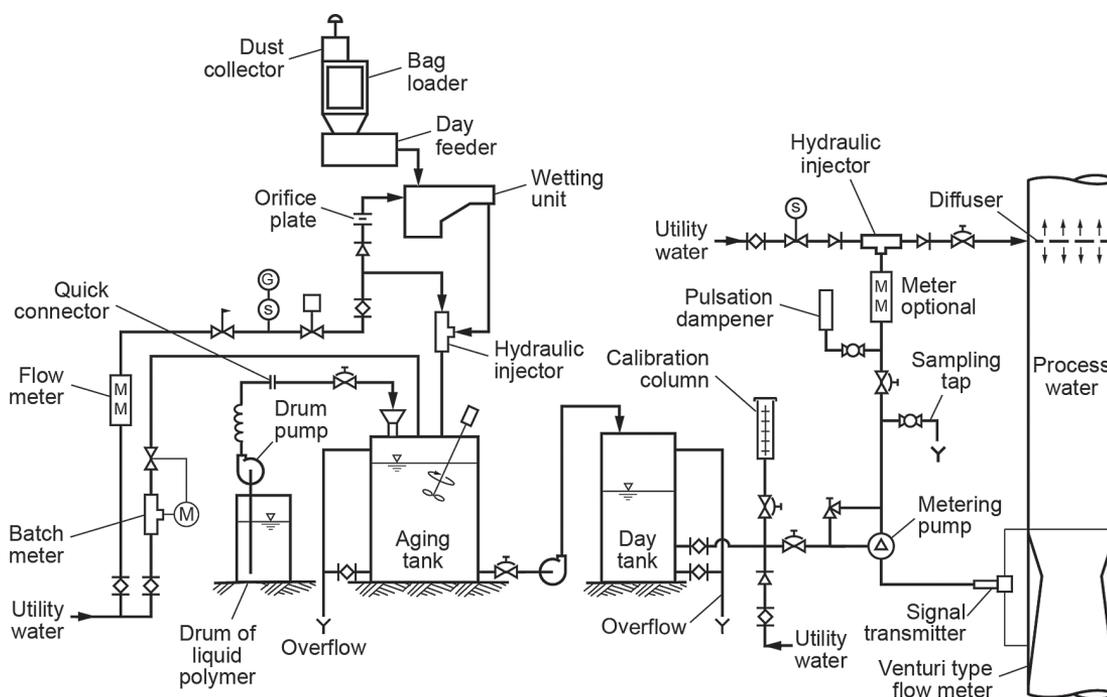

As in thickening, successful dewatering often depends on proper conditioning of the sludge in advance. The objectives of conditioning are to improve the physical properties of the sludge so that water will be released easily from the sludge, improve the structural properties of the sludge to allow free draining of the released water, improve the solids recovery of the process (i.e., to reduce the fraction of solids lost in the removed water), and minimize dewatering process cycle times.

### **CHEMICAL ADDITION**

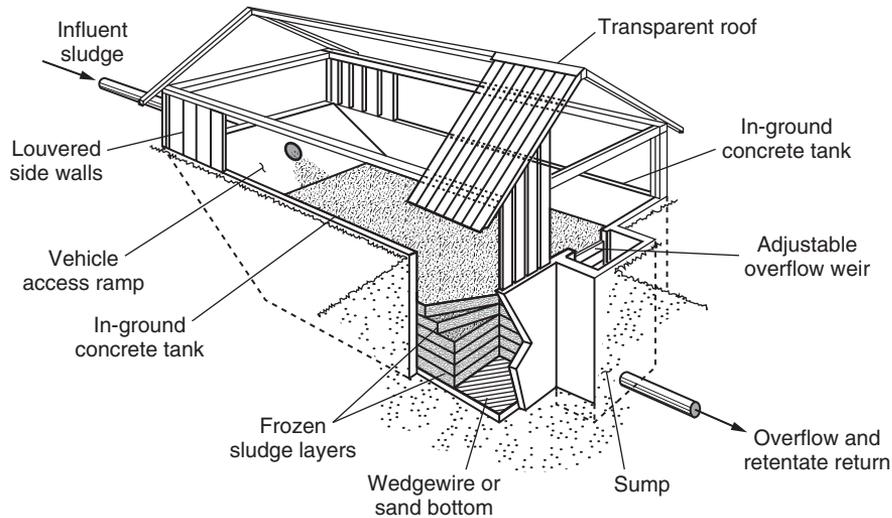

Polymers are the most commonly used conditioners for dewatering water treatment sludges. Based on full-scale operating experience, it has been

found that most types of polymers will improve the dewatering characteristics of sludges. The selection of a polymer for a given application should be based on bench tests or, preferably, pilot- or full-scale tests, as described in Chap. 9. Also, in general, higher molecular weight polymers are more effective, except that the viscosity of very high molecular weight polymers may cause handling problems.

Successful use of polymers is dependent on good dispersion of the polymer into the sludge to be conditioned. A typical blending device for polymers is shown on Fig. 21-19. As with any chemical addition, provision must be made for good initial mixing. Sizing of polymer feeding equipment should be based on bench-scale determination of dosage requirements. If that is not practical (such as in the design of a new plant), facilities can be sized based on estimated sludge solids concentrations and quantities. Polymer doses required are typically in the range of  $10 \times 10^{-4}$  to  $100 \times 10^{-4}$  kg polymer/kg sludge solids for metal hydroxide sludges.

**Figure 21-19**  
Blending diagram for organic polymers used to condition sludge. (Adapted From Kawamura, 2000.)

**Figure 21-20**  
Typical installation for conditioning of sludge by freezing.

### **FREEZING**

Freezing is very effective for metal hydroxide sludges such as alum and iron sludges (see Fig. 21-20). The effect is to destroy completely the gelatinous structure, leaving the sludge (after thawing) in the form of a fairly coarse granular material such as sand or coffee grounds. The process is irreversible. Unfortunately, the mechanical efficiencies of equipment for freezing and thawing sludge are low, so this process is usually applied only where natural freezing will occur in a lagoon. The lagoon must have sufficient capacity to allow the sludge to sit over the winter. With natural freezing of alum sludge, a 2 percent solids sludge can be converted to a 20 percent solids granular slurry that will readily drain to over 30 percent solids and can be easily handled. Additional details on the design of freeze–thaw sludge dewatering beds may be found in Martel (1989).

### **HEAT TREATMENT**

Although heat treatment has been investigated as a sludge-conditioning process, results are not as dramatic as with freezing. Heat treatment of storage is not being employed on a full scale. With rising energy costs, heat treatment is not an attractive alternative for sludge conditioning.

### **ADDITION OF INERT MATERIALS**

Another conditioning step often applied in pressure filtration of alum sludges is the addition of lime or inert granular materials such as fly ash or diatomaceous earth. Relatively high proportions of these materials are required.

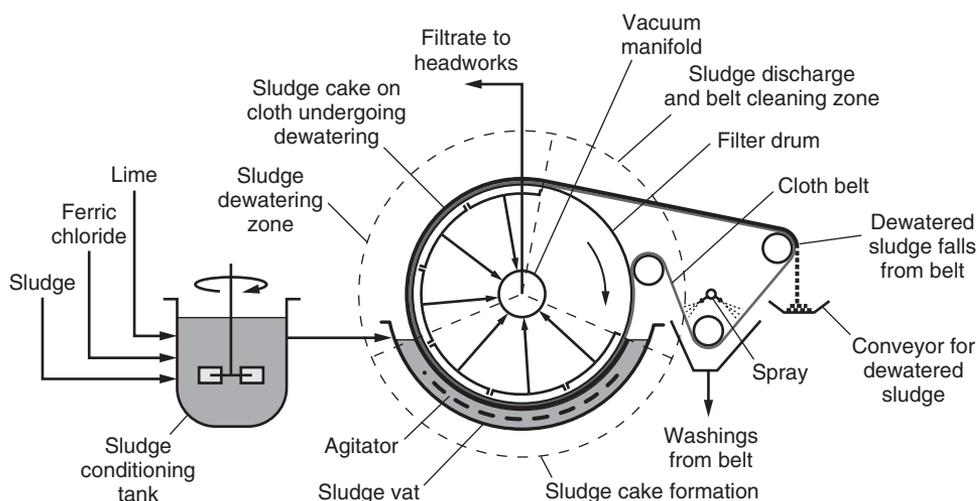

## Mechanical Dewatering

Dewatering includes all those processes intended to remove free water from sludges beyond that which can be removed by decanting from a thickener. The objective is to reduce the sludge volume and produce a sludge that can be easily handled for further processing. As the use of open storage lagoons and drying beds becomes less feasible for dewatering, some form of mechanical dewatering is now used at most large treatment plants. The principal types of mechanical dewatering devices now used are (1) vacuum filtration, (2) plate and frame filter presses, (3) belt filter presses, and (4) centrifuges.

### VACUUM FILTRATION

The type of vacuum filter employed almost exclusively is the rotary drum vacuum filter. There are two basic types of rotary drum filters: (1) traveling media and (2) precoat media filters. The precoat filter is used mainly for dewatering coagulated sludges such as alum sludge (see Fig. 21-21). For alum and ferric hydroxide sludges, successful operation of vacuum filters requires the use of polymer or lime as sludge-conditioning chemicals. Lime sludges, however, generally do not require conditioning prior to vacuum filtration.

The variables to be considered in designing a vacuum filter system are the size and type of filter, the cake discharge mechanism, the filter media, vacuum level, cycle time, and sludge conditioning. For a specific sludge, filter leaf tests are used to help determine the appropriate conditioner and dose, filter media, and cycle time. Typical performance and design data for sludge dewatering with vacuum filtration are reported in Table 21-15.

**Figure 21-21**  
Schematic diagram of typical vacuum filtration installation.

	in. Hg	5–20

#### PLATE AND FRAME FILTER PRESSES

Filter press dewatering is achieved by forcing the water from the sludge under high pressure. Although the filter press produces high solids concentration and low chemical consumption, its disadvantages include high labor costs and limitations on filter cloth life. A filter press consists of a number of plates or trays supported in a common frame (see Fig. 21-22). During sludge dewatering, these frames are pressed together either electromechanically or hydraulically between a fixed and moving end. A filter cloth is mounted on the face of each plate. Sludge is pumped into the press until the cavities or chambers between the trays are completely filled. Pressure is then applied, forcing the liquid through the filter cloth and plate outlet. The plates are then separated and the sludge removed.

Conditioning of the sludge prior to filtration is required and the degree of conditioning dictates the performance. In general, a filter cake of about 30 to 40 percent solids concentration is expected after pressure filtration with lime and polymers as sludge-conditioning chemicals. Lime sludges have been reported to readily dewater to above 50 percent solids without sludge conditioning. The filtrate may contain less than 10 mg/L of suspended solids if the sludge is conditioned properly. Both capital and operation and maintenance (O&M) costs for this process are high.

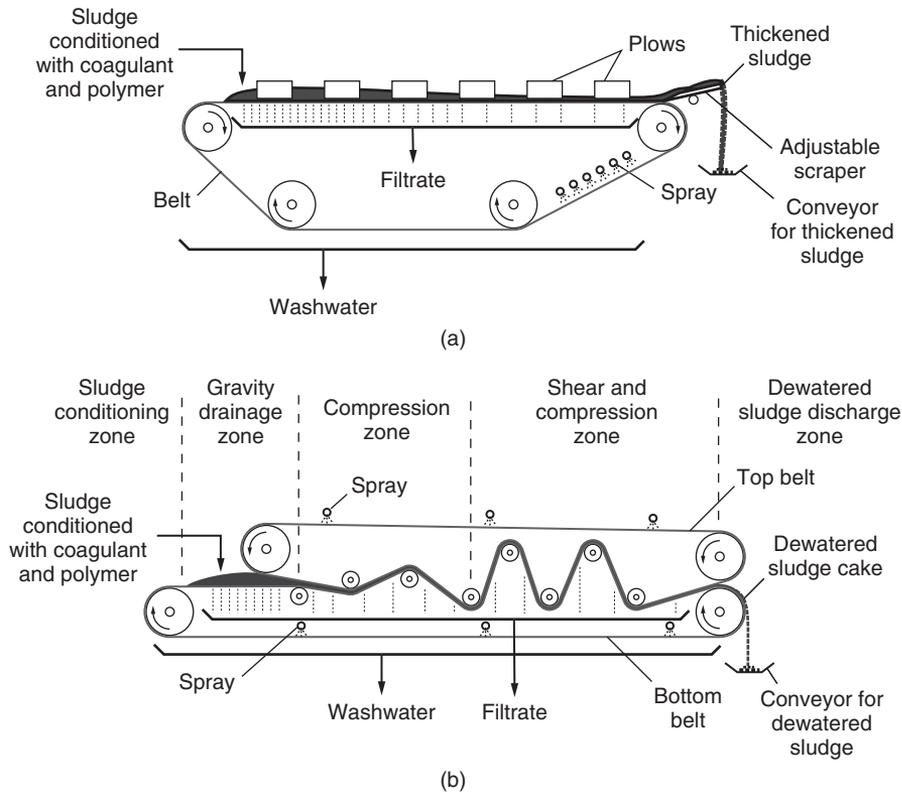

**Figure 21-22**  
Schematic view of plate and frame filter press.  
(Adapted from Tchobanoglous, et al., 2003.)

#### GRAVITY AND PRESSURE BELT FILTERS

The application of belt filters for water sludge thickening and dewatering is a relatively recent application dating back to the early 1970s, although belt filters were developed much earlier. Thickening with a gravity belt filter involves two operational steps: (1) chemical conditioning of the sludge and (2) gravity drainage using a single belt as illustrated on Fig. 21-23a. In some designs a vacuum is applied to the under side of the belt to enhance dewatering. Sludge dewatering with a belt filter press involves three operational steps: (1) chemical conditioning of the sludge, (2) gravity drainage, and (3) mechanical application of pressure. To accomplish the application of pressure, two or more belts are used, depending on the manufacturer. A belt filter press employing two belts for dewatering is illustrated schematically on Fig. 21-23b and pictorially on Fig. 21-23c. For both types of belt filters, the key to successful performance is the sludge chemical conditioning step.

In thickening dilute sludges, both coagulant and polymer addition is employed. Coagulant addition is used to concentrate the solids. Polymer addition is used to coagulate and flocculate the sludge before it is applied to the gravity belt thickener. Once applied to the belt thickener, the sludge is distributed uniformly across the width of the belt and moves with the belt. Fixed guide veins or plows located just above the surface of the moving belt create clear zones for free water released from the sludge to drain through the belt. Typically, from 70 to 80 percent of the free water is drained within the first meter. Thickened solids, scraped from the belt, are collected in a hopper for further processing, transport, or disposal (see Fig. 21-13a). Thickened sludge cake with up to 20 percent solids is possible with proper conditioning.

**Figure 21-23**

Belt filters for sludge thickening and dewatering: (a) schematic gravity belt thickener, (b) schematic belt filter press for dewatering sludge, and (c) view of typical belt filter press used for dewatering alum sludge.

Sludge dewatering as illustrated on Fig. 21-23b involves subjecting chemically conditioned sludge to gravity drainage, mechanical pressing, and shearing. Often shear and compression dewatering are shown as occurring together. Chemical conditioning typically involves the use of organic polymers. Complete and thorough mixing of the polymer and the sludge is the key to successful dewatering with belt presses. Once the coagulated solids are applied to the filter, gravity drainage occurs. The partially dewatered sludge then moves into the compression zone where it is squeezed between two moving belts. Additional dewatering occurs by shearing as the sludge moves to the outlet. Dewatered sludge, which falls off the belt, is transported by a conveyor belt to storage facilities for further processing or disposal (see Fig. 21-26). The capital cost and space requirements for pressure belt filtration sludge dewatering are generally significantly lower than for plate and frame pressure filter sludge dewatering systems. Typical performance and design data for sludge dewatering with belt filter presses are reported in Table 21-16.

#### CENTRIFUGES

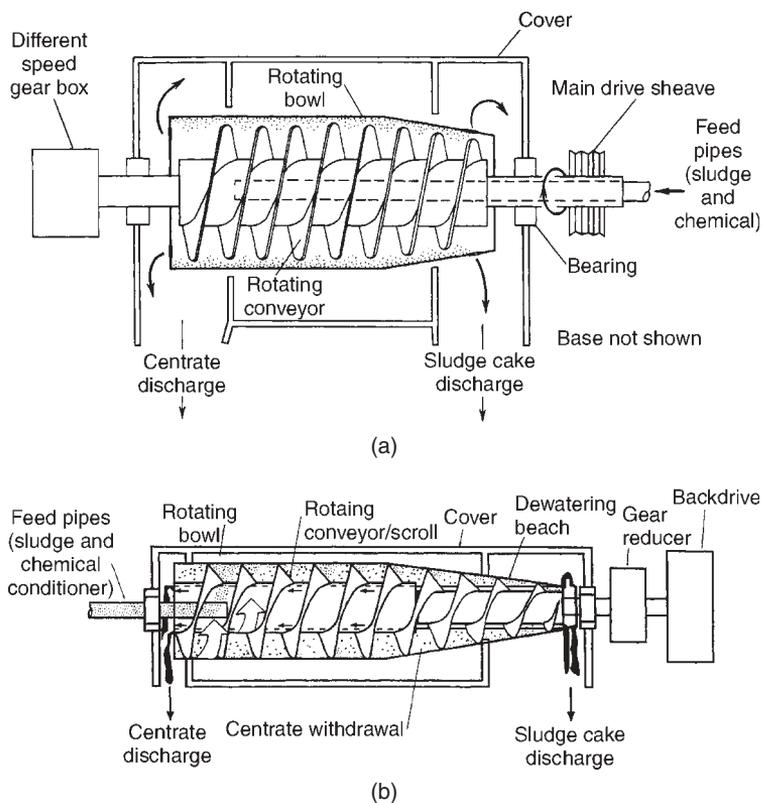

Centrifuges are used to both thicken and dewater sludges. The centrifuge is basically a sedimentation device in which the solids/liquid separation is improved by rotating the liquid at high speeds to increase the gravitational forces applied on the sludge. There are two basic types of centrifuges: (1) solid-bowl and (2) basket centrifuges. The two principal elements of centrifuges are the rotating bowl, which is the settling vessel, and the conveyor discharge of the settled solids (see Fig. 21-24).

Application of centrifuges in the water treatment field has normally been in dewatering lime-softening sludges. Solids concentrations of 35 to

**Table 21-16**

Typical performance and design data for belt filter press dewatering of water treatment plant sludges

Parameter	Unit	Range of Values
Feed solids	%	4–30
Thickened sludge		
Alum sludges	%	15–30
Lime sludges	%	25–60
Solids recovery	%	95–99+
Cake yield	kg/m <sup>2</sup> · h	0.8–4.0
	lb/ft <sup>2</sup> · h	4–20
Filtrate solids	mg/L	950–1500
Filter speed	rev/min	0.2–0.5
Operating pressure	kPa	550–830
	lb/in. <sup>2</sup>	80–120

**Figure 21-24**

50 percent are typical with lime sludges, although higher values have been reported. In centrifugation of predominantly alum sludges, solids concentrations of 12 to 15 percent have been obtained. Effective dewatering of alum sludge by centrifugation requires conditioning of the sludge with polymers and lime. Twenty to 25 percent solids may be obtained from 3 to 4 percent solids alum sludge. Polymer doses of approximately 1 to 2 g/kg (2 to 4 lb/ton) of feed solids are typical. Feed solids concentration for alum sludge centrifugation is in the range of 1 to 6 percent and 10 to 25 percent for lime sludge. Typical performance and design data for centrifuge thickening of coagulant and lime-softening sludges are reported in Table 21-17. Both capital and operation and maintenance costs for this process are relatively high.

### Lime Sludge Pelletization

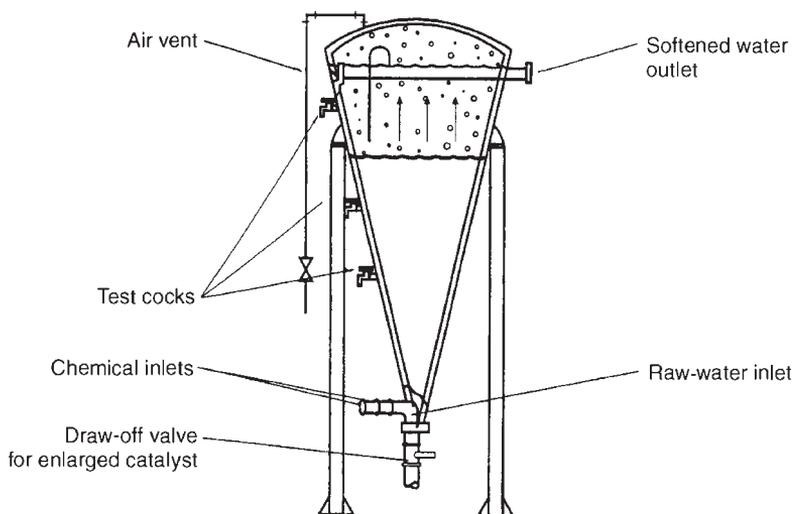

Taking advantage of the observation that sludge pelletization occurred during the suspended-bed cold-softening water treatment process led to the development of the lime sludge pelletizer shown on Fig. 21-25. Operationally, the conical vessel is charged with a silica catalyst. Lime sludge injected into the reactor reacts with calcium bicarbonate (hardness) in

**Table 21-17**

Typical performance and design data for centrifuge thickening of coagulant and lime-softening sludges

Parameter	Unit	Type of Sludge	
		Coagulant	Lime Softening
Feed solids	%	1–6	10–25
Thickened solids	%	12–15 <sup>a</sup>	35–50
Solids recovery	%	90–96	90–97
Polymer dosage	g/kg	1–2	na
	lb/ton	2–4	na

<sup>a</sup>Up to 25% solids has been achieved with the use of conditioning chemicals.

(Courtesy of US Filter.)

the carrier water to form calcium carbonate precipitates on the silica catalyst. The softened water is removed from the top of the reactor. The calcium pellets removed from the reactor are discharged to a storage and drainage facility. The solids content of the calcium carbonate pellets is about 60 percent.

The Aqua Pellet system employs proprietary equipment of a Japanese firm and has been used successfully to treat alum sludge in Japan. The process consists of multistage thickening of the sludge using sodium silicate and polymer and a dewatering process using a large horizontal rotating drum called a Dehydrum. Based on a full-scale operating system, it appears that 20 to 25 percent solids can be obtained by the Dehydrum starting with a 0.5 to 2 percent solids alum sludge.

### Aqua Pellet System

## Recovery of Coagulant

Aluminum and iron recovery can be accomplished by adding acid (normally sulfuric acid) to sludges to solubilize the metal ion salts. Lime recovery from lime sludge has also been practiced by the recalcination process.

### ALUM AND IRON RECOVERY

Alum and iron recovery can be accomplished by acidification with sulfuric acid. In simplified form, the reactions involved are

Normally, over 80 percent of alum and iron recovery is achieved at a pH of about 2.5. Unfortunately, heavy metals, manganese, and other organic compounds are often found in the recovered alum and iron. The presence of potential contaminants, as well as rising costs, has limited the recovery of alum and iron as a viable processing alternative.

### LIME RECOVERY

Lime recovery by recalcination has been practiced in a number of locations in the United States. Quicklime (CaO) can be recovered from softening sludges after purification and dewatering. To recover CaO, water-softening sludges are burned at a temperature of 1010°C (1850°F). The pertinent reactions are

The types of furnaces that have been used for recalcining include the rotary kiln, flash calciner, fluidized-bed calciner, and multiple-hearth calciner. The primary consideration in selecting the recalcination process is the overall economics of the process because the process is energy intensive ( $10 \times 10^9$  to  $15 \times 10^9$  J/kg of sludge).

### MAGNESIUM BICARBONATE RECOVERY

The magnesium bicarbonate recovery process was developed as a part of an overall treatment process that would use magnesium bicarbonate (precipitating magnesium hydroxide and calcium carbonate) as the primary coagulant. The pertinent reactions are

Precipitation

Magnesium Bicarbonate Recovery

During the late 1960s and the early 1970s, recycling magnesium carbonate was a developing and promising technology. Although the magnesium bicarbonate recovery process is technically feasible, based on pilot plant studies, the economics could not justify scale-up to a full-size facility. Presently, there are no known existing full-scale water treatment facilities that employ the magnesium bicarbonate recovery process; however, recovery of magnesium bicarbonate is being practiced in the paper and pulp industry.

## 21-15 Ultimate Reuse and Disposal of Semisolid Residuals

---

Several alternatives are available for the disposal or reuse of water treatment plant residuals. In practice, the options available for ultimate disposal or reuse of water treatment plant residuals frequently dictate the type of in-plant handling system necessary. Selection of an alternative should be based on economic as well as regulatory considerations. The type of sludge and sludge characteristics are also important criteria to be used in developing disposal or reuse alternatives. It is critical that the ultimate solids disposal or reuse program be a reliable, environmentally sound practice to ensure that it does not affect the primary goal of the treatment plant—the production of potable water. Alternatives available for disposal or reuse of water treatment plant residuals include

- Landfilling
- Disposal on land (reuse as a soil amendment)
- Discharge to a wastewater collection system
- Codisposal with wastewater biosolids
- Reuse in building or fill materials

Landfilling, land spreading, and lagoon storage followed by landfilling or spreading are typical land disposal options. Residuals disposed of in a wastewater collection system end up in the wastewater treatment plant, where they are removed and disposed of with wastewater sludge. Codisposal involves the mixing of water treatment plant residuals with wastewater treatment plant sludges followed by disposal or reuse. Reuse as building or fill material is site specific. However, before discussing the various disposal methods, it is appropriate to consider the impacts of arsenic in residuals.

As the regulations for arsenic in drinking water have become more stringent, water treatment processes have shifted to include greater arsenic removal from raw water, increasing arsenic concentrations in residuals. Arsenic in water treatment plant residuals comes from two sources: the raw water

and the chemicals used for treating the raw water. The amount of arsenic contributed from treatment chemicals may be considered minor (Cornwell et al., 2003), but earlier research (Cornwell and Koppers, 1990) found up to 40 percent of the arsenic in water treatment plant residuals was contributed by iron coagulants.

The U.S. EPA has evaluated water treatment plants specifically designed to remove arsenic and the residuals in these plants (U.S. EPA, 2000a, 2000b). Adsorption and coprecipitation of As(V) with iron and aluminum flocs are believed to be the primary arsenic removal mechanisms in the water treatment plants in these studies.

The effectiveness of arsenic removal from water is dependent upon both the pH of the water and the oxidation state of the arsenic. Once arsenic is in the treatment plant residuals, changes in pH or changes that result in a reducing environment may cause the arsenic to resolubilize. Processes commonly used for water treatment plant residuals that may cause pH or oxidation state changes include dewatering, lagooning, and landfilling.

## Landfilling

The most common disposal method for water treatment plant sludge in the United States is landfilling (see Fig. 21-26) in a commercial nonhazardous landfill (or monofill that receives only drinking water treatment plant residuals) or a hazardous waste landfill, which is regulated by the U.S. federal government. Water treatment plant sludge is tested to determine if it is a hazardous (Resource Conservation and Recovery Act, RCRA, subtitle C) or nonhazardous (RCRA subtitle D) waste to determine which type of landfill is appropriate for final disposal.

**Figure 21-26**

Dewatered sludge is placed in large storage containers that are hauled to a landfill, emptied, and returned. The elevated conveyor belt system used to transport the dewatered sludge to the storage containers is used in conjunction with the belt press shown in Fig. 21-23c.

Water treatment plant sludge testing is performed to meet the U.S. EPA requirement for solid waste characterization by the toxicity characteristic leaching procedure (TCLP). The TCLP test exposes a waste to a mildly acidic solution similar to what might be found in a municipal landfill (U.S. EPA, 1992). If the waste leachate contains any of the regulated compounds at or above the minimum concentration in leachate for toxicity characteristics, it is considered to be toxic and, therefore, a hazardous waste.

California has more stringent regulations than the U.S. EPA and requires solid waste to be tested according to the California waste extraction test (WET) (State of California, 2005). The WET uses a slightly more aggressive leaching procedure than is used by the TCLP test, as shown in Table 21-18. Both the TCLP test and the WET are designed to simulate landfill leaching. If the leachate contains any of the regulated compounds on the *List of Inorganic Persistent and Bioaccumulative Toxic Substances and Their Soluble Threshold Limit Concentration* (U.S. EPA, 1992) and the concentration of the compound is equal to or exceeds its listed soluble threshold limit concentration (STLC) or total threshold limit concentration (TTLC), the waste is considered toxic and therefore a hazardous waste.

A study of water treatment plant sludge leachate from plants that use either alum or iron as the primary coagulant was done by the American Water Works Research Foundation (Cornwell et al., 1992). The sludges were analyzed using the TCLP test, and all were found to be nonhazardous. Thus, landfilling of coagulant sludges in nonhazardous waste landfills is, in general, an appropriate disposal method.

**Table 21-18**

Comparison of toxicity characteristic leaching procedure (TCLP) and the waste extraction test (WET)

Parameter	Test Procedure	
	TCLP <sup>a</sup>	WET <sup>b</sup>
Extraction fluid	Acetic acid	Citric acid
Extraction fluid pH	4.93	5.00
Extraction duration, h	18	48
Dilution of waste to extraction fluid of solid portion of waste	20-fold	10-fold
Anaerobic conditions	No	Yes, by purging with N <sub>2</sub> gas prior to agitation
Inorganic constituents measured	8	19
Organic constituents measured	23	18
Aggressiveness for inorganic constituents	Less	More

<sup>a</sup>U.S. EPA (1992).

<sup>b</sup>State of California (2005).

There is concern that the current testing procedure, the TCLP, is not adequate for determining the long-term leachability of a material in its final disposal site. A variety of conditions can exist (wet, dry, acidic, basic) at a disposal site, making it unlikely that one test can assess all possible conditions. Research by the Department of Energy's Mixed Waste Focus Area and the U.S. EPA Office of Solid Waste evaluated six different testing protocols using a tiered approach. The conclusion reached in this study was that a better picture of how waste would behave at its final disposal site was obtainable but was expensive to achieve (Hulet et al., 2000).

### **Land Application**

Land application of water treatment plant residuals is a disposal method that is regulated in the United States by the federal government under the Resource Conservation and Recovery Act (RCRA) as well as state and local governments. Sludges to be spread on land must be tested to determine if they are a hazardous (RCRA subtitle C) or nonhazardous (RCRA subtitle D) waste by either the TCLP or WET, which are compared in Table 21-18.

Residuals that have been land applied include coagulant sludges, lime-softening sludges, reverse osmosis concentrate, and slow sand filter washings (Novak, 1993). Benefits from land application of coagulant sludges have not been clearly demonstrated, while concerns have been reported (Gendebien et al., 2001). Specific concerns raised include aluminum having a negative impact on barley growth in soils where the pH is below 5.5; high levels of aluminum reducing the availability of phosphorus and increasing soil compaction; and iron becoming concentrated in grazing land resulting in a negative effect on copper metabolism, especially in sheep (Gendebien et al., 2001; Marshall, 2002).

Depending on local soil conditions, the spreading of lime sludges may have beneficial impacts on the soil and crop yields when used in appropriate amounts (see Fig. 1-3d, Chap. 1). Nitrogen fertilizers typically lower soil pH, resulting in a decrease in calcium availability and reduced crop production (Marshall, 2002). The addition of lime sludge raises the soil pH comparable to commercially available agricultural limestone materials (Bly et al., 2001). The effectiveness of lime sludge, measured in terms of the total neutralizing power (TNP), is typically around 100, which is comparable to the TNP of commercial agricultural lime products (Marshall, 2002). A small number of facilities use land application or irrigation for concentrate disposal. Land application is often limited by salinity, which can accumulate in soil and prevent plants from growing or leach into underlying freshwater aquifers. Land application disposal methods are more appropriate for low-pressure systems that primarily remove hardness or NOM; the concentrate from these systems have lower salinity.

### **Lagooning Prior to Disposal**

As noted above, lagooning of water treatment plant residuals is typically an intermediate step prior to final disposal in a landfill. Lagooned residuals separate into sludge and supernatant. The sludge settles to the bottom

of the lagoon and becomes more compressed, and less porous, anoxic and anaerobic conditions may develop leading to a reducing environment in the settled sludge layer. Under reducing conditions, arsenic may gain electrons, going from As(III) to As(IV), and resolublize into the lagoon supernatant.

Based on recent research, it has been found that the release of arsenic from settled sludge in lagoons into the supernatant is associated with the release of iron and generally follows a lowering of the redox potential (Cornwell et al., 2003). Arsenic release being associated with the release of iron was correlated with the change in iron concentration, not the total iron concentration, and was found to occur for both ferric and alum sludges. Results from lagoon simulations were used to conclude that reduced pH and biodegradable organic matter cause an increase in arsenic release from sludge.

Seven different sludges in a simulated lagoon study were tested at periodic intervals for toxicity using both the TCLP and the WET, and the test results were compared to the arsenic levels measured in the lagoon supernatant (Cornwell et al., 2003). In all cases, the WET results were much higher, up to 700 times higher, than the measured arsenic levels in the supernatant. The TCLP results tracked more closely to the actual measured concentrations, exceeding the measured concentrations four times and understating the measured concentrations three times.

The conclusion drawn from TCLP testing on sludges from settling ponds and lagoons in arsenic removal studies (Cornwell et al., 2003; U.S. EPA, 2000a, 2000b) is that these sludges did not qualify as hazardous waste as the arsenic levels were under 5.0 mg/L. However, some of the same sludges were also tested using the WET and were found to be hazardous because arsenic levels above 5.0 mg/L were measured. In California, where hazardous waste guidelines are stricter than the federal requirements, lagoon sludges with high arsenic concentrations may not pass the WET, so individual evaluation should be performed to confirm the type of waste that is present and to determine the appropriate disposal method.

## 21-16 Management of Spent Solid Sorbents

---

With the exception of activated carbon most solid sorbents such as AA and GFH are used in a once-through basis. As with granular activated carbon, regeneration of these sorbents is only economical for large installations, if then. The most common reuse and disposal methods for spent solid sorbents are given in Table 21-19. If the spent solid sorbent can pass the TCLP test (see Sec. 21-15), conventional landfilling in a certified landfill is the most cost-effective method for disposal. Alternatively, the solid sorbents must be disposed of in a hazardous waste landfill.

**Table 21-19**

Management of sorbents used in water treatment or the removal of specific constituents

Sorbent	Reuse or Disposal Method
Activated carbon, granular (GAC)	Spent GAC is not reactivated in water treatment applications unless the usage is greater than 150,000 kg/yr (see Chap. 15). If usage is less than 150,000 kg/yr, the spent GAC is shipped to a central facility for reactivation. Because reactivated GAC cannot be used again for potable water treatment, it is typically stored for use in other applications such as industrial wastewater treatment. In some parts of the country, the demand for reactivated carbon is lower than the quantity available, and as a result some reactivated GAC is ultimately disposed of in landfills.
Activated carbon, powdered (PAC)	Contained in sludge from a coagulation process, PAC is not reactivated and is disposed of along with the sludge (see Sec. 21-3 and 21-4).
Ion exchange resins, mixed bed resins	Resins whose useful life has been reached are typically disposed of in lined municipal or hazardous waste landfills or hazardous waste processing facilities. Depending on their use, some resins are destroyed by combustion or pyrolysis.
Activated alumina (AA)	Spent adsorbents (sorbents that have lost significant adsorptive capacity and cannot be reactivated effectively) must be disposed in a lined municipal or hazardous waste landfills or hazardous waste processing facilities, depending on the constituent sorbed and local regulations.
Granular ferric oxide (GFO), Granular ferric hydroxide (GFH)	Spent adsorbents (see above) that are not reactivated must be disposed in a lined municipal or hazardous waste landfills or hazardous waste processing facilities, depending on the constituent sorbed and local regulations.
Fibroid chemosorbents, various	Spent adsorbents (see above) are typically not reactivated and must be disposed in a lined municipal or hazardous waste landfills or hazardous waste processing facilities, depending on the constituent sorbed and local regulations.

## 21-17 Process Selection

The selection of process steps and unit processes for a specific installation depends on factors such as availability and cost of raw water, space available at the site, local weather conditions, type of residual, cost of reuse versus disposal, sophistication of the plant operations personnel, distance to an ultimate disposal site, and types of ultimate disposal available. In most cases it will be possible to rule out most of the options by inspection (e.g., a small site surrounded by residential development would not have space available for sludge lagoons or drying beds; an inland site could not consider ocean disposal), leaving a limited number of options that can be evaluated in more depth to determine the least cost alternative. With most water treatment plant residuals, the general treatment objective is to recover as much of the usable liquid as possible and reduce the volume as much as possible to reduce the costs of subsequent recovery or disposal steps. Because most of the residuals from the treatment process are fairly dilute, the simplest

and most economical first step in liquid recovery and reducing volume is gravity thickening.

Operational factors that must be evaluated are the plant location, size, and reliability. An extremely complicated system would probably not be either economical or effective for a small, simple plant. Similarly, the plant reliability history must be evaluated to determine if a complex system would be well operated and maintained at the particular facility.

### Operational Factors

Economic factors that must be considered are capital, operation and maintenance, and solids disposal costs. Capital costs should include such items as construction costs, trucks, and special equipment needed for the process. Operation and maintenance costs should include power, chemicals, labor, parts replacement, and equipment repair costs. Disposal costs are typically such items as fees at the landfill or wastewater collection system discharge fees.

### Economic Factors

## Problems and Discussion Topics

---

- 21-1 An alum sludge contains 10 percent solids. If the density of alum is  $2400 \text{ kg/m}^3$ , estimate the density of the wet sludge at  $25^\circ\text{C}$ .
- 21-2 A ferric iron sludge contains 15 percent solids. If the density of iron is  $2500 \text{ kg/m}^3$ , estimate the density of the wet sludge at  $11^\circ\text{C}$ .
- 21-3 Determine the total kilograms of sludge on a dry-solids basis that will be produced for each kilogram of alum  $[\text{Al}_2(\text{SO}_4)_3 \cdot 6 \text{ or } 12 \text{ or } 18\text{H}_2\text{O}]$  added. Value of bound water to be selected by instructor.
- 21-4 Determine the total kilograms of sludge on a dry-solids basis that will be produced for each kilogram for ferric sulfate  $[\text{Fe}_2(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}]$  and ferric chloride  $[\text{FeCl}_3 \cdot 6\text{H}_2\text{O}]$  added. How do the computed values compare to the values given in Table 21-4.
- 21-5 Determine the total kilograms of sludge on a dry-solids basis that will be produced for each kilogram for ferrous sulfate  $[\text{FeSO}_4 \cdot 7\text{H}_2\text{O}]$  added. How does the computed values compare to the values given in Table 21-4 for ferric sulfate and ferric chloride.
- 21-6 Determine the mass and volume of sludge produced and the volume of sludge as percentage of the total flow from the use of alum  $[\text{Al}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}]$  for the removal of turbidity. Assume the following conditions apply: (1) flow rate is  $0.05 \text{ m}^3/\text{s}$ , (2) average raw-water turbidity is 45 NTU, and (3) average alum dose is 40 mg/L, sludge solids concentration is 5 percent with a corresponding specific gravity of 1.05, and temperature is  $10^\circ\text{C}$ . Assume

the ratio between total suspended solids and turbidity expressed as NTU is 1.33 and 0.3 kg of alum sludge is produced per kg of alum added. Assume 1 mg/L of a coagulant aid will also be used.

- 21-7 Determine the mass and volume of sludge produced and the volume of sludge as a percentage of the total flow from the use of PACl for the removal of turbidity. Assume the following conditions apply: (1) flow rate is  $0.1 \text{ m}^3/\text{s}$ , (2) average raw-water turbidity is 20 NTU, and (3) average alum or PACl dose is 45 mg/L, sludge solids concentration is 5 percent with a corresponding specific gravity of 1.05, and temperature is  $15^\circ\text{C}$ . Assume the ratio between total suspended solids and turbidity expressed as NTU is 1.5, the PACl contains 13 percent Al by weight and that 1.25 mg/L of a coagulant aid will also be used.
- 21-8 Referring to Chap. 20, demonstrate the correctness of the coefficients for  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  in Eq., 21-17 which is used to determine the amount of lime sludge.
- 21-9 Using the following information, estimate the yearly volume of waste washwater relative to the throughput for a granular ferric hydroxide (GFH) filter for arsenic. The amount of water processed on a yearly basis is 40,000 bed volumes. The filter is backwashed every 4 weeks for 10 min at a rate of 22 m/h. The cross-sectional area of the filter is  $1 \text{ m}^2$ , the depth of the filter is 1 m, and the porosity of the filter bed is 0.33.
- 21-10 Estimate the quantity and quality of the waste stream and the total quantity of water that must be processed from a reverse osmosis facility that is to produce  $48,000 \text{ m}^3/\text{d}$  of demineralized water. Assume that the recovery and rejection rates are 86 and 92 percent, respectively, and that the concentration of total dissolved solids in the feed stream is 400 mg/L.
- 21-11 Estimate the quantity and quality of the waste stream and the total quantity of water that must be processed from a reverse osmosis facility that is to produce  $3800 \text{ m}^3/\text{d}$  of demineralized water. Assume that the recovery and rejection rates are 80 and 85 percent, respectively, and that the concentration of total dissolved solids in the feed stream is 500 mg/L.
- 21-12 Using a loading rate of  $60 \text{ kg}/\text{m}^2$ , estimate the effective area of lagoons required to handle alum sludge from a water treatment plant with a flow rate of  $0.35 \text{ m}^3/\text{s}$ . Assume that solids and alum dose are as described in Problem 21-6 and that at least two lagoons will be used and that the filling cycle will be 120 days. Allow an additional area of 40 percent times the lagoon area for berms and access roads.

- 21-13 Review and cite three articles dealing with the disposal of water treatment plant sludges on land. What general conclusions can you draw regarding this practice based on your review? Are there any critical issues that stand out in your mind?
- 21-14 Review and cite three articles dealing with the processing of alum sludge. What are the similarities and differences between the recommended processing technologies?

## Terminology for Internal Corrosion of Water Conduits

---

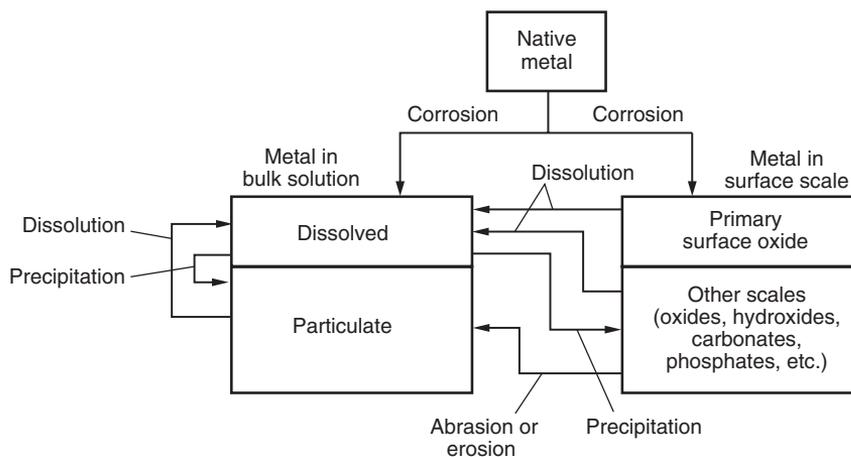

<b>Term</b>	<b>Definition</b>
Calcium carbonate scale	Natural scale that sometimes forms on the surface of materials used for conduits when the concentration of calcium carbonate in solution exceeds solubility.
Cathodic protection	A technique to control the corrosion of metal pipes using a sacrificial electrode.
Corrosion cell	The components of a system necessary to cause aqueous corrosion of metals: namely, an anode, a cathode, a conductor, and conducting electrolyte (the water).
Corrosion	Erosion of a structural material through chemical transformation—for metals, through oxidation.
Corrosion inhibition	Actions taken to reduce the rate of corrosion by inhibiting the rate of cathodic and anodic reactions.

<b>Term</b>	<b>Definition</b>
Corrosion, localized	Crevice corrosion and pitting are two types of localized corrosion as contrasted to uniform corrosion (see below).
Corrosion, uniform	Corrosion that occurs uniformly over the surface of a pipe as contrasted to localized corrosion.
Crevice corrosion	Localized corrosion that occurs in locations where conditions are stagnant with respect to water flow.
Current density	Rate of corrosion by oxidation, expressed as the flow of an electrical current per unit of surface area.
Electrolytic corrosion	Corrosion caused by stray electrical currents, which occurs at the point where the electrical current exits the pipe.
Galvanic corrosion	Corrosion that occurs when dissimilar metals or alloys are placed in contact with each other in the presence of an electrolyte (e.g., water).
Langelier saturation index (LSI)	An estimate of the thermodynamic driving force for either the precipitation or dissolution of calcium carbonate.
Mixed potential theory	Theory in which the concepts of thermodynamics, exchange current, and Tafel slopes are combined to provide one integrated model of the corrosion process.
Passivity	Formation of a nearly “perfect” protective oxide coating on transition metals, which reduces the rate of corrosion significantly.
Pitting	Localized corrosion in which small pits, holes, or cavities develop on the wall of a pipe.
Pourbaix diagram, $E_H$ -pH diagram	Diagram drawn to display three regions for a metal with respect to corrosion: (1) immunity, (2) corrosion, and (3) passivity.
Tafel slope	Slope of the linear portion of plot of the logarithm of the current versus electrode potential.
Tubercles	Mounds of corrosion products on the inside of iron pipe by localized corrosion.

The interactions of water with the materials used to transport, distribute, and store it are presented and discussed in this chapter. Where mineral materials such as rock or concrete are concerned, the interaction is generally a question of the ability of water to dissolve them directly (e.g., solubility). Although metals do not dissolve directly in water, the metals used in water conduits are generally not stable in water and, as a result, they oxidize or corrode. In the case of these metals it is important to understand

the phenomena that govern the underlying rate of oxidation as well as the solubility of the oxidation products. The plastic materials used as water conduits are generally stable in water. With these materials the issues are the leaching of organic contaminants in the plastic matrix or the leaching of solvents used to bind one plastic surface to another and the penetration of the pipe by organic solvents from the exterior environment. For all materials, microbiological activity can be important as well.

Recently, concern about the impact of metals on water quality has led to an increased emphasis on the release of metals from the pipe surface into solution. Although corrosion and the release of metals to solution are related, they are not the same. *Corrosion* is the oxidation process by which the native metal is converted to an oxidized species. If corrosion takes place slowly, the metal is often converted directly to an oxide of the metal on the metal surface. When corrosion takes place rapidly, as it often does in a pit, in crevice corrosion, or in galvanic corrosion, the oxidized metal is often released directly to solution in the form of ions. Once corrosion has taken place, other processes control the concentration of metal in solution. Prominent among these other processes are precipitation and dissolution. With some metals, particularly lead, iron, and copper, abrasion and erosion can also be important. Metals such as iron and copper, which exist in more than one oxidized state, are subject to particularly complex processes. In the case of both of these metals, understanding multiple oxidation states is important to understanding the dynamics between the primary surface oxide (the oxide formed immediately against the metal surface) and the rest of the surface scale. The relationship between corrosion of metals and the release of metal contaminants into the bulk water solution is conceptually illustrated on Fig. 22-1.

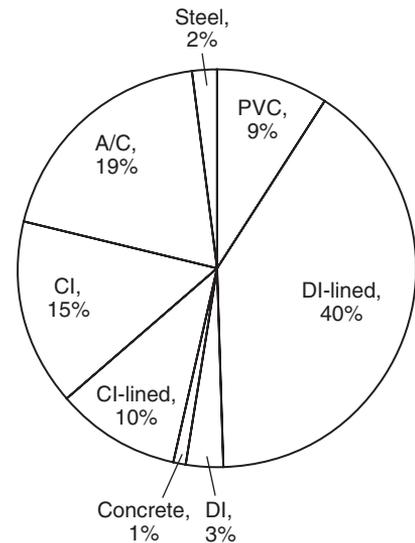

**Figure 22-1**  
Dynamics of corrosion  
and metals release.

## 22-1 Materials Used to Transport, Distribute, and Store Water

Over the years water has been transported in conduits made of many materials. The earliest records are of bamboo pipes in China and of earthenware pipes used in early Greek and Middle-Eastern civilizations (Baker, 1948). The Roman aqueducts were primarily composed of local natural materials, and in many cases they were just carved in the local rock. An ancient Roman version of concrete was used to line and cover the canal, making the structure long-lasting and impervious. Ancient Roman concrete was prepared by mixing hydrated lime, pozzolan ash, and rock with minimal water. The mix was then pounded into place to produce a concrete surface superior to most produced today (Moore, 1993). Many early water systems in the United States were ditches or canals constructed of local materials; some were also constructed using concrete or wooden pipes and wooden flumes. In fact, wooden materials continued to be used, worldwide, until the end of the nineteenth century. Unfortunately, most of these systems had a useful life of 20 years or less; nevertheless, an occasional wooden pipe is still uncovered today.

Based on a recent inventory of the materials used in public water supply distribution systems in the United States (see Fig. 22-2) the principal materials in place are ductile iron (DI), cast-iron (CI), and asbestos-cement (AC) pipe. In fact, together, ductile iron and cast iron account for nearly 70 percent of the total. Conduits lined with a cementaceous surface account for an even greater share of present installations (mortar-lined cast iron, ductile iron and steel, AC, and concrete pressure pipe). The primary uses, advantages, and disadvantages of these and other pipe materials are summarized in Table 22-1.

Gray cast iron was used for cannons as early as 1313, but it was eventually adapted for water systems as well. The first recorded use was at Dillenburg Castle in Germany in AD 1455. From the start, the use of cast iron has a pretty good record in water supply systems. In 1664, King Louis XIV of France had a cast-iron pipe installed to bring water to his palace in Versailles. This same cast-iron line was still functioning after 335 years of service. Once methods for refining iron improved enough, every progressive city was using cast iron for water mains. By the middle of the nineteenth century, gray cast iron had become the dominate choice for new water pipelines, worldwide. In the last half of the twentieth century ductile iron pipe began to displace gray cast iron in developed countries.

**Figure 22-2**

Pipe material in place in North America in 2002. (Source: waterstats 2002 distribution survey based on 542,600 km of pipe as reported by 337 utilities.)

### Cast and Ductile Iron

**Table 22-1**

Types of pipe, primary usage, and advantages and disadvantages when used in water supply systems

<b>Pipe Material</b>	<b>Standard</b>	<b>Primary Use</b>	<b>Advantages</b>	<b>Disadvantages/ Limitations</b>
Asbestos cement (AC) pipe (ACP)	AWWA C400-03	Distribution systems	Rigid light weight in long lengths	No longer used in new construction or manufactured in North America Contains asbestos
Cast iron (CI)	AWWA 106, 108	Transmission lines, distribution systems	Inexpensive, durable	Heavy, brittle Corrodes in soft water, water with high chloride or sulfate Tuberculation reduces carrying capacity No longer manufactured in North America: replaced by ductile iron
Cast iron—mortar lined	AWWA C151	Transmission lines, distribution systems	Inexpensive, durable, corrosion resistant	Heavy, brittle No longer manufactured in North America: replaced by ductile iron
Concrete cylinder pipe (CCP)	AWWA C303	Transmission lines	Adaptability of steel with the corrosion resistance of concrete and cement mortar	Limited pressure range Used in very large, gravity flow pipe
Copper tubing	ASTM B88	Consumer plumbing	Easy to work with	Can corrode in aggressive water; also due to poor workmanship during installation
Ductile iron pipe (DIP)	AWWA C150	Transmission lines, distribution systems	High strength for supporting earth loads Less brittle than CI Lighter than CI	May require wrapping or cathodic protection in corrosive soils or water. Typically lined to limit corrosion
Ductile iron pipe, cement lined (DIP)	AWWA C150, C104	Transmission lines, distribution systems	High strength for supporting earth loads Less brittle than CI Lighter than CI Extremely resistant to internal corrosion	May require wrapping or cathodic protection in corrosive soils
Fiberglass-reinforced plastic pipe (FPR)	AWWA C950 ASTM D2996	Transmission lines, water treatment systems	Light weight Corrosion resistance Long service life (durable)	Pipe can be coated for specific applications for piping

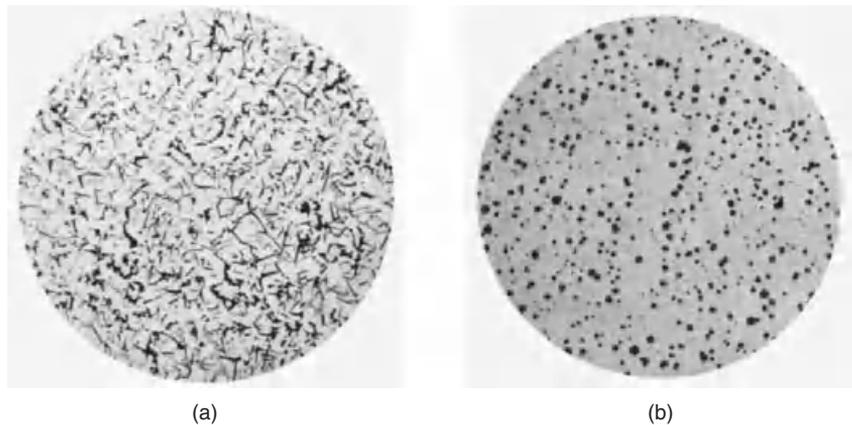

**Table 22-1** (Continued)

Pipe Material	Standard	Primary Use	Advantages	Disadvantages/Limitations
Galvanized steel pipe	ASTM53/53M-07	Consumer plumbing used in homes before 1960	Inexpensive Zinc protective coating reduces tendency to corrode	Prone to turburculation and corrosion (severe in many cases) Corrodes from the inside Limited service life (~40 years)
High-density polyethylene pipe (HDPE)	AWWA C901-02 ASTM D2513, D3350	Distribution systems, consumer plumbing	Corrosion resistance Reduced formation of chemical scales Chlorine free Long service life (durable)	Limited structural properties (not very rigid) Thick walls in large-diameter pipe
Polypropylene (PP)	ASTM D2146, D4101	Water mains, consumer plumbing	Light weight Corrosion resistance Long service life (durable)	Protective coating required if installed outside
Chlorinated polyvinyl chloride pipe (CPVC)	ASTM D1784	Consumer plumbing	Light weight Corrosion resistance Long service life (durable)	Can have problems with chemical permeation (solvents like TCE, gasoline, etc)
Polyvinyl chloride pipe (PVC)	AWWA C900, C905	Consumer plumbing, water treatment plants	Light weight, high strength Corrosion resistance Long service life (durable)	Can have problems with chemical permeation (solvents such as TCE, gasoline, etc). Used for cold water
Prestressed concrete, steel cylinder pipe (PCCP)	AWWA C301	Transmission lines, distribution systems	Corrosion resistance	Often used in large pipe Corrosion of reinforcement can be a problem Expensive
Lead		Service lines and internal plumbing	Easily installed (malleable) Banned by U.S. EPA in 1986	No longer used in the U.S. in new construction for water service. A legacy material
Reinforced concrete pipe (RCP)	ASTM C76	Transmission lines, distribution systems	High strength for support of earth loads	Attacked by soft water May require protective coating Water hammer can rupture outer shell
Reinforced concrete pressure pipe (RCP)	AWWA C300, 302	Transmission lines, distribution systems	Different types are available for different soil conditions High strength for support of earth loads Variety of sizes available Relatively inexpensive	Attacked by soft water May require protective coating Water hammer can rupture outer shell

(continues)

**Table 22-1** (Continued)

Pipe Material	Standard	Primary Use	Advantages	Disadvantages/Limitations
Steel pipe	AWWA C200	Transmission lines, distribution systems	High strength for support of earth loads	Poor corrosion resistance Must be lined and protected on the outside against corrosion Corrosion resistant when used with both internal and external mortar lining
Stainless steel (SS) tubing	ASTM A312	Water treatment plants, building water supply lines	Corrosion resistance	Relatively expensive

**Figure 22-3**  
Photomicrographs of (a) gray cast iron and (b) ductile iron.

The difference between these two types of cast irons is evident in the photomicrographs displayed on Fig. 22-3. All cast irons include certain additives that make them easy to manufacture; prominent among these are carbon and silicon. The carbon in gray cast iron takes the form of graphite flakes, as may be observed in the photomicrograph on Fig. 22-3a. Unfortunately, although the graphite makes manufacturing and machining easier, when it takes the form of flakes, it also makes the pipe brittle, reducing its useful strength.

In 1948, German metallurgists discovered that the introduction of a small amount of magnesium or cerium in the molten cast iron could prevent the full development of the traditional graphite flakes, forcing the formation of round nodules instead (see photomicrograph on Fig. 22-3b). When the

graphite in the final cast takes this form, ductility, toughness, and useful strength are substantially increased. As a result, whereas a 20-ft segment of 24-in. gray cast-iron pipe weighs 4065 lb (200 psi Class), the equivalent ductile iron pipe weighs 1710 lb, less than half as much. The approximate metric equivalents are 6 m, 600 mm, and 1850 kg for gray cast iron and 780 kg for ductile iron. Ductile iron almost completely displaced gray cast iron in the United States within a decade and a half after it was introduced in 1955. Its principal competitors are now plastic materials. Gray cast iron, which is easier to manufacture, still sees significant use on a worldwide basis. In fact, gray cast iron is still the dominant pipe material in many countries where ductile iron is not yet readily available.

Most modern water systems are made of cast iron, ductile iron, steel, galvanized steel, AC, polyvinyl chloride (PVC), lead, and copper (see Table 22-1). Of these, AC and lead are no longer used in new pipe, and lead and copper tubing are found almost exclusively in buildings and related connections. Galvanized iron is found both in residences and in smaller distribution system piping. However, since approximately 1980, it has seen limited use in new domestic plumbing in developed countries. Both ductile iron and steel are typically lined with a bitumastic seal coat, cement mortar, or both, to reduce corrosion. In older pipe, coal tar coatings were common and the pipe was often installed with no lining at all. Recent surveys show that approximately half the inventory of installed water pipe in the United States today is gray cast iron and half of that is unlined (Kirmeyer et al., 1994). Because it is stronger and more malleable, steel has also been employed as an alternative to cast iron or ductile iron, although most steels are more susceptible to corrosion than ductile iron. Steel is relatively long-lived in most systems when a cement–mortar lining is used. Asbestos–cement pipe, very popular between 1955 and 1970, is no longer used in new construction.

Lead was once used extensively in service lines and interior plumbing because of its ductility and its relatively long life. Its longevity is due to a low corrosion rate and the fact that it does not form the sort of thick surface scale and encrustation that often reduces the carrying capacity of ferrous pipe. Lead service connections between distribution mains and consumer plumbing were often used until lead materials were prohibited in the United States by the Lead Contamination Control Act of 1988 (Public Law 100-572).

Today galvanized pipe is probably the most common material in existing consumer plumbing worldwide. However, since 1950 copper tubing has gradually displaced it in most new consumer plumbing in the United States and Western Europe. Plastic materials are used for consumer plumbing with increasing frequency and also for many distribution mains.

### **Other Materials in Distribution Systems**

### **Materials in Consumer Plumbing**

**Reservoir  
Materials**

The materials used in the construction of water reservoirs have also changed with time. Many older facilities are made of wood or have wooden surfaces, which are often associated with bacterial contamination problems because they serve as a reservoir for bacteria. Today, new water storage tanks are made of either concrete or steel, and the issue of concern is the leaching of contaminants from materials used to coat the surface or seal joints.

## 22-2 Thermodynamics of Metallic Corrosion

---

Corrosion of metallic water conduits is of concern for three reasons: (1) it can reduce the wall thickness, (2) it can cause encrustation, reducing carrying capacity, and (3) it contributes to water contamination. These are separate but related phenomena. Understanding one of the three does not necessarily lead to understanding the others.

Most metals used to construct water conduits corrode when exposed to water, particularly when oxidants such as dissolved oxygen or chlorine are present. Thermodynamics can be used to find the free energy of the corrosion reaction. *If the free energy of the reaction is positive, then corrosion will not occur. If the free energy of the reaction is negative, then corrosion may occur.* The fact that the corrosion reaction is favored thermodynamically is a necessary condition but not a sufficient condition for corrosion to proceed. Sometimes thermodynamics favor corrosion, but the rate of the reaction is so slow that no significant corrosion occurs. This low rate occurs because the rate at which corrosion takes place is not just a question of thermodynamics. It is also a question of kinetics. The type of kinetics that control the rate of a corrosion reaction is called *electrode kinetics*. Electrode kinetics are influenced by thermodynamic conditions but also by the condition of the metal's surface, limitations of mass transport, as well as other factors. Thermodynamics cannot be used to determine the rate of the reaction, but thermodynamics can be used to determine if corrosion is possible. The relevant thermodynamics, discussed in Chap. 5, are half reactions, Faraday's law, standard electrode potentials, and  $E_H$ -pH diagrams. Selected standard electrode potentials of interest in solving problems in this chapter are listed in Table 22-2.

**Components  
of Corrosion Cell**

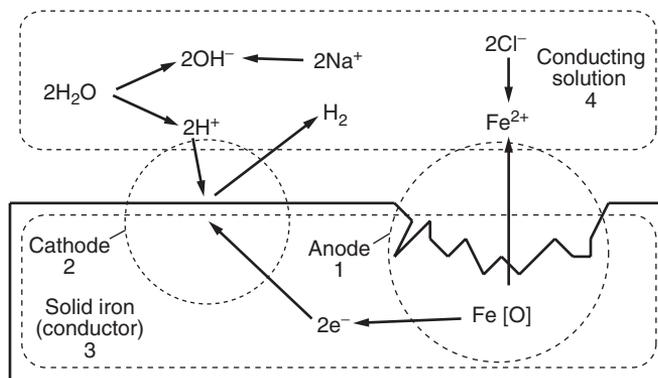

It is important to understand the basic components of a corrosion cell. An idealized diagram of a corrosion cell is illustrated on Fig. 22-4. The four necessary components of a corrosion cell are illustrated based on the corrosion of iron. These components are (1) the anode, (2) the cathode, (3) a conductor, and (4) a conducting electrolyte. At the anode the iron metal loses two electrons and goes into solution as a ferrous iron. At the cathode, hydrogen ions near the metal surface (probably absorbed to it) accept the electrons generated by the corroding iron, become reduced to nascent hydrogen, and, eventually, combine to form hydrogen molecules

**Table 22-2**

Selected standard oxidation–reduction (redox) potentials

Reaction		Reaction

$\text{Na}^+ + \text{e}^- \rightleftharpoons \text{Na(s)}$	-2710		

<sup>a</sup>Approximation from Oxidation/reduction potential (ORP) data.Source: Adapted from Lide (2000) and Lange (1985). (See also [www.webelements.com](http://www.webelements.com).)

**Figure 22-4**

Idealized corrosion cell for iron. The four components involved in the corrosion of iron are identified as 1 through 4.

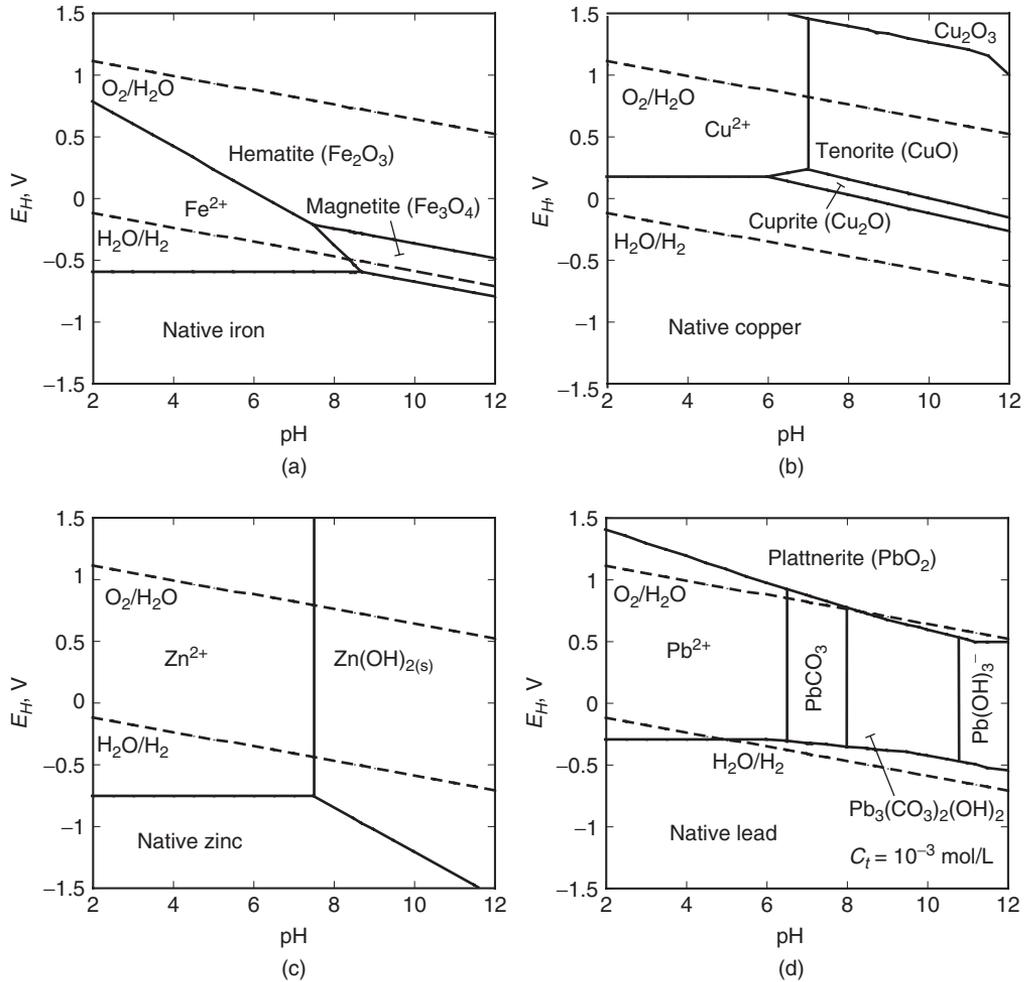

and leave the surface. The electrons travel from one site to another through the conductor. A conducting solution is also necessary to complete the electrical circuit. The movement of electrons is illustrated on Fig. 22-4 by the transport of positively charged sodium ions toward the cathode and negatively charged chloride ions toward the anode. The reaction couple for metallic iron corroding in an acid solution is shown below:

Reaction	$E^\circ$ (V)		
$\text{Fe} \rightleftharpoons \text{Fe}^{2+} + 2e^-$	$-(-0.44)$	Oxidation	(22-1)
$2\text{H}^+ + 2e^- \rightleftharpoons \text{H}_2$	0.00	Reduction	(22-2)
$2\text{H}^+ + \text{Fe} \rightleftharpoons \text{Fe}^{2+} + \text{H}_2$	+0.44		(22-3)

It should be noted that the overall potential of this reaction must be obtained by the simple addition of the two half reactions as both reactions have the same number of electrons. When this is not the case, the reader should follow the procedure dictated by the Faraday equation and described in Chap. 5. The oxidative half reaction and the reductive half reaction do not need to take place at the same physical location, as the free electrons generated at the oxidative site can migrate through the conductor (and also through some metal oxides if they are semiconductors) to find a reductive half reaction.

### Pourbaix Diagrams

The  $E_H$ -pH diagrams are shown for the four metals of greatest concern in drinking water on Fig. 22-5. These diagrams provide a pictorial view of the chief thermodynamic forces acting on the metal. The principles behind these diagrams are introduced in Chap. 5. The region where water is stable is depicted in each diagram by the dashed line. At potentials above the upper dashed line, water is converted to oxygen. At potentials below the lower dashed line, water is converted to hydrogen gas. It should be noted

**Figure 22-5**

The  $E_H$ -pH diagrams for four metals common in water conduits: (a) iron, (b) copper, (c) zinc, and (d) lead.

that iron, the most common material used for water conduits, is unstable throughout this region. Similarly, zinc, the material used to increase the life of iron pipe, is also unstable. Lead, probably the most corrosion resistant of the three, is only stable at very low redox potentials and alkaline conditions. Copper is the only conduit metal that is thermodynamically stable in a significant part of this range. Nevertheless, all of these materials have been known to serve for several decades as water conduits. Clearly, thermodynamic stability is not the only prerequisite for the proper choice of materials.

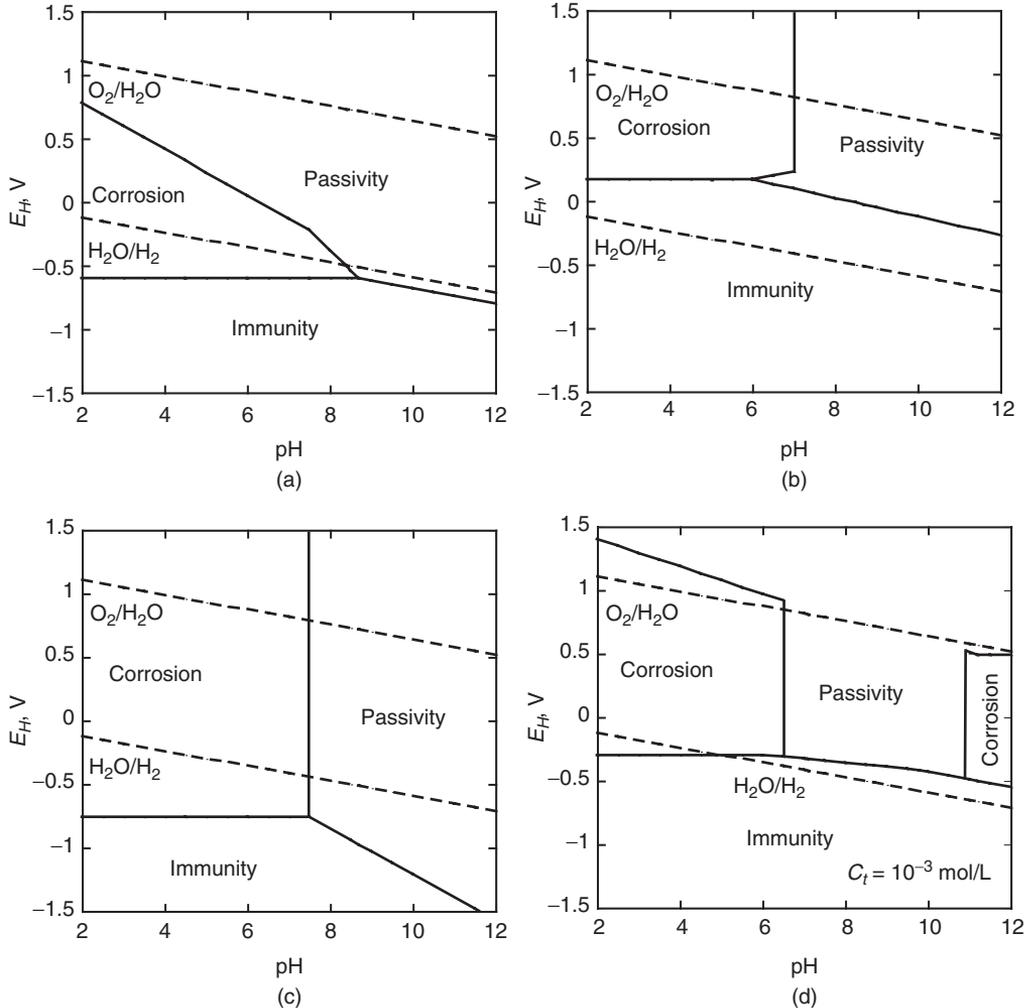

Expanding on his practical knowledge of corrosion phenomena, Pourbaix edited the  $E_H$ -pH diagrams on Fig. 22-5, and those for other metals, to better portray the metal's corrosion behavior, producing a new diagram that had both thermodynamic and practical meaning. In deference to Pourbaix's contribution, diagrams of this kind have become known in the corrosion industry as *Pourbaix diagrams*. Pourbaix diagrams are used to identify three regions for each metal: (1) immunity, (2) corrosion, and (3) passivity (Pourbaix, 1949). The region labeled "immunity" corresponds to that region of the  $E_H$ -pH diagram where corrosion of the metal is not thermodynamically possible. The label "corrosion" is applied to conditions where the stable metal species are highly soluble and, as a result, no natural protective layer can form. The region labeled "passivation" is applied to conditions where the stable species of the metal can form insoluble products that might retard corrosion to a significant degree. Thus, Pourbaix's use of the term *passivation* is broader than the meaning used elsewhere in this chapter.

Pourbaix diagrams for the same four metals analyzed on Fig. 22-5 are shown on Fig. 22-6. These diagrams are useful for discussing the influence of both pH and solution redox potential on corrosion, but they must be used with care because they are one step removed from the basic thermodynamic diagrams, which already suffer from an inability to reflect kinetic considerations. Such diagrams are most useful as a tool for communicating the influence of pH and redox conditions on the corrosion of a particular metal among practitioners who already have broad experience with a metal's behavior in corrosion.

### Limitations of Pourbaix Diagrams

The position a sample of metal corroding in water occupies on these diagrams may be approximated directly by measuring the pH of the solution and the potential of the metal with respect to the solution, usually referred to as the metal's corrosion potential,  $E_{\text{corr}}$ . The corrosion potential can be approximated by measuring the potential of the corroding specimen with respect to a reference electrode, while the freely corroding specimen is immersed in and is at steady-state with the solution of interest. These  $E_{\text{corr}}$  measurements are subject to error and must be made with care. For example, the distance between the reference electrode and the specimen must be minimized to avoid interference from solution resistance. One of the most difficult aspects is obtaining a specimen without altering its conditions in a fashion that will significantly change its corrosion rate and, hence, its corrosion potential. Any  $E_{\text{corr}}$  measurements made in this fashion must be made with a particular specimen and are not a general property of the solution itself.

The unknowns do not end with the  $E_{\text{corr}}$  measurement. Any  $E_H$ -pH diagram is necessarily constructed at a particular temperature, a particular ionic strength, and with specific assumptions about the concentration

**Figure 22-6**

Pourbaix diagrams for four metals common in water conduits: (a) iron; (b) copper; (c) zinc; and (d) lead.

of species relevant to the metal's behavior. The  $E_H$ -pH diagrams are particularly useful as a didactic tool, illustrating the relationship between pH, potential, and other solution properties and the stable species of the material of concern. Even if the  $E_H$  is correctly measured and all the appropriate species were considered in drawing the diagram, the result is based on equilibrium concepts and can only be used to determine feasibility of corrosion. It cannot be used to predict the rate of corrosion. To pursue these answers, electrokinetics must be considered.

## 22-3 Electrokinetics of Metallic Corrosion

---

Environmental engineers tend to view the corrosion process as an interaction of cathodic and anodic sites on the macroscale and often analyze corrosion control through the solubility of surface scales and occasionally through some of the thermodynamic properties discussed in the preceding section. Through the first six decades of the twentieth century, the corrosion profession as a whole took a similar view. In the late 1950s, Stern and Geary (1957) presented a new and powerful description of the mixed-potential theory of corrosion that had been advanced nearly two decades earlier (Wagner and Traud, 1938) but had received little attention. Mixed-potential theory provides a rigorous connection between the fundamentals of corrosion and the principles of electrochemistry. The theory began to appear in corrosion texts in the late 1960s (Donahue, 1972; Fontana and Greene, 1967; Uhlig, 1967) and is now generally accepted (Fontana, 1985; Jones, 1996; Roberge, 1999; Revie and Uhlig, 1985). Mixed-potential theory is introduced here because it is the most powerful conceptual tool available for understanding the dynamics of the corrosion process. Before describing mixed-potential theory, three related concepts must be introduced: (1) corrosion as an electrical process, (2) the relationship between polarization and current flow, and (3) exchange current density.

### Corrosion as an Electrical Process

Corrosion involves oxidation and reduction reactions and electrons as well. In fact, the process of corrosion can be viewed in electrical terms. Consider the oxidation of a metal to metal ions:

The rate of this reaction is characterized by weight loss on the left and by electricity on the right. One can be converted to the other using Faraday's law:

$$M_w = \frac{Ia_M}{nF} \quad (22-5)$$

where  $M_w$  = rate of weight loss, g/s  
 $a_M$  = atomic weight of metal, g/mol  
 $I$  = electrical current, A, C/s (coulombs per second)  
 $n$  = equivalents of metal in reaction, eq/mol  
 $F$  = Faraday's constant, 96,500 C/eq

Although corrosion measurements are often made by measuring the weight lost by test coupons, the results are normally expressed as a rate of uniform attrition of the metal surface: mpy or mm/y. The acronym "mpy" stands for "mils per year," where 1 mil = 1/1000 in. The acronym "mm/y" stands for "mm per year." The conversion to these more conventional measures

**Table 22-3**

Converting corrosion rates and current densities

Metal	$\mu\text{A}/\text{cm}^2$	eq/mol	Density, Atomic		mpy	mm/y	mg/dm <sup>2</sup> · d
			g/cm <sup>3</sup>	Mass			
Iron	1	2	7.87	55.8	0.458	0.0116	2.50
Copper	1	2	8.96	63.5	0.457	0.0116	2.85
Lead	1	2	11.34	207	1.178	0.0299	9.28
Zinc	1	2	7.13	65.4	0.591	0.0150	2.93
Aluminum	1	3	2.7	27.0	0.430	0.0109	0.81
Tin	1	2	7.3	118.7	1.049	0.0266	5.32
Nickel	1	2	8.9	59.2	0.429	0.0109	2.65

of corrosion rate is made by introducing the density of the metal and the concept of current density. In this manner Eq. 22-5 becomes

$$\text{Rate (mpy)} = 0.129 \left( \frac{a_M i}{n D_M} \right) \quad (22-6)$$

$$\text{Rate (mm/y)} = 0.00327 \left( \frac{a_M i}{n D_M} \right) \quad (22-7)$$

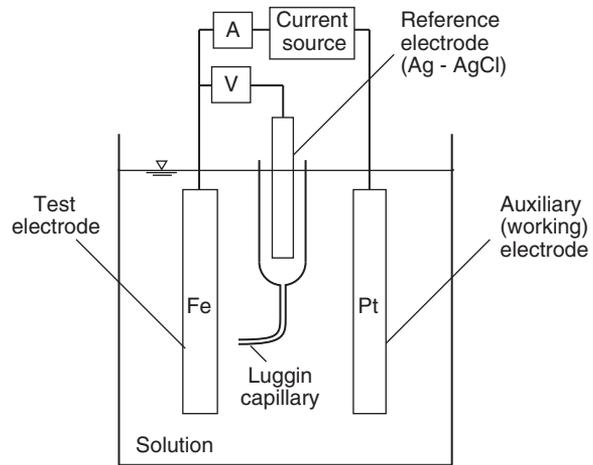

where  $i$  = corrosion current density,  $\mu\text{A}/\text{cm}^2$   
 $D_M$  = density of metal,  $\text{g}/\text{cm}^3$

Conversions for most metals encountered in water supply are summarized in Table 22-3.

Mixed-potential theory begins with the relationship between electrode polarization and current flow. Perhaps the best way to develop an understanding of this aspect of electrode kinetics is by examining a simple polarization experiment. To make polarization measurements requires a three-electrode setup like the one illustrated on Fig. 22-7. In the sketch shown, the auxiliary or “working” electrode is platinum, the reference electrode is a Ag–AgCl electrode, and the test electrode is made of iron. A potentiometer is used to measure the potential of the test electrode with respect to the reference electrode. A source of current is placed between the test electrode and the working electrode along with a current meter so that the electrical current flowing into or out of the test electrode can be measured. The current of the working electrode divided by its surface area represents the net current produced by the electrokinetic reactions taking place on its surface. When the electrode is being oxidized, this is also the corrosion rate. It is usually expressed in  $\text{A}/\text{cm}^2$  or  $\text{mA}/\text{cm}^2$ .

The apparatus includes an iron test or “working” electrode, a platinum auxiliary electrode, and a silver–silver chloride reference electrode

**Relationship  
between  
Polarization  
and Electrical  
Current**

**Figure 22-7**

Apparatus used to measure polarization effects in metals.

immersed in the same acid solution. A high-impedance voltmeter (V) is connected between the reference electrode and the iron electrode to measure the potential between the iron test electrode and the solution. A Luggin capillary is used for the reference electrode to reduce solution resistance between the reference and test electrodes. A variable emf (current source) is connected between the strip of iron and the platinum electrode. Using the platinum electrode as a working electrode, a current is passed between the iron strip and the solution, polarizing the iron electrode. A low-resistance ammeter (A) is connected between the iron and platinum electrodes so that the current flow between them can be measured. The apparatus shown on Fig. 22-7 is conceptual only. A more detailed description of this experiment and apparatus may be found in Reiber et al. (1986).

Understanding electrode kinetics on the surface of an iron electrode corroding in acid solution begins with the realization that both cathodic and anodic reactions take place on the surface of the iron simultaneously. The cathodic reaction is the reduction of hydrogen ion ( $2\text{H}^+ + 2\text{e}^- \rightleftharpoons \text{H}_2$ ) and the anodic reaction is the oxidation of the iron itself ( $\text{Fe} \rightleftharpoons \text{Fe}^{2+} + 2\text{e}^-$ ). The polarization experiment is conducted by imposing an electrical current on the iron electrode, raising its potential and accelerating the density (or the rate) of anodic reactions taking place on its surface. By the convention established by Benjamin Franklin, electrical current flows in the opposite direction as the electrons. As a result, imposing a current on the iron electrode means drawing electrons from it. Corrosion engineers refer to this as “polarizing” the electrode. The increase in the rate of this reaction on the surface of the electrode corresponds to the increase in current observed. The experiment is then repeated, but with the current flowing in the opposite direction. In this second case, the potential of the iron

electrode is reduced, and the current flow is generated by acceleration of the cathodic reaction on the surface of the iron electrode surface ( $2\text{H}^+ + 2\text{e}^- \rightleftharpoons \text{H}_2$ ).

When such polarization experiments are conducted, the slope of the plot of the logarithm of the current versus electrode potential quickly becomes linear. As Tafel was the first to make this observation (Tafel, 1905), the slope of this straight line is commonly referred to as the Tafel slope. In equation form, Tafel's concept is as follows:

$$\eta = \alpha \pm \beta \log(i) \quad (22-8)$$

where  $\eta$  = electrode overpotential =  $E_H - E_0$

$\alpha$  = constant

$E_H$  = electrode potential, mV

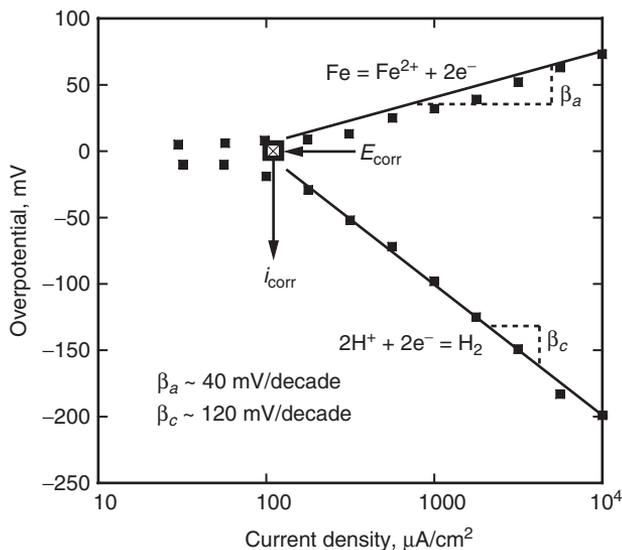

$E_0$  = electrode potential at equilibrium, mV

$\beta$  = Tafel slope, mV/decade

$i$  = current density,  $\mu\text{A}/\text{cm}^2$

$\pm$  is + for the anodic reaction and - for the cathodic reaction

Tafel's concept applied to the polarization data from a polarization experiment conducted on iron in 1 N  $\text{H}_2\text{SO}_4$  is illustrated on Fig. 22-8. The data are plotted in the form of an Evans diagram (Evans, 1948) where the logarithm of the absolute value of the current is plotted versus the electrode potential. To create the plot, the apparatus on Fig. 22-7 is used to impose a current on the electrode and to increase that current in a stepwise

**Figure 22-8**

Polarization plot for iron corroding in acid solution. Note: In this plot the Evans convention is used in which the current is given no sign and both the anodic and cathodic currents are treated in the same manner (as if the absolute value of the current were being plotted).

### Example 22-1 Estimating corrosion rate

Estimate the corrosion rate of the iron coupon on which the polarization test was being conducted on Fig. 22-8. Provide an answer in both mpy and mm/y.

#### Solution

1. Estimate the corrosion current density. From Fig. 22-8, the corrosion current density,  $i_{\text{corr}}$ , is estimated to be  $110 \mu\text{A}/\text{cm}^2$ .
2. Estimate the corrosion rate. Using the conversion coefficients provided for iron in Table 22-3, the  $i_{\text{corr}}$  value corresponds to a corrosion rate of

$$\begin{aligned} \text{mpy} &= 110 \mu\text{A}/\text{cm}^2 \times 0.46 = 51 \text{ mpy} \\ \text{mm/y} &= 110 \mu\text{A}/\text{cm}^2 \times 0.012 = 1.3 \text{ mm/y} \end{aligned}$$

fashion. The result is an *acceleration of the anodic reaction* on the surface of the electrode *and an increase in its potential*. The apparatus is then used to run the current in the opposite direction. Now the *cathodic reaction is accelerated and the potential is reduced*.

In 1905, Tafel observed that such curves become a straight line as they are extrapolated. As a result, the slopes of the lines bear his name. The anodic and cathodic slopes ( $\beta_a$  and  $\beta_c$ ) are often different as different reactions generate their behavior. These slopes can be extrapolated to estimate the corrosion current density ( $i_{\text{corr}}$ ) and, hence, the corrosion rate. At rest, the electrode is at its corrosion potential ( $E_{\text{corr}}$ ).

### Exchange Current Density

Another important concept in mixed-potential theory is the exchange current density ( $i_0$ ). The exchange current density is a fundamental kinetic parameter and is characteristic of a particular reduction–oxidation half reaction on a particular surface. Consider the redox reaction for hydrogen:

The reversible potential for this reaction,  $E_{\text{H}_2}$ , can be determined by the Nernst equation. When the potential of the metal coupon with respect to the solution equals  $E_{\text{H}_2}$ , the hydrogen redox reaction on its surface is presumed to be at reversible equilibrium. That is, the rate of the reaction in the forward direction ( $r_f$ ) is equal to its rate in the backward direction ( $r_b$ ). Using Faraday's law, the rate of this reaction can also be expressed as a current. The following expression describes the exchange current:

$$I = r_f nF \quad (22-10)$$

or

$$I = r_b nF \quad (22-11)$$

where  $I$  = exchange current, A (C/s)

$r_f$  = rate of forward reaction, mol/s

$r_b$  = rate of backward reaction, mol/s

$n$  = electrons transferred per mol of reaction, eq/mol

$F$  = Faraday constant, 96,500 C/eq

Arranging these rates as the sum of all the couples of that reaction reacting on the metal's surface divided by its area  $A$  produces the exchange current density  $i_0$ :

$$i_0 = \frac{\sum (r_f n_{\text{H}_2} F)}{A} = \frac{\sum (r_b n_{\text{H}_2} F)}{A} \quad (22-12)$$

Thus, the exchange current is the current equivalent of the rate at which the reaction goes in both the forward and reverse directions on a surface divided by the area of that surface—when that surface is maintained at the reaction's reversible potential. Whereas the potential of the half reaction is its fundamental thermodynamic parameter, the exchange current density is the fundamental kinetic parameter for that reaction when it occurs on a particular surface. It can be shown that the exchange current density is determined by the activation energy of the reaction (Jones, 1996), but it is not usually determined from first principles, rather it is measured. Also, whereas the equilibrium potential for a particular reaction does not depend on the nature of the surface upon which the reaction occurs, the exchange current density is specific to a particular surface.

The exchange current density for the hydrogen half reaction on a number of surfaces is displayed on the scale shown in Table 22-4. It is evident from these data that the exchange current density is extremely sensitive to the surface involved. The difference between the rate on platinum and on lead in acid conditions is 10 orders of magnitude. Not only is the particular metal important, but the condition of its surface is also important. The condition of the surface is influenced by solution conditions and other environmental factors such as temperature and velocity. For example, returning to Table 22-4, the difference between the hydrogen exchange current on a mercury surface in acid and basic conditions is 2 orders of magnitude. Finally, the condition of the surface changes with time and the exchange current density changes with it. Usually the exchange current density decreases as the film on the metal's surface continues to develop.

**Table 22-4**

Selected exchange current densities and Tafel slopes

Electrode Surface	Solution Condition	$i_0, \mu\text{A}/\text{cm}^2$	$\beta, \text{mV}/\text{decade}$

### Example 22-2 Exchange current for zinc in an acid solution saturated with oxygen

A zinc electrode is immersed in 2 N  $\text{H}_2\text{SO}_4$  solution that is saturated with an overlying atmosphere of pure oxygen at  $25^\circ\text{C}$ . The electrode is observed to be at the reversible potential for the oxygen reduction half reaction (+1230 mV). For these conditions, estimate the rate at which oxygen is converted to water. Express the answer in atoms/ $\text{cm}^2 \cdot \text{s}$ . (*Hint*: At the given potential it is the same rate at which water is converted back to oxygen again.)

#### Solution

1. Estimate the exchange current. From Table 22-4, the exchange current for oxygen reduction on a zinc surface at these conditions is  $0.1 \mu\text{A}/\text{cm}^2$ .

2. Convert  $\mu\text{A}/\text{cm}^2$  to coulombs/ $\text{cm}^2 \cdot \text{s}$ :

$$(0.1 \mu\text{A}/\text{cm}^2)(10^{-6}\text{A}/\mu\text{A})(1 \text{ C/s} \cdot \text{A}) = 10^{-7} \text{ C}/\text{cm}^2 \cdot \text{s}$$

3. Use Faraday's law to convert coulombs/ $\text{cm}^2 \cdot \text{s}$  to moles of oxygen/ $\text{cm}^2 \cdot \text{s}$ :

$$\begin{aligned} \text{mol O}_2/\text{cm}^2 \cdot \text{s} &= (1 \text{ eq Zn}/96,500 \text{ C})(1 \text{ mol Zn}/2 \text{ eq Zn})(10^{-7} \text{ C}/\text{cm}^2 \cdot \text{s}) \\ &= 5.2 \times 10^{-13} \text{ mol}/\text{cm}^2 \cdot \text{s} \end{aligned}$$

4. Estimate the rate in atoms/ $\text{cm}^2 \cdot \text{s}$ . Using Avagadro's number, convert moles to atoms:

$$\begin{aligned} \text{Rate} &= (5.2 \times 10^{-13} \text{ mol}/\text{cm}^2 \cdot \text{s})(6.02 \times 10^{23} \text{ atoms/mol}) \\ &= 3.1 \times 10^{11} \text{ atoms}/\text{cm}^2 \cdot \text{s} \end{aligned}$$

The mixed-potential diagram provides a useful view of the overall corrosion process and the principles that control it from the perspective of mixed-potential theory. Construction of a mixed-potential diagram from the polarization plot on Fig. 22-8 begins with the extrapolation of the polarization curves to their reversible potential as determined by the Nernst equation. The current density at which each of these two reactions reaches its reversible potential is the exchange current density for that half reaction on the surface of iron corroding in acid conditions. The construction of the diagram is illustrated in the following example problem.

### Mixed-Potential Diagram

### Example 22-3 Construction of a mixed-potential diagram

Construct a mixed-potential diagram for the results displayed in Fig. 22-8. Both  $[\text{Fe}^{2+}]$  and  $[\text{H}^+]$  are present at 1 mol/L and that the partial pressure of hydrogen,  $p_{\text{H}_2} = 1$  atm. The corrosion potential,  $E_{\text{corr}}$ , was measured to be  $-270$  mV. *Hint:* Use the slope of the anodic reaction ( $\beta_a$ ) of 40 mV/decade and the slope of the cathodic reaction ( $\beta_c$ ) of 120 mV/decade.

#### Solution

- A. The anodic reaction,  $\text{Fe} \rightleftharpoons \text{Fe}^{2+} + 2e^-$
1. Overview: Start at  $(i_{\text{corr}}, E_{\text{corr}})$  and extrapolate at the given anodic slope,  $\beta_a$ , until  $E_H$  is equal to the reversible potential for the anodic reaction,  $E_{\text{Fe}/\text{Fe}^{2+}}$ . The current at this potential is the exchange current for this reversible reaction on an iron surface.
  2. Find  $i_{\text{corr}}$ : From Example 22-1,  $i_{\text{corr}} = 110 \mu\text{A}/\text{cm}^2$ .
  3. Find  $E_{\text{corr}}$ :  $E_{\text{corr}}$  is obtained by measuring the potential of the corroding iron electrode when no current is imposed from the working electrode. In this problem,  $E_{\text{corr}}$  has been given as  $-270$  mV.
  4. Therefore  $(i_{\text{corr}}, E_{\text{corr}}) = (110 \mu\text{A}/\text{cm}^2, -270 \text{ mV})$ .
  5. By inspection of Table 22-4, the slope of the anodic reaction is found to be 40 mV/decade.
  6.  $\text{Fe}^{2+}$  is given as 1 mol/L. Thus the reversible potential for the anodic reaction can be directly obtained from Table 22-2:  $E_{\text{Fe}^{2+}/\text{Fe}^{3+}} = -440$  mV.
  7. Rearranging Eq. 22-8 for the anodic reaction:

$$\log(i_0) = \log(i_{\text{corr}}) + \frac{E_{\text{Fe}} + E_{\text{corr}}}{\beta}$$

$$\log(i_0) = \log(110) + \frac{270 - 440}{40} = -2.2$$

$$i_0 = 10^{-2.2} \mu\text{A}/\text{cm}^2$$

- B. The cathodic reaction,  $2\text{H}^+ + 2e^- = \text{H}_2(\text{g})$
1. Overview: Start at  $(i_{\text{corr}}, E_{\text{corr}})$  and extrapolate at the cathodic slope of  $\beta_c$  until  $E_H$  is equal to the reversible potential for the cathodic reaction,  $E_{\text{H}^+/\text{H}_2}$ . The current at this potential is the exchange current for the reaction.

- The starting point has already been determined in step 4 above ( $i_{\text{corr}}, E_{\text{corr}} = (110 \mu\text{A}/\text{cm}^2, -270 \text{ mV})$ ).
- The slope of the cathodic reaction is given as 120 mV/decade.
- For the purposes of these estimates,  $\text{H}^+ = 1 \text{ mol/L}$  and  $p_{\text{H}_2} = 1 \text{ atm}$ . Thus the reversible potential for the cathodic reaction,  $E_{\text{H}_2}$  is 0 mV (Table 22-2).
- Rearranging Eq. 22-8, the equation for the anodic reaction is

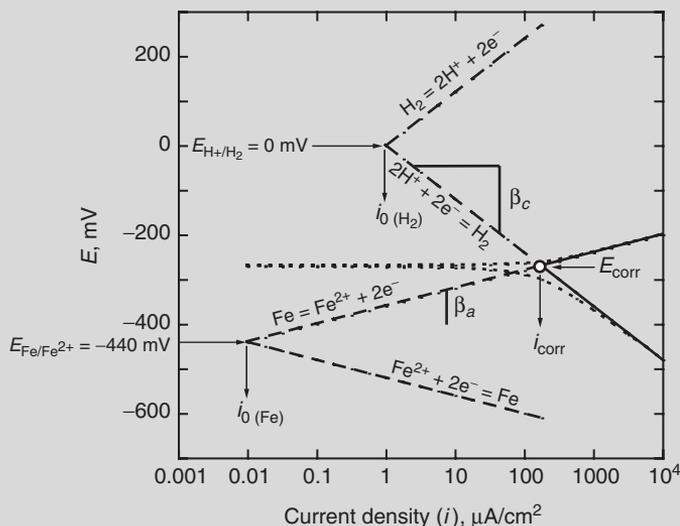

$$\log(i_0) = \log(i_{\text{corr}}) - \frac{E_{\text{H}_2} + E_{\text{corr}}}{\beta}$$

$$\log(i_0) = \log(110) - \frac{0 + 270}{120}$$

$$\log(i_0) = 0$$

$$i_0 = 1 \mu\text{A}/\text{cm}^2$$

- The completed mixed-potential diagram for iron corroding in acid solution is shown below.

Mixed potential diagram for iron corroding in acid solution.

In the diagram constructed in the preceding example, the information shown on Fig. 22-8 has been augmented so that the important relationships between the anodic and cathodic reactions can be better understood. Diagrams of this kind, often called Evans diagrams in honor of their originator, Dr. Evans of the United Kingdom, can be used to illustrate most of the important concepts in the corrosion of metals.

The shape of the plot is determined by three factors, each for the anodic and cathodic reactions: (1) the Nernst potential at which the reaction is at equilibrium ( $E_H$ ), (2) the exchange current of the reaction on the electrode surface ( $i_0$ ), and (3) the reaction's characteristic Tafel slope on the electrode surface ( $\beta_a$  or  $\beta_c$ ). The potential of the corroding electrode and the corrosion current are then determined as the point where the cathodic and anodic reactions are at equilibrium. As can be seen by inspection of the diagram, the reversible potentials of the cathodic and anodic reactions have important influence on the corrosion potential and on the corrosion rate. Note that the exchange current of the cathodic reaction for iron is on the order of a few nanoamperes per square centimeter, much lower than that of the anodic reaction, which is on the order of a few microamperes per square centimeter.

The preceding example (22-3) was prepared for the purpose of illustrating the dynamics of mixed-potential theory. Simple extrapolations such as those used in Example 22-3, while effective for iron immersed in sulfuric acid, are generally not practical under the environmental conditions in drinking water systems. In such systems it is unusual to find anodic and cathodic reactions where data gathered to the right side of  $i_{corr}$  on an Evans plot can be used to produce reasonable estimates of the exchange currents. Problems with simple extrapolation are particularly the case for cathodic reactions of the sort found in drinking water systems where scales and mass transfer limitations significantly influence the shape of the cathodic polarization curve. In fact obtaining good values of exchange current densities is so difficult that most important values are generally unknown. Nevertheless, the forces illustrated on Fig. 22-8 are involved in every corrosion reaction.

### Mixed-Potential Corrosion Model

Mixed-potential theory combines the concepts of thermodynamics, exchange current, and Tafel slopes to provide one integrated model of the corrosion process. The model basically puts the concepts depicted on Fig. 22-8 in mathematical form. The model arrangement can be derived by restructuring the Tafel equation in the following manner:

$$E_H = E_a^0 + \beta_a \log \left( \frac{i}{i_a^0} \right) \quad (\text{for the anode}) \quad (22-13)$$

$$E_H = E_c^0 - \beta_c \log \left( \frac{i}{i_c^0} \right) \quad (\text{for the cathode}) \quad (22-14)$$

where  $E_H$  = potential of electrode, mV  
 $E_a^0$  = reversible equilibrium potential for anodic half reaction, mV  
 $E_c^0$  = reversible equilibrium potential for cathodic half reaction, mV  
 $\beta_c$  = Tafel slope of cathodic reaction, mV/decade

$$\begin{aligned} \beta_a &= \text{Tafel slope of anodic reaction, mV/decade} \\ i &= \text{measured current density at } E_H, \mu\text{A/cm}^2 \\ i_a^0, i_c^0 &= \text{current density at } E_H = E_a^0 \text{ and } E_c^0, \text{ respectively} \end{aligned}$$

Measurements of electrode kinetics take advantage of the fact that the measured potential of the electrode with respect to the solution,  $E_H$  is well represented by Eq. 22-13, if its potential is depressed, and by Eq. 22-14, if its potential is elevated. If the reversible potential, the exchange current, and the Tafel slopes are known for both the cathodic and anodic reactions, then it is possible to combine Eqs. 22-13 and 22-14 to prepare an estimate of the corrosion current density ( $i_{\text{corr}}$ ):

$$\log(i_{\text{corr}}) = \frac{\beta_c \log(i_c^0) - E_a^0 + \beta_a \log(i_a^0) + E_c^0}{\beta_a + \beta_c} \quad (22-15)$$

At the corrosion current ( $i_{\text{corr}}$ ) the electrode potential ( $E_H$ ) is equal to the corrosion potential ( $E_{\text{corr}}$ ); therefore  $E_{\text{corr}}$  can be determined by either Eq. 22-13 or 22-14, once Eq. 22-15 is solved.

Estimating corrosion rates using these equations is not the most powerful thing about mixed-potential theory. In fact too many empirical parameters must be determined ( $i_c^0, i_a^0, \beta_a, \beta_c$ ) before Eq. 22-15 can be used. It is easier to just measure the corrosion rate. The more significant use of mixed-potential theory is to conceptualize the forces that drive the corrosion process and to anticipate the outcome of contemplated system changes.

The reversible potential of a cathodic or anodic reaction on the surface of a corroding electrode can be estimated using the Nernst equation as shown below:

$$E_H = E_H^0 + \left( \frac{2303RT}{nF} \right) \log \left( \frac{\text{oxidized}}{\text{reduced}} \right) \quad (22-16)$$

where  $E_H$  = reversible potential of reaction, mV  
 $E_H^0$  = reversible potential of reaction under standard temperature and pressure, mV  
 $R$  = universal gas constant, 8.314 J/K · eq  
 $T$  = temperature, K  
 $n$  = equivalents of electrons per mole in reaction, eq/mol  
 $F$  = Faraday's constant, 96,500 C/eq

## 22-4 Application of Electrokinetics

---

In the preceding sections the thermodynamics of metallic corrosion have been reviewed and an electrokinetic model of the corrosion process has been introduced. In the following discussion, some aspects of the application of these principles to understanding the corrosion of metallic conduits in water systems are reviewed.

### Applying Mixed-Potential Corrosion Model

A simple way of examining the implications of the mixed-potential model is to examine the effect of the strength of the acid solution on the corrosion rate. In the examples so far, it has been assumed that all ions are at a concentration of 1 mol/L. The consequences of a milder acid solution are examined in the following example using mixed-potential theory.

#### Example 22-4 Corrosion of iron in a mild acid solution

Construct a mixed-potential diagram to examine and compare the corrosion rate of iron at pH 0 and at pH 2 for the following conditions:

1. For the cathodic reaction:  $2\text{H}^+ + 2\text{e}^- \rightleftharpoons \text{H}_2$

$$\text{Exchange current} = 1 \mu\text{A}/\text{cm}^2$$

$$\text{Tafel slope} = 120 \text{ mV}/\text{decade}$$

2. For the anodic reaction:  $\text{Fe} \rightleftharpoons \text{Fe}^{2+} + 2\text{e}^-$

$$\text{Exchange current} = 0.01 \mu\text{A}/\text{cm}^2$$

$$\text{Tafel slope} = 40 \text{ mV}/\text{decade}$$

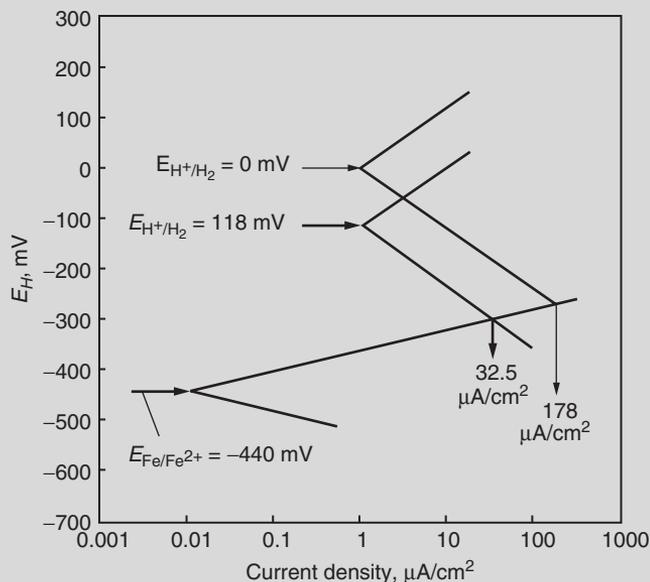

For purposes of this example, assume that  $\text{Fe}^{2+}$  is present at a concentration of 1 mol/L, that the partial pressure of  $\text{H}_2$  is 1 atm, and that the temperature is 25°C. The effect of any change in ionic strength may be neglected.

#### Solution

1. Determine the reversible potential for the anodic reaction. Because  $\text{Fe}^{2+}$  remains at 1 mol/L, the reversible potential of the anodic reaction remains at  $-440 \text{ mV}$  (Table 22-2).
2. Find the reversible potential of the cathodic reaction:
  - a. At pH 0,  $\text{H}^+ = 1 \text{ mol/L}$  and  $p\text{H}_2 = 1 \text{ atm}$ , thus from Table 22-2,  $E_H = 0 \text{ mV}$ .
  - b. At pH 2, Eq. 22-16 can be used:

$$\begin{aligned} E_H &= 0 \text{ mV} + \frac{59}{1} \log \left( \frac{1}{10^{-2}} \right) \\ &= 0 - 59 \times 2 = -118 \text{ mV} \end{aligned}$$

3. Compare the corrosion rates at pH 0 and 2. A mixed-potential diagram in which the two conditions described is presented in the diagram below. Using both the diagram and Eq. 22-16, a reduction in corrosion rate of more than fivefold is estimated when the pH is changed from 0 to 2. All this change results from the reduction in the reversible potential of the cathodic reaction.

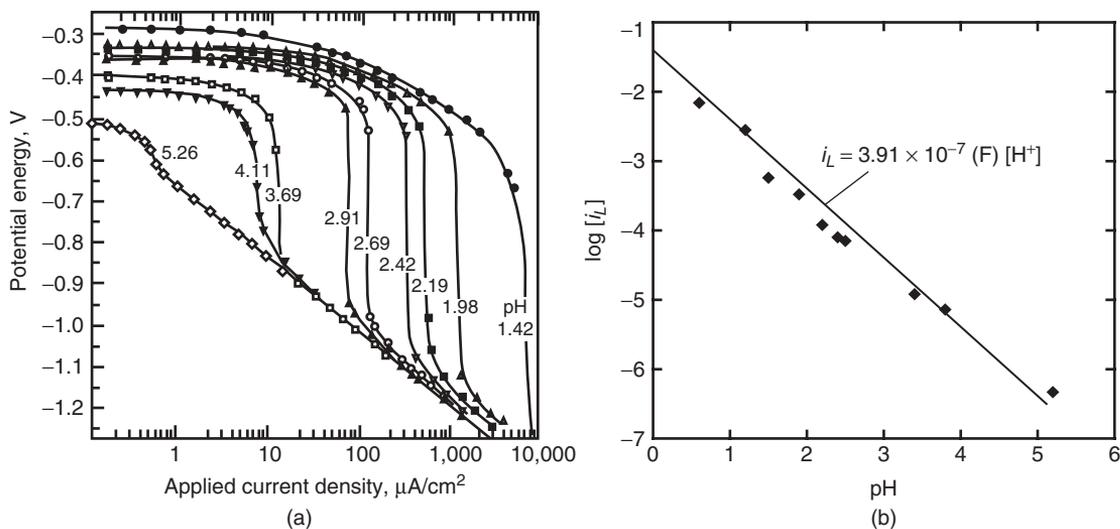

So far, the examination of mixed-potential theory has been limited to *activation polarization*. In activation polarization, the change in electrode potential is governed by the activation energy of the redox reaction on the electrode surface. Although common with iron in acid solution and useful for purposes of illustration, activation polarization does not occur under the conditions present in drinking water systems. A more common rate-controlling phenomenon in such systems is concentration polarization. In concentration polarization, the rate of the redox reaction (and hence the current flow) is not governed by the activation energy but by mass transport considerations.

Mass transfer limitations are particularly important with respect to the cathodic reactions where a chemical species in the water is to be reduced ( $\text{H}^+$ ,  $\text{O}_2$ ,  $\text{Cl}_2$ , etc.) and must be transported from the bulk solution to the electrode interface. Under these circumstances, concentration polarization results in a maximum or limiting current that cannot be exceeded. Above the limiting current, current flow is relatively insensitive to electrode potential. The extensive literature on mass transport can be used to examine the impact of flow rate, shape, and other factors on limiting current, but this is beyond the scope of this discussion. In simple terms, the diffusion-limited current density may be characterized in the following manner:

$$i_L = nF k_f C_b \quad (22-17)$$

### Concentration Polarization

**Figure 22-9**

Stern's experiments on limiting current for reduction of hydrogen ion in quiet (unstirred) NaCl solution at room temperature: (a) cathodic polarization curves at various pHs and (b) limiting current versus pH.

where  $i_L$  = limiting current density,  $\text{A}/\text{cm}^2$   
 $k_f$  = mass transfer constant for reacting ions,  $\text{L}/\text{cm}^2 \cdot \text{s}$   
 $C_b$  = concentration of ions in bulk solution,  $\text{mol}/\text{L}$   
 $n$  = equivalents of ions per mole in reaction,  $\text{eq}/\text{mol}$   
 $F$  = Faraday's constant ( $96,500 \text{ C}/\text{eq}$ )

In an unstirred solution with dissolved oxygen as the cathodic reactant (electron acceptor), the value of  $k_f$  is approximately  $9.2 \times 10^{-7} \text{ L}/\text{cm}^2 \cdot \text{s}$ . Stern (1955) conducted a series of experiments examining the limiting cathodic current for the reduction of hydrogen ion on pure iron at several different pH values in a 4 percent NaCl solution at room temperature. The diffusion-limited current found in Stern's experiments and the data fitted to Eq. 22-17 are shown on Figs. 22-9a and 22-9b, respectively. Based on Fig. 22-9a, in an unstirred solution with hydrogen ion as the electron acceptor, the value of  $k_f$  is approximately  $3.91 \times 10^{-7} \text{ L}/\text{cm}^2 \cdot \text{s}$ .

### Limitations of Mixed-Potential Theory

Mixed-potential theory is a powerful way of looking at the fundamental driving forces for the corrosion process, and useful perspectives can be gained by examining the corrosion of water conduits using the mixed-potential approach. At the present time, with the exception of the work of Reiber (1989, 1991) on copper and lead solder, the power of mixed-potential theory in exploring the internal corrosion of drinking water systems remains largely unexplored.

### Example 22-5 Further examination of effect of pH on rate of iron corrosion in acid solution

Review Example 22-4 and determine if the conclusion derived from the analysis can be altered in light of the concept of limiting current. Also examine the fundamental changes that take place as higher pH values are considered and discuss the implications.

#### Solution

- Using Eq. 22-17, determine the limiting current. From the paragraph preceding this example,  $k_f = 3.91 \times 10^{-7} \text{ L/cm}^2 \cdot \text{s}$ .

- At pH 0,  $C_b = C_{\text{H}^+} = 10^0 \text{ mol/L}$ :

$$i_L = (1 \text{ eq/mol})(3.91 \times 10^{-7} \text{ L/cm}^2 \cdot \text{s})(96,500 \text{ C/eq})(10^0 \text{ mol/L})(1 \text{ A/C} \cdot \text{s})$$

$$= (3.77 \times 10^{-2} \text{ A/cm}^2 \cdot \text{s})(10^6 \text{ } \mu\text{A/A}) = 3.77 \times 10^4 \text{ } \mu\text{A/cm}^2 \cdot \text{s}$$

- At pH 2,  $C_b = C_{\text{H}^+} = 10^{-2} \text{ mol/L}$ :

$$i_L = (3.77 \times 10^4 \text{ } \mu\text{A/cm}^2 \cdot \text{s})(10^{-2}/10^0) = 377 \text{ } \mu\text{A/cm}^2 \cdot \text{s}$$

- Compare the limiting current computed in step 1 to the corrosion current predicted earlier. For both pH 0 and pH 2, the corrosion rates estimated in Example 22-4 are lower. Thus, the conclusions reached in Example 22-4 do not change.
- Examine the effect of higher pH values on the limiting current.
  - Using the procedure from step 1, compute the limiting value as a function of pH. The computed values are summarized in the following table:

pH	$i_L, \mu\text{A/cm}^2$
0	37,770
1	3,777
2	378
3	37.8
4	3.78
5	0.378

- Between a pH of 4 and 5, the limiting current for hydrogen reduction falls below the exchange current density for hydrogen ion reduction on an iron surface as reported in Table 22-4. Under these conditions, corrosion is no longer possible via this mechanism.

Based on a limited exploration of mixed-potential theory, it appears that the determination of a few critical constants for certain materials of importance in water systems could lead to a powerful system for comprehensive modeling of corrosion behavior. In fact, the corrosion process is complex, and mixed-potential theory is not well suited for making direct predictions of corrosion rates under the conditions in which drinking water systems operate. As a result, it is important to understand the limitations of mixed potential theory as well as its strengths.

Most shortcomings have to do with the parameters the model uses. In summary the parameters required for the model are:

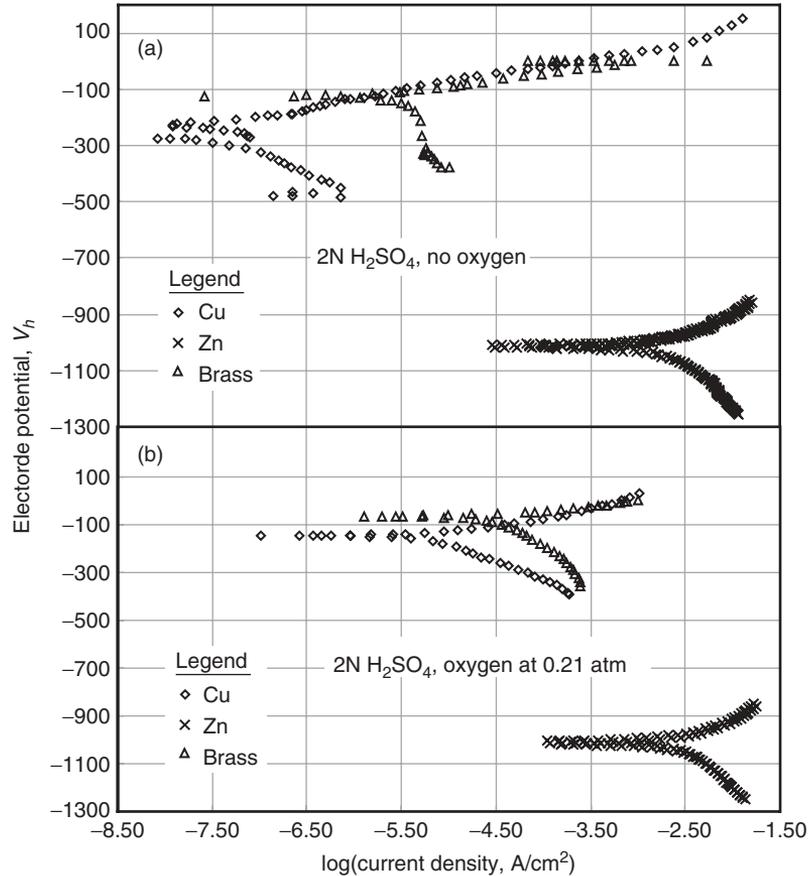

1. The reversible potential for the cathodic and anodic half reactions.
2. The exchange currents for the cathodic half reactions on the materials of interest. For drinking water systems, these would include cast iron, ductile iron, mild steel, galvanized iron, lead, copper, solder, and brass, among others. Electron acceptors of interest as cathodic reactants include the hydrogen ion, oxygen, and all the oxidants being used in drinking water systems. These include free chlorine, combined chlorine, chlorine dioxide, ozone, hydrogen peroxide, hydroxyl radical, and permanganate.
3. The Tafel slopes for the anodic reactions for the conduit materials.
4. The Tafel slopes for the various electron acceptors on these same materials.

Some of the limitations of each of these critical parameters are summarized in Table 22-5. The discussion of these limitations should not be taken to suggest that the principles of mixed-potential theory do not apply to corrosion of water conduits. Rather, it is important to understand that much needs to be learned before the corrosion process in water systems can be modeled adequately and the nature of further research determined. The relationship between scale formation and these electrokinetic behavior is particularly important.

One of the more important limitations identified in Table 22-5 is understanding the concentration of oxidized ions immediately adjacent to the corroding metal surface. It should be noted that in Table 22-4 the anodic constants are only for iron. Constants for copper, lead, and zinc are not provided, even in acid solution where, presumably, they are soluble as well. In fact, iron is the only common metal that corrodes in acid solution at a potential that corresponds to reasonably high levels of oxidized ion (e.g., near its standard potential). Recently published data on the polarization curves for copper, zinc, and brass in a solution of 2 N  $\text{H}_2\text{SO}_4$  (Jinturkar et al., 1998) are presented on Fig. 22-10. It should be noted that the corrosion potential of these metals is substantially below their standard potential, suggesting that, despite the strong acid conditions, the surface of

**Table 22-5**  
Parameters of mixed-potential model and their limits

Parameter	Comment on Limitations
$E_a$ , reversible potential for anodic reaction	For conceptual purposes, the potentials in Table 22-2 are often used directly. But these values are only valid at unimolar concentrations and at standard temperature and pressure. Correction for pressure is generally not significant and corrections for temperature, while complicated, are straightforward. These can be accomplished using the same principles as are used for correction of other chemical equilibria. Where the reversible potential at the anode is concerned, the big difficulty is that the concentration of the oxidized form of the metal at the electrode surface (e.g., $\text{Fe}^{2+}$ ) is not ordinarily available. In these examples the ion is often assumed to be at unimolar concentration (allowing the values in Table 22-2 to be used directly). Generally, the potentials of corroding surfaces are at or below this reversible potential itself, suggesting that the concentration of oxidized ions at the anode surface is very low. Assuming that the concentration of these ions is controlled by solubility phenomena at the electrode surface is a promising approach that needs to be explored further.
$E_c$ , reversible potential for cathodic reaction	Perhaps the reversible potential of the cathodic reactions is the parameter that can be most easily estimated with what we know today. This reversible potential is not dependent on the material corroding. Normally, it is just dependent on the properties of the solution, such as the concentration of the oxidizing agent of interest, and it can be determined using the Nernst equation.
$i_a^0$ and $i_c^0$ , exchange current densities for anodic and cathodic reactions at their reversible potential	The exchange current densities for metals of interest in water systems cannot be directly measured. Moreover, they change as the film on the metal's surface changes. These two parameters are probably the most inaccessible, and we are forced to make some generous assumptions to estimate them.
$\beta_a$ and $\beta_c$ , Tafel slopes of anodic and cathodic reactions	Polarization experiments can be conducted and the corresponding Tafel slopes measured, but, except for acid conditions, the factors that control these slopes are poorly understood. This is particularly true of cathodic Tafel slopes on metals with the sort of scales that normally develop after a period of sustained service in drinking water systems. It is not always so easy to determine whether the slope observed is under activation control or is controlled by some other process, such as diffusion.

**Figure 22-10**

Polarization curves for copper, zinc, and brass: (a) in acid solution with no oxygen and (b) in acid solution with oxygen at 0.21 atm (data from Jinturkar, et al., 1998).

the metal is not exposed to high concentrations of the  $Me^{2+}$  ion. In fact, the levels that are implicated are far below solubility. It is likely that the data can only be explained through detailed knowledge of the microstructure and surface chemistry of the corroding surface.

### Example 22-6 Estimation of $Me^{2+}$ concentrations near the surface of zinc and copper corroding in acid solution

Using the data on Fig. 22-10 for acid solution in the absence of air, estimate how low the concentration of Zn(II) or Cu(II) ions would have to be to bring the reversible potential 50 mV below the corrosion potentials observed.

**Solution**

1. The corrosion potentials, estimated using Fig. 22-10, are as follows:

$$\text{Copper} \quad -235 \text{ mV}$$

$$\text{Zinc} \quad -1010 \text{ mV}$$

2. The reversible potential at standard conditions are found in Table 22-2:

$$\text{Copper} \quad +340 \text{ mV}$$

$$\text{Zinc} \quad -763 \text{ mV}$$

3. According to mixed-potential theory, the reversible potential of the anode must be *below* the metal's corrosion potential. According to the Nernst equation, this is possible if the oxidized ion is at a low enough concentration:

$$E_H = E_H^0 + \frac{59}{2} \log(\text{Me}^{2+})$$

4. Determine the concentration of the metal ions necessary to bring the reversible potential 50 mV below the corrosion potential.

- a. The required values are:

$$\text{For Cu(II)} : E_H = -235 \text{ mV} - 50 \text{ mV} = -285 \text{ mV}$$

$$\text{For Zn(II)} : E_H = -1010 \text{ mV} - 50 \text{ mV} = -1060 \text{ mV}$$

- b. Using the Nernst equation to estimate the level of metal ions:

For copper,

$$-285 \text{ mV} = +340 \text{ mV} + 29.5 \log[\text{Cu}^{2+}]$$

Rearranging,

$$\log[\text{Cu}^{2+}] = \frac{-285 \text{ mV} - 340 \text{ mV}}{29.5} = -21.2$$

$$[\text{Cu}^{2+}] = 10^{-21.2} \text{ mol/L}$$

For zinc,

$$-1060 \text{ mV} = -760 \text{ mV} + 29.5 \log[\text{Zn}^{2+}]$$

Rearranging,

$$\log[\text{Zn}^{2+}] = \frac{-1060 \text{ mV} + 760 \text{ mV}}{29.5} = -10.2$$

$$[\text{Zn}^{2+}] = 10^{-10.2} \text{ mol/L}$$

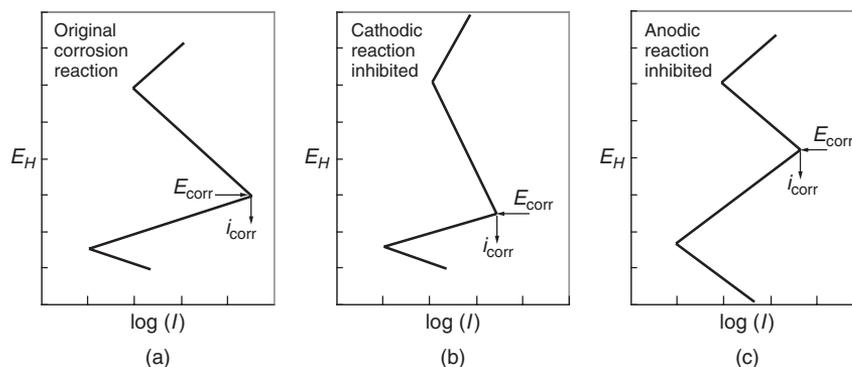

Because these reactions take place in a solution of 2 N  $\text{H}_2\text{SO}_4$ , the metal concentrations are extraordinarily low when compared to traditional solubility equilibria for metal hydroxides. The current tools available are not sufficient to characterize these electrode phenomena. Current understanding is limited to observations that can be made from the figure, namely: (1) brass corrodes at a potential that is higher than that for either of its alloy components, copper and zinc, especially zinc, (2) copper corrodes at an extremely low rate in acid solutions, (3) zinc, on the other hand, corrodes much more rapidly, and (4) the presence or absence of oxygen seems much more significant to copper and 60/40 brass (60 percent copper, 40 percent zinc) than it does to zinc.

Changes in the condition of the corroding metal surface with time can also have important impacts on the exchange current that the surface can support. As the condition of the surface changes, the Tafel slopes change, and it is likely that the exchange currents change as well. For example, while examining the behavior of copper tubing exposed to Seattle tap water over a 100-day period, Reiber (1989) observed a shift in the anodic Tafel slope from 55 to 95 and in the cathodic slope from 145 to 245.

## Inhibition of Corrosion

The inhibition of corrosion involves actions that can be taken to reduce the rate of corrosion by cathodic and anodic reactions. There are several modes of corrosion inhibition that are implicated by the mixed-potential theory of corrosion. In the future, it seems likely that inhibitors will be designed to target each of the parameters that control the mixed-potential plot: the exchange current, the reversible potentials, and the response of both of the anodic and cathodic reactions to changes in polarization. Current understanding is not adequate to support interpretations that are too complex.

It is useful to think of inhibitors as being either anodic or cathodic in their action. These two modes of corrosion control are illustrated on Fig. 22-11. The original corrosion reaction is illustrated on Fig. 22-11a. The sketch displayed on Fig. 22-11b illustrates the effect of actions taken to

**Figure 22-11**  
Modes of corrosion inhibition: (a) original corrosion reaction, (b) cathodic reaction inhibited, and (c) anodic reaction inhibited.

inhibit the cathodic reaction, for example, limiting the mass transfer of the electron acceptor (like  $H^+$ ,  $O_2$ , or  $HOCl$ ) to the cathode. Figure 22-11c is drawn to show the effect of actions taken to inhibit the anodic reaction. Reducing the solubility of the oxidized metal, causing the reversible potential of the anodic reaction to increase is such an action. Note that actions taken to inhibit the anodic reaction raise the potential of the corroding electrode, whereas actions taken to inhibit the cathodic reaction lower it. Thus, some basic conclusions about the mechanism of the action of a corrosion inhibitor can be drawn from the impact it has on the potential of the corroding specimen.

Insights about the mechanism of inhibition can be gained from measurements of the potential of the corroding surface. There are complications in making this measurement as the potential is not always stable, but insight can be gained by looking at the change in potential before and after the inhibitor is applied and over time as changes in the surface scales take place. Nevertheless, in an effort to gather data to understand the mechanisms underlying the corrosion of drinking water systems, the water industry has not gathered enough data on these potential measurements. As a result, the potentials that typically occur are not available. The following approximate potentials were reported after 96 h of exposure to Seattle water that had been adjusted to pH 8 and saturated with dissolved oxygen (Reiber et al., 1986):

Galvanized iron	-800 mV
Black iron	-200 mV
Copper	0 mV

The corrosion potential of 50/50 Pb-Sn solder was measured over a period of time:

Time of Exposure, Days	Corrosion Potential, mV
1	-345
14	-200
180	20

These and other observed corrosion potentials are summarized and compared with the standard electrode potentials of the relevant metals in Table 22-6. These corrosion potentials are given for purposes of illustration, and it is important to understand that the corrosion potentials observed in other water supplies will be different. Nevertheless, some important observations can be made. Once again, with the exception of iron, the corrosion potentials are lower than the standard electrode potentials. Second, it should be noted that the corrosion potential of copper is substantially higher than that of either galvanized iron or lead-tin solder. The higher potential for copper has important implications where galvanic corrosion is concerned.

**Table 22-6**

Comparison of observed corrosion potentials and standard electrode potentials

<b>Metal</b>	<b>Potential in Seattle Water after Few Days, mV</b>	<b>Potentials Observed by Jones in Seawater, mV</b>	<b>Metals in Alloy</b>	<b>Standard Electrode Potential, mV</b>
Galvanized iron <sup>a</sup>	-800	—	Fe <sup>a</sup> Zn <sup>a</sup>	-440 -760
Steel	-200	-603	Fe	-440
Copper	0	-350	Cu	+340
Lead-tin solder	-200	—	Pb Sn	-130 -140
Zinc	—	-1100	Zn	-760
Brass	—	-378	Cu	+340

30% Cu, 70% Zn				
Brass	—	-999	Zn	-760
15% Cu, 85% Zn				

<sup>a</sup>A new hot-dip galvanized pipe actually presents an alloy surface to the water that is 95% zinc (see Fig. 22-22). As the pipe ages and this nearly pure zinc layer is corroded away, alloy layers that are increasingly iron rich are exposed. Thus the corrosion potential of a galvanized pipe can be expected to shift gradually from the corrosion potential of nearly pure zinc to nearly pure iron over time. The reported potential for Seattle water is representative of fairly new pipe.

## 22-5 Microbiologically Induced Corrosion

Microorganisms can play a significant role in fostering corrosion of pipe materials. Bacteria have the ability, in certain situations, to:

1. Form microzones of high acidity or high concentrations of corrosive species.
2. Increase electrolytic concentration at surface sites.
3. Favor electron transfers.
4. Mediate the oxidation of reduced chemical species.
5. Disrupt the protective influence of surface films.
6. Mediate the removal of corrosion reaction products, enhancing the corrosion kinetics.
7. Take advantage of local gradients in redox potential to obtain energy for their metabolic needs.

Thus, bacteria are able to facilitate corrosion kinetics by accelerating the rate of redox reactions. Even anaerobic bacteria may thrive in otherwise aerobic water because of the formation of microbiological consortia in the biofilms on the surface of pipes, especially when the surface of the pipe

has the heterogeneous surface associated with pitting or other microscopic irregularities. The most significant bacteria involved in mediation of corrosion reactions are sulfate reducers, methane producers, nitrate reducers, sulfur bacteria, and iron bacteria. In particular, the sulfate-reducing and iron bacteria groups are nuisances in corrosive behavior.

Under anaerobic environments, such as those that may occur within a corrosion pit, sulfate-reducing bacteria, such as *Desulfovibrio desulfuricans*, obtain their energy needs by reducing sulfate to sulfite, elemental sulfur, or other reduced forms. Bacteria in general can thrive at an interface between oxygenated and anaerobic areas because of the energetic difference associated with the oxygen gradient and the presence of oxidized species such as sulfate in an anaerobic region where sulfate is not thermodynamically stable. Sulfate reducers require ferrous iron and hydrogen gas as substrates. The uptake of  $\text{Fe}^{2+}$  and  $\text{H}_2$ , which are reaction products of the corrosion of iron metal, serves to lower the concentration of  $\text{Fe}^{2+}$  and  $\text{H}_2$  in the microzone and thereby to enhance the kinetics of the forward direction of the corrosion reaction.

Hydrogen-oxidizing bacteria promote corrosion by removing the hydrogen gas produced at the cathode and, thus, depolarizing it. Iron bacteria such as *Gallionella* and *Sphaerotilus lepothrix* are aerobic organisms that mediate the oxidation of Fe(II) to Fe(III), reducing Fe(II) at the anode surface and depolarizing it. Iron bacteria may also be involved in the formation of  $\text{FeOOH}$  (goethite), which can result in the mineralization of *Gallionella* colonies and the formation of encrustations (Kolle and Rosch, 1980). Nitrate-reducing bacteria and methane-producing bacteria may play a role in altering the pH of a surface site, affecting the driving force for a corrosion reaction.

Current understanding of the interactions of microbiological and electrochemical reactions does not permit quantitative prediction of the role of microorganisms in enhancing corrosion reactions. It appears likely that complex ecosystems involving a variety of genera can arise in microzones on the surface of pipes where corrosion reactions take place. Empirical evidence suggests a major role for microbiological reactions in some systems. For example, in many instances, the chlorination of well water supplies has reduced corrosion rates, suggesting that disinfection can inhibit the role of bacteria. Laboratory studies of the corrosion of cast iron shows that unsterilized water can lead to significantly more rapid corrosive attack than sterilized water. Similarly, aeration of otherwise anaerobic or microaerobic water can reduce the activity of anaerobic bacteria.

A practical consequence of the effect of microorganisms in promoting corrosion is the relationship between disinfection and corrosion. Water utilities can experience relatively severe corrosion in parts of the distribution system where water stagnates. The decline in chlorine residual and lack of scouring action in distribution dead ends result in increased growth of microorganisms on surfaces, especially where pitting has taken place or

**Figure 22-12**  
Bacteria attacking copper  
surface.

organic content is high. As a result, corrosive failures and main breaks tend to be more common in these locations. It is common practice for utilities to flush such dead ends routinely to minimize bacterial growth by scouring and by lowering the detention time of the chlorinated water.

Bacteria have even been found to attack copper surfaces (Lin and Olson, 1995). In the SEM photomicrograph shown on Fig. 22-12, from unpublished work of B. Olson (UC Irvine) and M. Keitz (U. Minnesota) gram-negative bacteria are shown growing on the surface of a copper ring. Copper is often thought to be toxic, but a number of instances have been reported where biological-mediated corrosion has occurred in copper tubing, particularly pitting. This photo is a particularly striking example demonstrating how some microorganisms can attack unlikely surfaces.

## 22-6 Surface Films and Surface Scales

---

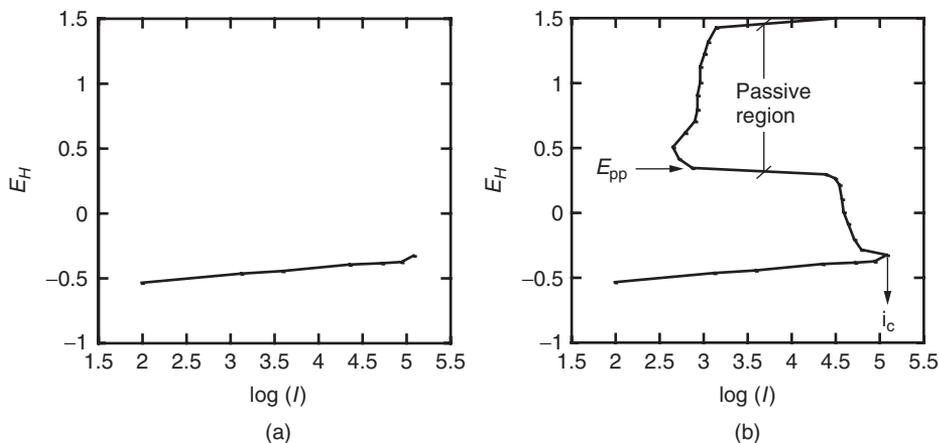

When they are not lined, the conduits used to transport water appear to operate with the water in direct contact with the metal. In reality, all metals form a film on their surface upon contact with water, and these films (or scales) have important influences on the metal's interaction with the water. Zinc is a good illustration of this occurrence. Based on thermodynamics, it would appear that zinc, with a reduction potential of  $-760$  mV, should be oxidized rapidly in water, especially if oxygen ( $+1230$  mV) is present. In fact, in many domestic waters, the zinc coating on galvanized pipe is quite stable. The stability of zinc is, in large part, due to the fact that zinc forms a stable oxide scale that interferes with the corrosion process.

In the middle of the nineteenth century Faraday performed an experiment that illustrates how important these surface films can be. Faraday observed that if he immersed iron in dilute nitric acid, it reacted immediately, reducing hydrogen ion to emit hydrogen gas while the metal was rapidly oxidized. On the other hand, if he immersed the iron in concentrated nitric acid, it did not react. Moreover, even after the concentrated acid solution was subsequently replaced with a more dilute one, the iron continued in a passive state for quite some time. On the other hand, in the dilute acid solution, the iron specimen began to react violently if it was scratched. Faraday suggested that these properties were imparted to iron by an invisible surface oxide film, formed upon exposure to the concentrated nitric acid. Now, many decades later, it is known that he was right. Faraday had identified the special role that surface films can play in the corrosion process. It turns out that the films that form on the surfaces of metals when they are submerged in water play a critical role in the corrosion process, particularly oxide films.

Passivity involves the formation of a nearly “perfect” protective oxide coating on transition metals, which reduces the rate of corrosion significantly. Since Faraday’s time, the term *passivation* has been used in the corrosion literature to describe the phenomena he observed. Passivity is used in reference to a special condition that can be achieved only with transition metals and only when these are elevated to a fairly high anodic potential, either by means of an external electromotive force or by the means of an oxidizing agent in solution, such as the fuming nitric acid that Faraday used. Under these conditions, transition metals form a nearly “perfect” protective oxide film, and their corrosion rate drops several orders of magnitude (one order is usual, three orders is common, six orders has been demonstrated). Also since Faraday’s experiment, it has been demonstrated that other oxidants besides nitric acid can form passivating films on the surface of iron (e.g., salts of chromate and nitrite). It has also been demonstrated that passivation can be accomplished by adjustment of the metal’s electrical potential by means of an external electromotive force. More than that, it is now possible to make stainless steels, steels that are able to form such films in the presence of the oxidants present in natural environments.

The passivation phenomenon is illustrated in the Evans diagrams on Fig. 22-13 in which the different behavior of active and active-passive metals is contrasted. Ordinary, active metals exhibit the behavior shown on Fig. 22-13a where, as the oxidizing power of the environment is increased, the potential of the metal surface is increased and the metal corrodes more rapidly. More specifically, the corrosion current density increases logarithmically with an increase in the electrode potential. The logarithmic increase corresponds to the anodic reaction line in the mixed-potential diagrams shown earlier in this chapter.

## Passivity

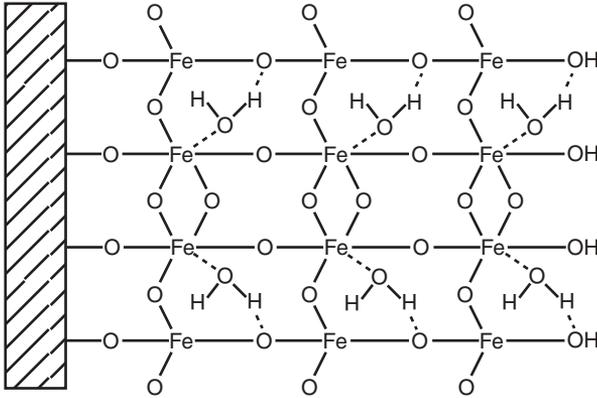

**Figure 22-13**  
Polarization diagrams for different metals: (a) active and (b) active-passive.

With certain transition metals, however, once the potential of the metal surface exceeds a certain critical *passivation potential* ( $E_{pp}$ ) (sometimes just called *critical potential*), the corrosion rate suddenly decreases. As potential is further increased, the corrosion rate remains low over a considerable range. In the zone where the corrosion rate remains low, the metal is described as passivated. The behavior shown on Fig. 22-13b is representative of the behavior of an active-passive metal such as iron. Once the potential of the electrode is driven past a certain critical potential ( $E_{pp}$ ), the anodic current (corrosion rate) drops dramatically. Among materials used in water systems, iron and all its alloys are active-passive, whereas the others, copper, zinc, and lead, are active only. This behavior has important implications for corrosion control.

Passivation behavior is observed with transition metals such as iron, nickel, silicon, chromium, titanium, and their alloys. For a transition metal to become passivated, two conditions must be met. The potential of the metal must be raised above its  $E_{pp}$ , and the cathodic reaction must support a current density greater than the *critical current density*,  $i_c$ . If the current density cannot reach this level, the cathodic reaction will never drive the reaction into the passive zone.

Although the subject of a great deal of research over the 16 decades since Faraday conducted his experiment, the exact nature of the passivating film and the mechanism by which such films protect the surface of metals on which they form is only just becoming understood. Most models of the passivation process envision the formation of a surface film, which is stable over a considerable range of potentials. In the case of iron, the passive layer appears to consist of an oxide of  $\text{Fe}_{3-x}\text{O}_4$  with a spinal structure, varying in composition from  $\text{Fe}_3\text{O}_4$  (magnetite), in oxygen-free solutions, to  $\text{Fe}_{2.67}\text{O}_4$

**Figure 22-14**

Formation of hydrated passive film on iron (Adapted from Pou et al., 1984).

in the presence of oxygen but which can, under certain conditions, transmit electrons from the metal surface to electron acceptors on the film surface (Newman, 2001). A schematic representation proposed by Bockris and collaborators (Pou et al., 1984) is shown on Fig. 22-14.

Stumm argues that it is the kinetics of the dissolution of this oxide film that controls the rate of corrosion. Perhaps more important, Stumm argues that dissolution also controls that rate of corrosion for the protective oxide films on copper and zinc as well (Grauer and Stumm, 1982; Stumm, 1990, 1998). If this view is correct, then understanding the phenomena that influence these kinetics may offer important insight into understanding corrosion kinetics as well. Moreover, passivity may just be an extreme case along a continuum of relative protection of metals by oxide films.

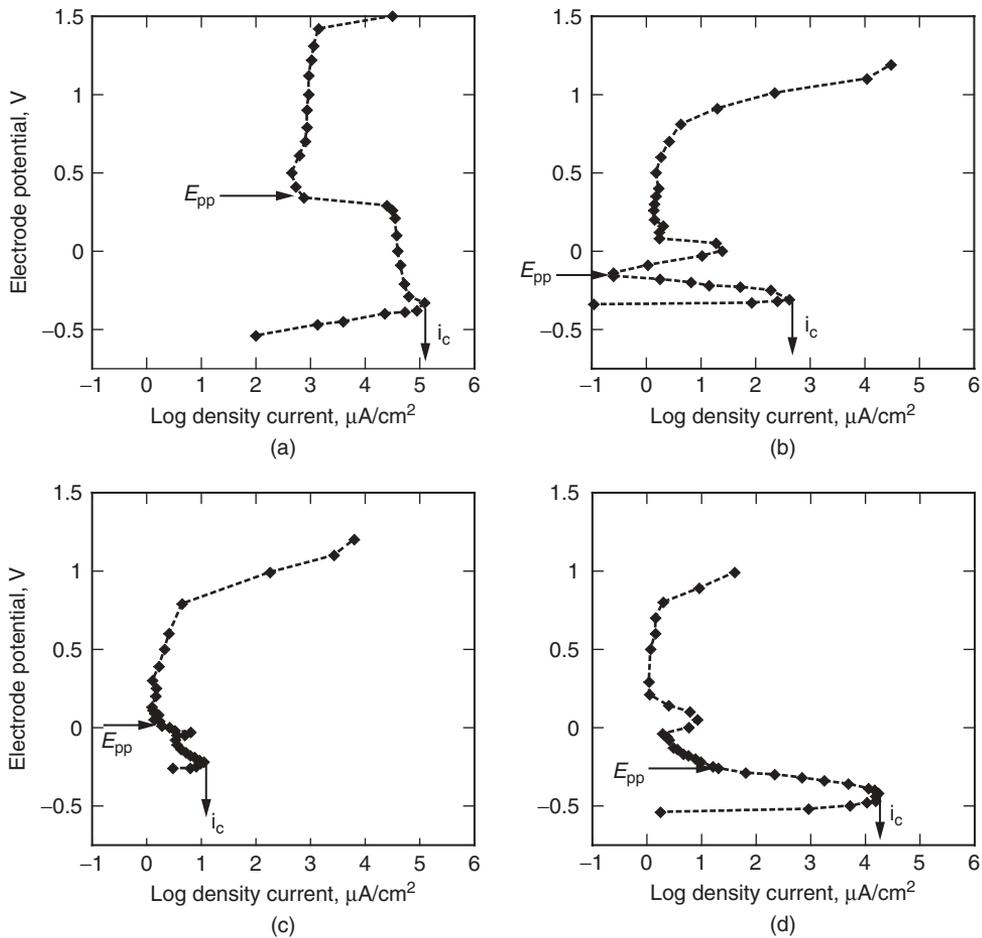

All the iron alloys used to transport drinking water exhibit active/passive behavior, though for many alloys, the conditions in drinking water rarely raise the surface of the metal to the potential where it can be passivated. Oxygen is the principal oxidant available in these systems, and, in water at room temperature, at equilibrium with oxygen in the atmosphere, the cathodic current is limited to about  $100 \mu\text{A}/\text{cm}^2$ . For iron to be passivated in tap water at room temperature, its critical current ( $i_c$  on Fig. 22-13) must be less than  $100 \mu\text{A}/\text{cm}^2$ . Based on experience, the critical current density for pure iron under near neutral conditions is on the order of  $500 \mu\text{A}/\text{cm}^2$  or more. As a result true passivation is not likely with a normally aerated solution.

Stainless steels have a composition designed to address this issue. There are two parts to the corrosion process, the cathodic process and the anodic process. If it is not possible to change the cathodic process, perhaps it is possible to change the anodic process. Changing the anodic process can be accomplished through alloying of the metal. Certain elements, when alloyed with iron, lower the critical current density of the metal ( $i_c$ ). Alloying

## Stainless Steels

with chromium significantly reduces the passivation potential ( $E_{pp}$ ) as well. Thus, the shape of the anodic polarization curve can be modified by using the alloying process.

The polarization curves for iron, 430 SS, 304L SS, and 316 SS in unagitated 1 N  $H_2SO_4$  are displayed on Fig. 22-15. Also shown are the passivation potential and the critical current. All the stainless steels have a passivation potential substantially below that of iron. As a result they can be passivated in milder environments. On the other hand, the critical current required for passivation ranges from  $104.3 \mu A/cm^2$  in the case of 430 SS to as low as  $10 \mu A/cm^2$  in the case of 316 SS. As a result, only 316 SS is passivated in most aerated tap water, with 304L SS being passivated when mass transfer is optimized.

**Figure 22-15**

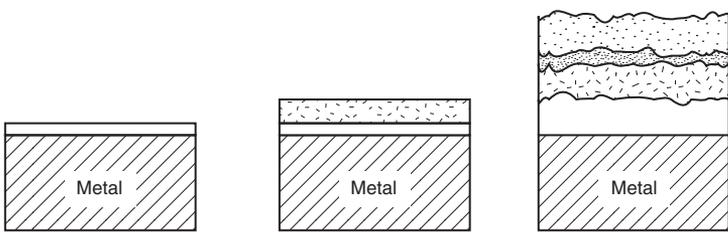

Polarization curves for iron and some common stainless steels in 1 N  $H_2SO_4$ : (a) iron, (b) 304L SS, (c) 316 SS, and (d) 430 SS.

In air-saturated solutions of 1 N sulfuric acid, with no agitation, the limiting current density for cathodic reduction of oxygen is about  $100 \mu\text{A}/\text{cm}^2$  and the reversible potential for this reaction is about  $-0.06 \text{ V}$ . As a result both iron and 430 SS are vulnerable in such a solution because of their high critical current densities. Type 304L may be stable under some conditions and type 316 SS should be fairly resistant at any reasonable dissolved oxygen (DO) levels because its critical current density is substantially less than  $100 \mu\text{A}/\text{cm}^2$ . These tests were all conducted in 1 N sulfuric acid. Consequently, the results do not directly translate to experience in domestic water supplies (lowering the pH significantly raises the required critical current by increasing the rate of dissolution of the passive layer). Nevertheless the behaviors illustrated on Fig. 22-15 demonstrate an important lesson about why stainless steels behave as they do.

Thus, the protection afforded by surface oxides extends beyond the narrow definition of passivation alone. Understanding and controlling the formation and behavior of surface films and scales on metal water pipes is the key to controlling both corrosion and metals release. Virtually all these scales are protective to some degree. As a result, the corrosion rate of fresh metal coupons is almost always higher than the corrosion rate observed after a period of exposure. The scale found on water pipes can be thought of as organizing into three broad categories: passive films, thin scales, and thick scales (see Fig. 22-16). In drinking water systems thin and thick scales are the most common. The thin scales, which are tightly adherent, usually form in a short time, and they can often be quite protective, which is certainly the case with the oxide scale that forms on zinc and also on copper. It appears that it is also true of the carbonate and hydroxycarbonate scales that form on lead. All these materials usually achieve equilibrium with the water they are exposed to in a few weeks. The most common examples of thick scales occur on iron conduits. In many cases these scales grow to such great thickness that they seriously compromise the conduit's capacity to carry water. Obviously, such scales also continue to form over a long period of time. Under some circumstances, iron water conduits require more than a year or two before their corrosion rates begin to stabilize.

Earlier in the chapter it was noted that none of the metals used to construct water conduits are thermodynamically stable in water. Thus, it is logical that the scales that form on the surface of the metals make the metals last long enough to be useful for transporting water. Thus it appears that the minerals that form on the surfaces of these metals are so inert and insoluble that they can protect the surface of the metal. The solubility of the common oxidation states of iron, zinc, copper, and lead in a solution having a total dissolved inorganic carbon (DIC) content of  $12 \text{ mg C/L}$  ( $C_t = 1 \text{ mmol/L}$ ) over a wide range of pHs is shown on Fig. 22-17. Of all these metals, only the copper oxide, tenorite, and the ferric oxide have solubility low enough in the pH range of interest to support an argument

### Other Surface Scales

Film	Passive film	Thin scale	Thick scale
Typical thickness	< 10 nm	$\mu\text{m}$ to mm	mm to several cm
Typical composition	Chromium oxides <sup>a</sup>	Mostly oxides, some hydrous oxides, some carbonates and hydroxycarbonates	Mostly oxides, some hydrous oxides, some carbonates and hydroxycarbonates, often multiple oxidation states
Metals of interest in drinking water	Stainless steels <sup>a</sup>	Copper, galvanized iron, lead, cast iron and ductile iron	Iron and its alloys, including cast, ductile and galvanized iron
Some important characteristics	Semiconductive, self-healing, tightly adherent, continuous coverage, anodic inhibitor	Often semiconductive, tightly adherent, usually continuous, usually cathodic inhibitors	Sometimes contains semiconducting components, usually porous, often not adherent

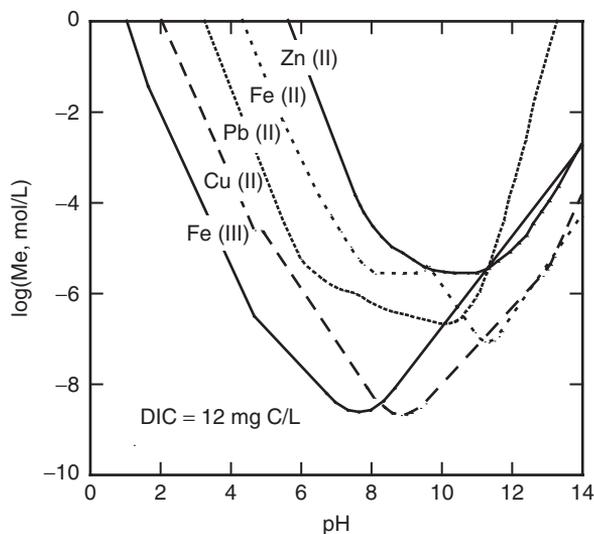

<sup>a</sup> The film formed in Faraday's experiment is thought to be a spiral hydrous ferrous oxide (Fig. 22-14) and it can form on most ferrous alloys used as drinking water conduits, but the types and concentrations of oxidants used in water systems are generally not sufficient to form a truly passive surface.

**Figure 22-16**

Types of surface scale that can form on metals.

that the reversible potential might be greatly depressed as a result of the low concentration of the oxidized species.

Neither of these oxides is thought to form a continuous, impervious film of the sort necessary to prevent corrosion, particularly, ferric oxide. Moreover, because iron has two oxidation states, it can form many complex oxides with different behaviors. Based on data presented on Fig. 22-17, it appears that, with the possible exception of copper, the solubility of these minerals provides limited insight into corrosion behavior. There is also some evidence that most surface scales exhibit much more limited solubility when they are in the form of a thin film on the surface of the metal. For example, copper, lead, and zinc are almost never observed at the levels suggested in these solubility diagrams in water transported by metal conduits, particularly zinc.

**Figure 22-17**  
Solubility of principal corrosion cations.

Nevertheless, natural scales formed by the metals themselves are often important. These stable species are formed by the oxidation products from corrosion. These scales can serve to protect the metal itself from further corrosion by inhibiting transport to the metal surface of species necessary for the corrosion reaction. The most common example cited is the inhibition of the transport of electron acceptors, such as hydrogen ion, oxygen, and chlorine, but, as will be seen in later discussion, when tubercles are present, other forms of inhibition can also be important.

The semiconducting properties of some oxides are also thought to be important. Snoeyink and Wagner (1996) illustrate a model as to how semiconducting oxide scales could be one of the principal mechanisms of uniform corrosion. Others argue that semiconducting properties of oxides are an important mechanism of corrosion inhibition for zinc (Gilbert, 1948), copper (Ives and Rawson, 1962a–d), and iron (Stumm, 1995). Ideas common to all these models is that the cathodic reaction occurs at the oxide–water interface, whereas the corrosion reaction takes place at the metal–oxide interface; that electrons generated by the oxidation of the metal are transmitted through the semiconducting oxide layer. Those arguing inhibition suggest that the rate of the reaction is no longer controlled by activation polarization of the metal surface or by mass transfer of the electron acceptor, rather the rate is controlled by the diffusion of electron holes through the semiconductor or by the activities that must take place on the oxide surface. As mentioned earlier, Stumm (1998) argued that it is controlled by the dissolution kinetics of the oxide itself.

### Example 22-7 Surface scale on lead–tin solder

Although a great deal of discussion continues regarding the mechanism of protection, there is a general consensus that these surface scales afford corrosion protection. In a study of the galvanic stimulation of corrosion on lead–tin solder joints in Seattle water, Reiber (1991) found that the nature of the corrosion reaction on the surface of lead–tin solder changed substantially with time, beginning with a corrosion potential ( $E_{\text{corr}}$ ) of  $-345$  mV, rising to  $-200$  mV after 2 weeks of exposure and settling at  $+25$  mV after 6 months. Using Fig. 22-11 as a guide, what sort of inhibition is occurring as the natural scale forms on the solder?

#### Solution

During the 6 months while the scale accumulated,  $E_{\text{corr}}$  increased from  $-345$  mV to  $+25$  mV and the corrosion rate dropped substantially. From Fig. 22-11 this behavior is consistent with an inhibitor that addresses (changes the slope of) the anodic reaction.

## 22-7 Common Forms of Corrosion

---

Up to this point, the discussion of corrosion has been approached broadly, viewing the process as being one where water conduits, made of metal materials that are not stable in water, react with the water and certain oxidizing agents to corrode or become oxidized. When corrosion occurs evenly across the metal surface, it is usually referred to as “uniform” corrosion, uniform in the sense that the metal surface is eaten away in a uniform manner. Corrosion of metal water conduits is universal, and uniform corrosion is the most common form, particularly where copper tubing is concerned. Uniform corrosion can also be a major contributor to the release of metal ions to the drinking water, an issue that became especially important in the last two decades of the twentieth century.

There are, however, other forms of corrosion that are also important, including (1) localized corrosion (pitting corrosion), (2) galvanic corrosion, and (3) concentration corrosion (crevice corrosion). All of these forms of corrosion are associated with local corrosion cells of a more permanent nature and all can result in important reductions in the useful life of the pipe.

### Localized Corrosion

In the case of uniform corrosion as discussed above, it is generally assumed that anodic and cathodic sites move around on the metal’s surface so that the entire surface is corroded at a more or less uniform rate. Another,

particularly destructive form that corrosion can take is localized corrosion, or pitting. Pitting is a situation where one small part of the pipe surface becomes a permanent anode and much of the surrounding surface serves as the cathode. Formation of a pit in the interior surface of a pipe is accompanied by conditions that further the corrosion of the material at a specific site. Under pitting conditions the corrosion reaction rapidly eats its way through the pipe wall and may lead to pipe failure. Pitting failures in consumer plumbing typically occur in new pipe between 1 and 3 years after installation.

Several good reviews have been written on the subject of pitting (Jones, 1996; Szlarska-Smialowska, 1986). The principal factors in the pitting process are (1) the oxidizing potential of the solution, (2) the presence of aggressive ions (particularly chloride), and (3) the condition of the metal surface (films, scales, etc.). In the case of passivated iron surfaces Jones (1996) postulates the following:

1. In the absence of chloride, the passive film (represented as FeOOH) dissolves slowly, releasing ferric ions (see earlier discussion regarding Stumm model of passive film behavior):

2. When chloride is present, it substitutes for  $\text{OH}^-$  in the passive film, creating "salt islands" (represented below as FeOCl) in the outer layer of the passive film:

3. These salt islands presumably dissociate and lead to the liberation of  $\text{Fe}^{3+}$ :

The pitting process is autocatalytic in nature. Once a pit is started, rapid dissolution of metal at the site produces an excess of positive charge within the pit. The positive charge attracts negatively charged chloride ions. Because hydrochloric acid is highly ionized ( $K_a \sim 10^6$ ), the presence of pits allows the hydrolysis of ferrous iron to drive the pH very low and the increase in acidity accelerates the corrosion rate. Pits normally expand in the direction of gravity because of the important role the dense, concentrated chloride solution plays in the pitting process. Oxygen reduction takes place on surfaces adjacent to the pit; however, the high salinity of the solution in the pit precludes significant reduction of oxygen there. High levels of chloride accelerate pit growth and seem to be associated with more frequent pit formation.

In addition to influencing the frequency and rate of growth of pits, aggressive ions, particularly chloride, also affect the induction time that precedes the initiation of the first pit. It has been shown (Engell and

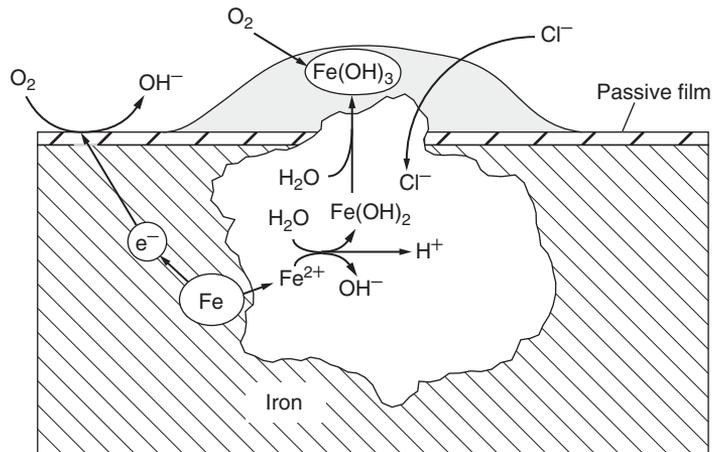

Stolica, 1959; Szlarska-Smialowska, 1971) that, all else being equal, the induction time ( $T_i$ ) can be predicted by the following relation:

$$T_i = \frac{1}{k(\text{Cl}^-)} \quad (22-21)$$

where  $T_i$  = induction time before first pits begin to appear, d  
 $(\text{Cl}^-)$  = chloride concentration, mol/L  
 $k$  = constant, d · L/mol

Unfortunately, for the waterworks industry, no values of the constant,  $k$ , are available for Eq. 22-21 for the conditions of importance in water supply. The equation is displayed because it suggests the principle that, for a given metal surface, the induction time before pitting is inversely related to the concentration of chloride ion.

Once a pit begins to form, its growth is often autocatalytic in nature. The sketch shown on Fig. 22-18 is modeled after the model Jones proposed for a pit on stainless steel (Jones, 1996), but it is analogous to the process of pitting in many other pits as well. Once the pit begins, metal ions released into the pit undergo hydrolysis, releasing hydrogen ions. These hydrogen ions create an electrostatic charge in the pit that attracts anions into the pit. The hydrolysis process also reduces the pH inside the pit, accelerating the anodic dissolution reaction. Certain anions, referred to as aggressive anions, are known to exacerbate the pitting process. Chloride is the most notorious of these because of its high mobility and because hydrochloric acid is highly ionized ( $K_a \sim 10^6$  compared to  $\sim 10^3$  for sulfuric acid). In the case of iron, as the ferrous hydroxide formed diffuses toward the exit from the pit, it meets the oxygen in the bulk solution and is further oxidized to ferric hydroxide. The ferric hydroxide forms a corrosion product cap on the top of the pit that is porous in nature. The shell blocks the transfer of  $\text{Fe}^{2+}$  but is porous enough so that chloride ions can migrate easily into the

**Figure 22-18**  
 Formation of autocatalytic pit in iron pipe.

pit. The diffusion of chloride is necessary to complete the solution circuit as demonstrated on Fig. 22-4.

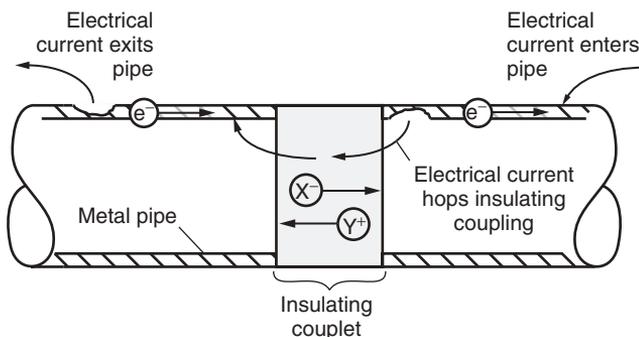

It is important to understand that a cathodic reaction is also required to support pit growth. As a result, pits are often widely spaced high-salinity solutions because oxygen has limited solubility and a large cathodic area is required to support each pit. Formation of new pits in the vicinity of an active existing pit will be suppressed by “cathodic protection,” that is, by the availability of a surplus of electrons in the pit’s immediate vicinity.

There are two types of corrosion that occur as a result of potential differences: (1) electrolytic corrosion and (2) galvanic corrosion. Often these two types of corrosion are confused. Electrolytic corrosion occurs when an external emf is imposed on the water conduit, and galvanic corrosion occurs when plumbing materials made of dissimilar metals are coupled to each other. It is important to understand that although a very small insulating coupling can eliminate galvanic corrosion, the same coupling can aggravate electrolytic corrosion, causing the corrosion to occur at new locations.

### Corrosion Due to Potential Differences

#### ELECTROLYTIC CORROSION

Whenever an electrical current travels along a water conduit, corrosion occurs. As mentioned earlier, according to the convention established by Benjamin Franklin, electrical current and electrons flow in opposite directions (Franklin, 1769). As a result, the point where corrosion will occur corresponds to the point where the electrical current exits the pipe (compare Figs. 22-4 and 22-19). External corrosion occurs when the current exits the outside of the pipe (usually in the ground), but internal corrosion can also occur when the current exits the inside of the pipe to jump an insulating coupling. The ordinary insulating couplings used to prevent galvanic corrosion are often not adequate to address problems of electrolytic corrosion. The length of the insulating coupling required to control a problem of electrolytic corrosion is greater for water supplies with higher conductivities (Sutherland and Tekippe, 1972).

**Figure 22-19**

Definition sketch for electrolytic corrosion. The circled ions complete the circuit (see also Fig. 22-4).

**GALVANIC CORROSION**

Galvanic corrosion occurs when two different metals or metal alloys are placed in contact with each other in a water system. The most common examples are probably brass fittings coupled to galvanized pipe and solder in contact with copper tubing. Occasionally, insulating couplings are used to separate such materials and prevent galvanic corrosion. Whenever a system for water conveyance is designed with different metals or different alloys, each of these materials will have a different corrosion potential than the other and a corrosion cell will result. The severity of the corrosion that results in these circumstances depends on many things, but foremost among them are (1) the difference in the independent corrosion potential of the two metals or alloys, (2) the difference in the relative areas of the two metals, and (3) the conductivity of the water itself. The geometry and proximity of the two dissimilar surfaces is also important, though rigorous consideration of these effects requires the use of field theory and is beyond the resources of most water utility staff and their consultants as well.

*Differences in corrosion potential*

From the earlier sections of this chapter, it is clear that the corrosion potential of each metal in a particular water quality depends not only on that metal's place in the redox potentials displayed in the table of standard reduction–oxidation potentials (Table 22-2) but also on other factors that influence all the parameters of the mixed-potential phenomena summarized in Table 22-5. Important among these is the nature of the scale that forms on that metal in the particular water. Once these potentials have been determined, a list can be prepared, ranking these materials with respect to their relative corrosion potential. Such tables are referred to typically as the galvanic series.

A galvanic series prepared for seawater is provided in Table 22-7. This particular series has been widely studied and is fairly practical because seawater has a similar composition throughout the world. The information in Table 22-7 is not accurate for waters of the composition of most domestic drinking waters. In fact, no universal table exists for drinking water use, and it is unlikely there will ever be one because the series is likely to be somewhat unique for each individual water quality.

Unfortunately, most utilities are not aware of the significance of these data, and standard procedures for making these measurements are not available. On the other hand, the standard redox potentials are much of what underlies the galvanic series, and many of the other variables are not a great deal different from one site to another. Also the metals grouped together in Table 22-7 generally have potentials that are different from the potentials in the groups above and below. In the absence of a local galvanic series, the rankings for seawater found in Table 22-7 are often used as a place to start. Water utilities would be wise to conduct testing to determine the corrosion potential of metals commonly used with the water they serve.

**Table 22-7**Galvanic series of metals and alloys in seawater<sup>a</sup>

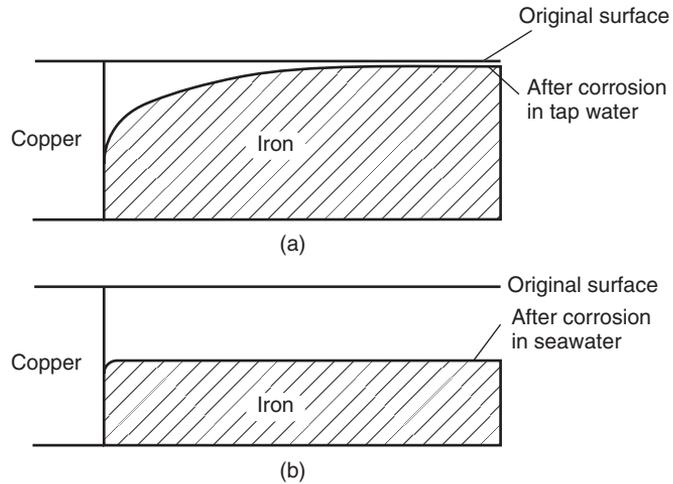

<i>Anodic (least noble, most likely to corrode)</i>
Magnesium
Magnesium alloys
Zinc
Aluminum
Cadmium
Steel or iron
Cast iron
Iron alloys
Lead-tin solders
Lead
Tin
Nickel
Brasses
Copper
Bronzes
Titanium
Monel
Silver solder
Silver
Carbon (graphite)
Gold
<i>Cathodic (most noble, least likely to corrode)</i>

<sup>a</sup>Metals within each of the groupings have similar corrosion potentials (Jones, 1996).

Information of this kind would prove valuable to the utility as well as to other corrosion engineers working on the design of systems that use that drinking water.

#### *Differences in area*

The relative area of the two dissimilar surfaces is also important to corrosion behavior as well as whether most of the area is in the form of the cathodic surface or the anodic surface. Consider a brass fitting coupled to galvanized pipe. These two metals have considerably different corrosion potentials, the brass being the more noble of the two. The more noble metal is the metal with the higher potential and, hence, the one that will become the cathode. Moreover, connecting the brass to the galvanized pipe will significantly reduce the corrosion potential of the brass, accelerating the cathodic processes there. On the other hand, the area of the brass is much smaller than the area of the galvanized iron connected to it. As a result, the cathodic processes promoted by the brass generally result in a small acceleration of anodic (corrosion) processes along a considerable length of galvanized pipe.

**Figure 22-20**

Effect of solution conductivity on nature of galvanic corrosion (Adapted from Uhlig, 1948): (a) corrosion of iron/copper galvanic cell in low-conductivity tap water and (b) corrosion of iron/copper galvanic cell in high-conductivity seawater.

#### *Conductivity of water*

Materials in waters with higher conductivity gain more benefit from the effects just discussed than those with lower conductivity. The extremes are best illustrated by comparing galvanic corrosion in the presence of a typical tap water (low conductivity) with galvanic corrosion in the presence of a typical seawater. The influence of conductivity on the behavior of corrosion near galvanic couples is illustrated with these two extremes on Fig. 22-20. With a low-conductivity tap water, the influence of the galvanic cell is intense but only in the immediate vicinity of the two metals. In seawater, with very high conductivity, the effect of the galvanic cell is spread widely across the surface of the less noble metal.

## 22-8 Metals of Interest in Domestic Drinking Water Systems

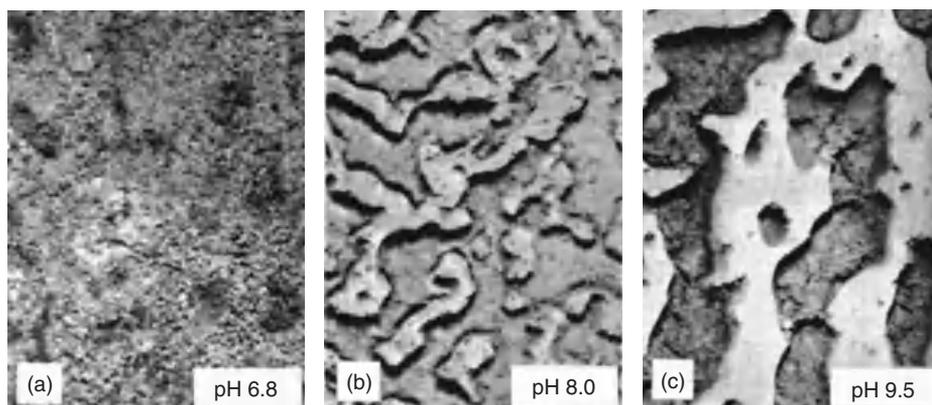

The metals of most interest in water systems are cast iron and ductile iron, galvanized iron, copper tubing, lead pipe, solders, and brass fittings. Each of these are addressed in the following discussion.

### **Iron Pipe**

Because of their low cost and a history of relatively good service, iron alloys have been the principal component of modern water systems. Today most new installations are (or should be) provided with a mortar lining. In this event, understanding corrosion becomes a question of understanding the behavior of the mortar lining. But iron, particularly cast iron and galvanized iron, has been around for a long time and, as a result, unlined iron alloy piping represents a significant part of the conduit in almost every active water system. There are a lot of problems that can develop with this iron

pipe, particularly loss of carrying capacity and red water. As a result, it is important to discuss iron and its alloys.

The reaction chemistry of domestic waters is extremely complex; attempting to characterize the effect in the immediate vicinity of a corroding iron surface is even more difficult. Long-term corrosion tests conducted in extremely soft waters show an increasing rate of corrosion with increasing pH (Larson and Skold, 1958a,b; Skold and Larson, 1957). Stumm (1960) made similar observations concerning the corrosion of iron in waters of various hardnesses. Both Stumm and Larson and Skold documented the effect of pH on the character of a corroding cast-iron surface, noting uniform corrosion at lower pH, and increased unevenness and tuberculation at higher pH (Larson and Skold, 1958a; Stumm, 1960). The photos taken by Werner Stumm in the late 1950s (see Fig. 22-21) illustrate the difference between corrosion behavior of cast-iron surfaces as a function of pH. Larson and Skold (1958a) produced similar photographs and made similar observations. Below pH 7, corrosion was found to be relatively uniform. Above pH 8, corrosion becomes increasingly more localized and at pH 9.5 serious tuberculation was observed. Stumm argued that it is likely that the change in the nature of the corroding surface is due in part to the influence of pH on the charge of ferric hydroxide micelles formed during the corrosion process. The isoelectric point of ferric hydroxide is slightly above a neutral pH. Thus at low pH, the micelles have a positive charge and will migrate toward the cathode. The change in charge reduces the rate of mass transport of other ions to the cathode surface and alters the distribution of anodic and cathodic areas. At more alkaline pH the  $\text{Fe}(\text{OH})_3$  micelles take on a more negative charge, causing them to remain at the anode; their presence at the anode increases the potential difference between the cathode and the anode, increases the rate of corrosion, and increases the heterogeneity of the corroding surface. Another argument

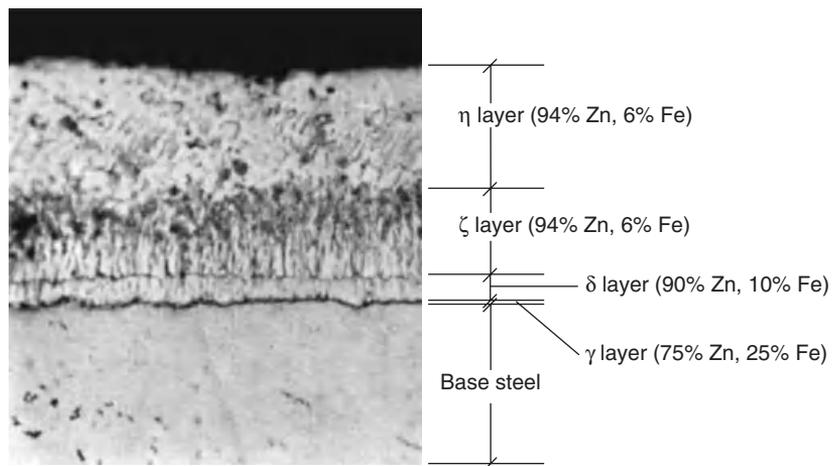

**Figure 22-21**  
Effect of pH on uniformity of corrosion on cast iron: (a) pH 6.8, (b) pH 8.0, and (c) pH 9.5. (Adapted from Stumm, 1960.)

can also be made that at high pH ferrous corrosion products are more likely to precipitate and stay at the anode, whereas at low pH, they would tend to remain dissolved and disperse. Similar arguments can be made regarding the rate of oxidation from Fe(II) to Fe(III).

### Galvanized Pipe

Galvanized pipe is an old and common material for plumbing used to transport domestic drinking water. For most of the twentieth century, it was the dominant plumbing material in the United States and Europe. However, since 1970, copper tubing has gradually displaced galvanized pipe as the leading material for domestic plumbing in most developed nations. The use of copper pipe for domestic plumbing is driven by the rising cost of labor, higher consumer standards for reliability, and more liberal standards on the thickness of copper tubing. Galvanized pipe remains the dominant plumbing material in much of the developing world.

To understand the corrosion of galvanized plumbing it is useful to understand how it is made and how a proper galvanized layer should appear. The structure of the alloy layers that are to be found on a normal galvanized surface is given on Fig. 22-22. This photomicrograph shows the five layers in a proper galvanized surface as identified in ASTM A385. According to this standard, a hot-dip zinc coating should show the following separate metallurgical layers: (1) the base steel, (2) the  $\gamma$  layer at the steel-coating interface, (3) the  $\delta$  layer, which is iron-rich zinc, (4) the  $\zeta$  layer, which can be characterized as the iron-zinc diffusion zone, and (5) the  $\eta$  layer, which is virtually pure zinc in composition. Impurities, such as cadmium, are usually at their highest level in the  $\eta$  layer. Common problems are in contamination of the interface between the  $\gamma$  layer and the base steel due to poor preparation and “galvanealing” or diffusion of iron too deeply in the zinc coating as a result of running the dip at too high a temperature or providing too much time at high temperatures.

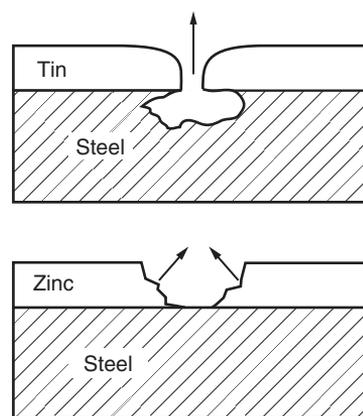

**Figure 22-22**  
Metallurgical layers in galvanized surface.

When galvanized pipe is to be used, its quality should be examined using a qualitative visual examination as well as tests of coating thickness, coating uniformity, and microscopic examination of the layers shown on Fig. 22-22. Details of such examination are given in the AWWARF book on internal corrosion (Trussell and Wagner, 1996). A normal galvanized coating should have an average weight of 550 g of zinc per  $\text{m}^2$  of pipe surface. An abbreviated description of the pipe manufacturing process is also given in Trussell and Wagner (1996). A more detailed description can be found in the earlier edition of the same reference (Trussell and Wagner, 1985). Manufacturing defects can be an important cause of a shortened lifetime for galvanized pipe, particularly inadequacies in welding or in the galvanizing process itself (Trussell and Wagner, 1996).

Galvanized pipe is not always that much better in service as compared to iron pipe. Once the zinc layer has corroded away, galvanized pipe actually does become iron pipe, and, of course, it then behaves as if it were. As a result, galvanized pipe gives its best service in regions where the zinc layer, itself, is stable. Generally, this good service is obtained in hard water with a pH between 7.5 and 8.5 and low chloride levels.

The method of protection provided by galvanized pipe is one of its important assets. The behavior near an imperfection in the tin layer in tin-plated steel with the behavior near an imperfection in the zinc layer in galvanized steel are illustrated on Fig. 22-23. Whereas tin is more noble than the steel, zinc is less so. Because of this, imperfections in the zinc coating are not of great significance. The nature of the protection of the galvanized layer allows for service to continue as the zinc layer is corroded away. Depending on the quality of the water, a substantial amount of the zinc layer can be corroded away before the galvanizing ceases to have its protective effect. Imperfections in tin plating can result in rapid failure by pitting. As will be seen later in the chapter, one of the more important causes of failure of galvanized pipe results from conditions where the potential between the zinc and steel layers becomes reversed.

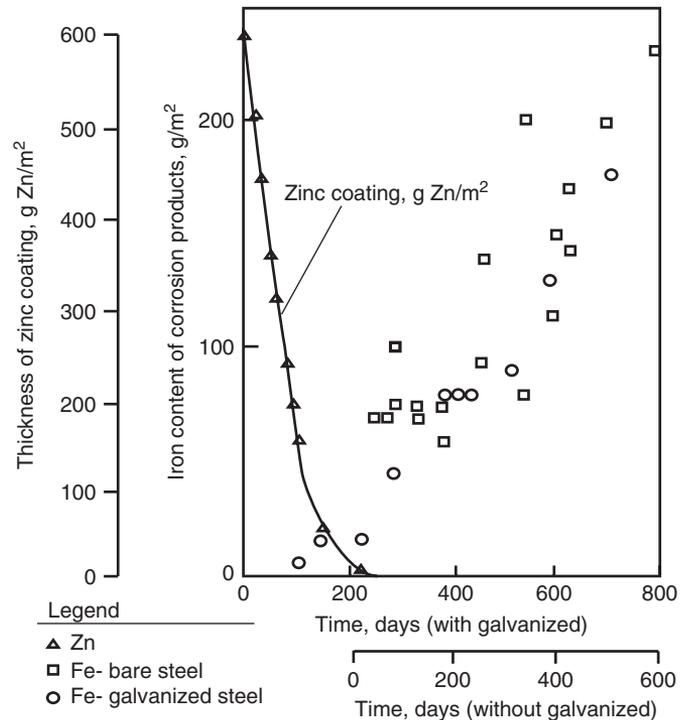

Returning to the corrosion of galvanized pipe, the transition from zinc to iron occurs, the behavior of the pipe can change materially, tuberculation is often observed, and the pipe's carrying capacity becomes reduced. Tuberculation refers to the formation of large, thick protrusions of oxide product on the inside of the corroding pipe, a phenomenon that is much more pronounced with the corrosion of iron. Some time after tuberculation develops fully, the consumer is often motivated to replace the pipe. The time sequence of the corrosion process in galvanized pipe is demonstrated on Fig. 22-24 in which the results of work by Bächle et al. (1981) are summarized. Bächle and co-workers examined the nature of the corrosion scale on the surface of galvanized pipe before and after

**Figure 22-23**  
Illustration of difference between protection provided between zinc and tin coating on iron.

**Figure 22-24**

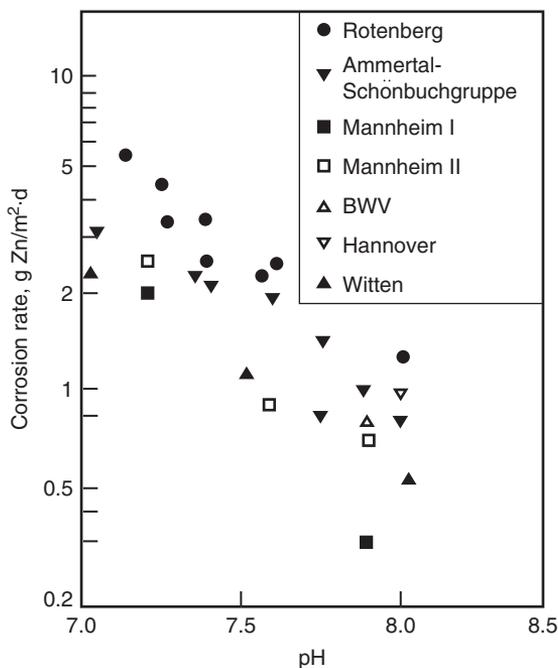

Loss of zinc layer. The corrosion of a galvanized pipe is compared with the corrosion of a bare steel pipe. For the galvanized pipe, for the first 200 days the zinc disappears (triangles) and then the iron corrodes (circles). The bare steel pipe, started 200 days into the test, corrodes the same (squares) (Adapted from Bächle et al., 1981)

the loss of the zinc layer and compared it to the behavior of steel pipe that had not been galvanized.

Bächle et al., (1981) studied the deposits on the surface of iron pipe and zinc pipe corroding in a local groundwater. In this particular case, the water was rather aggressive to zinc, and the zinc coating was almost entirely corroded away in less than a year. Here the iron content of the scale formed by the corrosion products is displayed in a way that demonstrates that the galvanized pipe behaves much like bare iron pipe once the zinc has been removed. As noted on Fig. 22-24, a rapid development of scale mass occurs once this process begins. Because iron scales are usually voluminous, this development often results in failure of the pipe to transport an adequate volume of water.

The single most important water quality parameter influencing the stability of the zinc coating on galvanized pipe is probably the pH. Work on the effect of pH has been conducted by Sontheimer and associates (Bächle et al., 1981; Kruse, 1983; Pisigan and Singley, 1985; Werner et al., 1973). From the results of Bächle et. al (1981) (see Fig. 22-25), it can be concluded that the corrosion behavior of galvanized pipe consistently improves with increasing pH. Bächle et al., studied the effect of pH on the corrosion of galvanized pipe in seven different water supplies. The issue of pH is more thoroughly discussed by Trussell and Wagner (1996).

**Figure 22-25**  
Corrosion of galvanized pipe as function of pH. (Adapted from Bächle et al., 1981.)

Trussell and Wagner (1996) also conducted a thorough examination of the chemistry of zinc ion and found that, under the conditions of importance in drinking water systems, zinc is typically coated with hydrozincite [ $Zn_5(OH)_6(CO_3)_2$ ], zinc oxide (ZnO), and zinc hydroxide [ $Zn(OH)_2$ ]. Occasionally, some calcium carbonate has also been observed on the zinc surface, usually in the form of aragonite, a form having slightly greater solubility than calcite. The solubility of zinc ion seems to be controlled by the oxide and the hydrozincite; but, as shown on Fig. 22-17, these zinc minerals do not have exceptionally low solubility. As a result, it is likely that there are conditions near the pipe surface that influence behavior to keep zinc levels in the bulk water matrix below those expected by consideration of mineral solubility.

Where satisfactory service is concerned, pitting is the mode of corrosion that has the most dramatic impact reducing the useful life of the pipe. There are three causes of pitting that are important to galvanized pipe: (1) pitting associated with manufacturing defects (discussed earlier), (2) pitting associated with copper in the water, and (3) pitting resulting from potential reversal between the steel and zinc.

#### PITTING ASSOCIATED WITH COPPER IN WATER

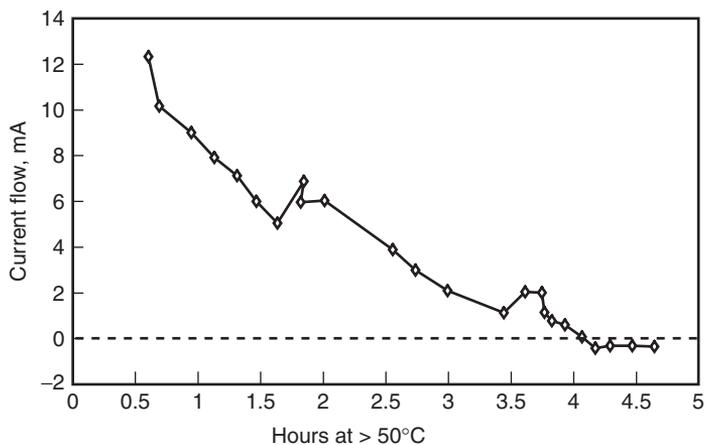

McKee (1932) reported that the use of copper algicides resulted in the pitting of galvanized pipe in cooling water equipment. Since that time, most

incidents of pitting due to copper have been associated with recirculating water systems (Kenworthy, 1943), but others have reported copper-induced pitting of galvanized pipe with copper from a variety of sources (Cruse, 1971; Treweek et al., 1978). The principle involved is that copper, being the more noble metal, plates out over much of the surface of the zinc, reducing the anodic zones on the surface of the pipe and increasing the risk of pitting. On the other hand, the Metropolitan Water District of Southern California sponsored extensive studies on the role of copper on the pitting of galvanized pipe (Grasha et al., 1981; Treweek et al., 1978; Fox et al., 1983), and these studies came up with equivocal answers, researchers being unable to duplicate copper-induced pitting after extensive efforts. Corrosion was accelerated, but pitting was not evident.

Based on available evidence, it appears that copper-induced pitting of galvanized pipe is a real phenomenon, but the circumstances when it will and will not occur are not understood adequately. Perhaps the presence of copper can exacerbate the conditions associated with the potential reversal phenomenon discussed below.

#### PITTING ASSOCIATED WITH POTENTIAL REVERSAL

Under certain conditions, the electrochemical potential between zinc and iron can be reversed, so that iron becomes the sacrificial metal in place of zinc. Schikorr was the first to publish clear evidence of potential reversal (1939). Schikorr connected iron and zinc electrodes and then watched their relative potential in a hot water bath maintained between 50 and 80°C. Potential reversal was observed after 4 h of contact time (Fig. 22-26). Beyond increased temperatures, bicarbonate concentration and/or nitrate concentration have also been noted as possible causes of potential reversal, while increased chloride, sulfate, calcium, and silicate levels will mitigate against potential reversal (Hoxeng, 1950; Hoxeng and Prutton, 1949). Perhaps the

**Figure 22-26**

Shikorr experiment. After 4 h in hot water, the current flow between iron and zinc electrodes is reversed. (Data from Schikorr, 1939.)

most thoughtful examination of the subject of potential reversal between iron and zinc was conducted by Gilbert (1948). Gilbert hypothesized that, at elevated temperatures (and perhaps elevated pH values), scale on the zinc surface is transformed from the zinc hydroxide normally present to zinc oxide. This zinc oxide is more effective in “healing” anodic sites (reducing their area) while at the same time, as a semiconductor, it is also effective in depolarizing cathodic sites (reducing  $\beta_c$  in Eq. 22-4). The depolarization of the cathodic sites reduces the potential of the corroding zinc with respect to the solution, thus reducing the overall rate of corrosion, but accelerating the rate of corrosion at the few anodic sites remaining.

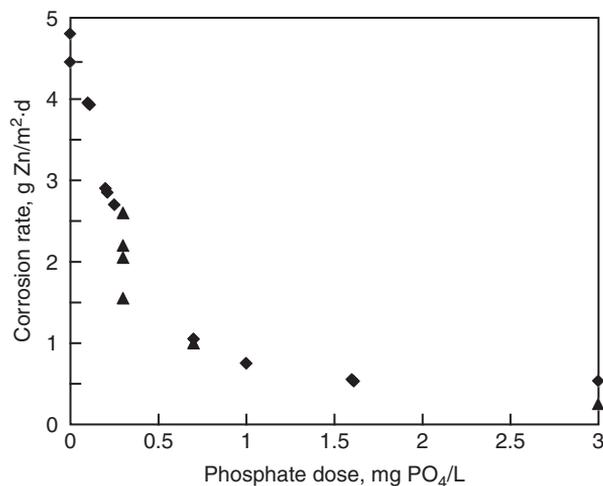

#### **TREATMENT TO REDUCE CORROSION OF GALVANIZED PIPE**

Much can be done in the design and installation of galvanized plumbing systems to reduce corrosion. Specifically, testing should be done to assure the quality of installed pipe and appropriate design and construction of galvanized systems. Once the system has been built, there are three approaches to water treatment that have been demonstrated to be successful under specific circumstances: pH adjustment, silicate addition, and the addition of orthophosphate. Adjustment of calcium carbonate saturation is also often advocated, but its role in controlling the corrosion of galvanized pipe has not been demonstrated as clearly.

Silicates have long been advocated for controlling corrosion in galvanized systems (Cox, 1934; Speller, 1926; Thresh, 1922); however, modern research has focused on their application in circumstances where pitting due to potential reversal in hot water systems is the principal issue (Lane et al., 1973, 1977; Lehrman and Schuldener, 1951, 1952). While it has been demonstrated in this more recent work that silicates can be successful in preventing the pitting of galvanized pipe, the dose of silicate typically required for successful treatment is rather high (8 to 25 mg/L as  $\text{SiO}_2$ ). As a result the use of this treatment is limited to industrial applications.

Murray (1971), working for the City of Long Beach, California, was the first to report successfully employing orthophosphates to control the corrosion of galvanized pipe. Murray’s inhibitor actually included zinc sulfate, orthophosphate, and sulfamic acid. Since that time, most studies examining Murray’s formulation, or simpler mixtures without sulfamic acid, have focused on controlling the corrosion of iron pipe (Kelly et al., 1978; Mullen, 1974). Later Nancollas (1983) proposed a theoretical basis for inhibition of corrosion of zinc surfaces by orthophosphate.

Since that time, German researchers have demonstrated that orthophosphates alone can successfully control the corrosion of both iron and galvanized pipe. Werner did extensive work examining the influence of orthophosphate addition on the corrosion of galvanized pipe (Trussell and Wagner, 1985). Werner found that the corrosion rate is inversely proportional to the orthophosphate dose and to the ratio of the hydrogen ion concentration. The results from the Werner studies are reported on

**Figure 22-27**  
Effect of orthophosphate on corrosion of galvanized pipe. (Data from Trussell and Wagner, 1985.)

Fig. 22-27. Examination of the figures confirms that the corrosion rate is inversely proportional to the orthophosphate dose. The technique of phosphate addition has not been shown to be as successful in waters with very low pHs or very low alkalinities.

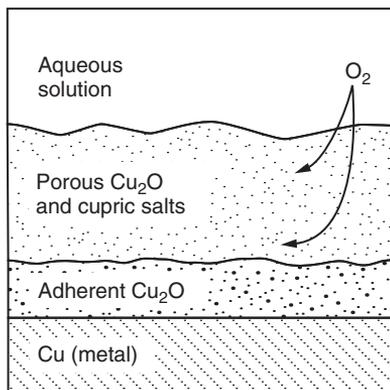

## Copper Tubing

Copper tubing in water systems is subject to three forms of corrosion: (1) general corrosion, (2) impingement attack, and (3) pitting attack (Cohen and Lyman, 1972; Hatch, 1961). General corrosive attack is rare and generally occurs at low rates so that the service life of the tubing is not reduced significantly. Impingement and pitting attack can be both rapid and severe.

### UNIFORM CORROSION

General corrosive attack of copper, which can produce “green” or “blue” water if the copper concentration is particularly high, is most often associated with soft, acid waters. General corrosion proceeds at a low rate and is characterized by a gradual buildup of corrosion products, generally basic cupric salts.

As described earlier, the oxide scale on the surface of copper tubing is understood to play an important role in the corrosion process. Evidence identified by Ives and Rawson (1962a–d) suggests that, when copper is immersed in water saturated with oxygen, the copper is rapidly oxidized to form a compact, adherent film of cuprite (cuprous oxide) and that this cuprite, a semiconductor, is in good electrical contact with the metal itself. When uniform corrosion occurs, the underlying copper is oxidized and the oxide formed remains in immediate contact with the metal’s surface. Oxygen is reduced to water at the exterior of this tight layer of cuprite. Ives and Rawson have argued that the tight adherent layer can only

**Figure 22-28**

Ives–Rawson duplex film model for copper (adapted from Ives and Rawson, 1962c). The Ives–Rawson duplex film model for copper corrosion. Copper corrodes to form a compact, adherent film of cuprite ( $\text{CuO}$ ), a semiconductor, that remains in electrical contact with the base metal. Over time, a more porous outer layer of cupric salts also forms. Oxygen from the aqueous solution can penetrate the outer layer, but when it reaches the cuprite, it does not penetrate but is reduced to water at the surface via electrons transported from the surface of the corroding base metal.

reach a certain thickness and still maintain its structural integrity. Beyond that thickness, a second, outer oxide layer also develops (see Fig. 22-28). This outer layer becomes a mixture of cuprous and cupric salts, and the difference in the coordination requirements of these two oxidation states of copper results in the formation of a porous scale layer. The formation of the two layers might also be a result of two processes, oxidation of the metal at the  $\text{Cu-CuO}$  interface and penetration of oxygen to form the  $\text{CuO-Cu}_2\text{O}$  interface. In any case, there is wide agreement that the cuprite scale ( $\text{CuO}$ ) is tight and continuous and that the tenorite scale ( $\text{Cu}_2\text{O}$ ) is not.

The most important factors influencing general corrosion are (1) pH, (2) hardness, (3) temperature, (4) age of the pipe, and (5) oxygen. As with most metal corrosion, low pH waters attack the protective oxide layer. Waters with pH values lower than 6.5 are aggressive to copper. Corrosive attack is more severe in hot water systems. Obrecht and Quill (1960, 1961) report that temperatures exceeding  $60^\circ\text{C}$  ( $140^\circ\text{F}$ ) cause an increased rate of corrosive attack. Most serious cases of corrosion in copper tubing occur in new installations where the protective oxide layer has not yet formed.

The impacts of general corrosion are mostly of a nuisance nature. Green and blue water are caused by dispersion of copper corrosion products into the water. A related problem is blue or green staining of plumbing fixtures. Such water often exhibits a rather unpleasant taste due to high concentrations of dissolved copper. Increased copper concentrations in water and sludge discharged from wastewater plants is also an issue. Uniform corrosion can be controlled by raising the pH to 7.5.

#### **IMPINGEMENT ATTACK**

Impingement attack is the result of excessive flow velocities [greater than  $1.25\text{ m/s}$  ( $4\text{ ft/s}$ )] and was at one time thought to be purely mechanical in nature (Hatch, 1961). It is now believed that high velocities disrupt formation of protective films, allowing electrochemical attack to proceed more rapidly. Factors besides velocity that aggravate impingement attack are

soft water, high temperature, and low pH. For hard, cold water, velocities of 2.5 m/s (8 ft/s) can be tolerated. Soft waters, temperatures above 60°C, and pH below 6.5 all contribute to destruction of the protective film.

Impingement attack is characterized by a rough surface, often accompanied by horseshoe or U-shaped pits. In severe cases, perforation of the tube wall occurs in as little as 6 months. It is most severe at points of turbulence, such as sites downstream of fittings, and is most prevalent in recirculating systems.

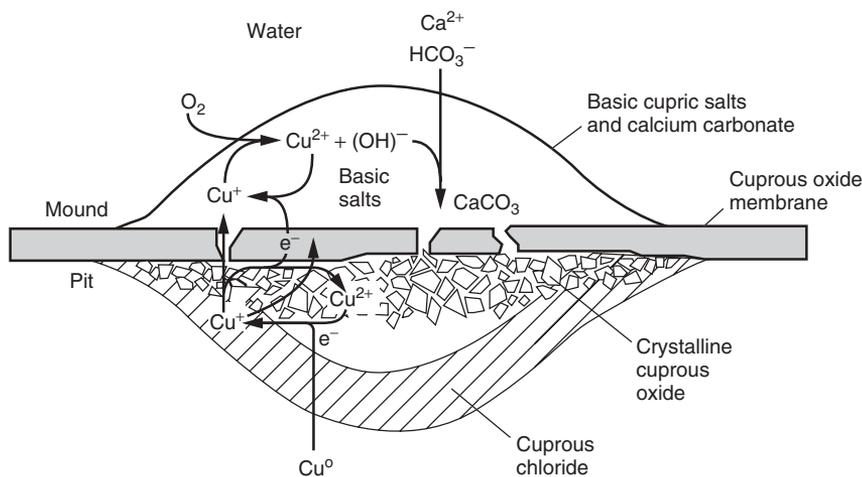

#### **PITTING ATTACK**

Pitting of copper tubing takes many forms and has many causes. Edwards et al. (1994) summarized the causes, characteristics, and remedies for the most common forms of copper corrosion, including pitting. The pitting of copper tubing is most commonly associated with hard well waters and most often occurs in cold water piping. Usually, dissolved carbon dioxide exceeds 5 mg/L and dissolved oxygen is 10 to 12 mg/L or more (Cohen and Lyman, 1972; Rambow and Holmgren, 1965). The water quality parameters typical for water systems having copper pitting problems are not the typical soft, low-pH waters normally associated with corrosion of copper. Surface waters containing organic or humic substances are not associated with pitting attack (Campbell, 1954; Lucey, 1967). In England, the presence of a carbon film due to residues of drawing lubricants from manufacturing processes was found to exacerbate problems of cold water pitting in copper pipe (Campbell, 1950).

Pitting occurs most often in horizontal runs of piping with the deepest pits concentrated in the bottom of the pipe. It appears that gravity holds dense solutions of copper salts in the pit, sustaining the corrosion reaction (Cruse and Pomeroy, 1974). Horizontal surfaces are more vulnerable to attack (Lucey, 1967), suggesting that corrosion products stream from the vertical surface and concentrate gravitationally.

Pitting attack is most common in new installations, with 80 to 90 percent of the reported failures occurring within the first 2 to 3 years. In some extreme cases, failure occurs in as little as 3 months (Cruse and Pomeroy, 1974). Pitting occurs in soft, annealed tubing rather than in hard-drawn tubing (Ferguson et al., 1996). Typically, hard copper tubing (types K, L, and M) is used inside structures and soft copper tubing underground and inside slabs. As the name implies, soft copper tubing is more malleable and hard copper tubing is more rigid. According to Cohen and Lyman (1972), the relative frequency of failure does not appear to vary among types of tubing, even though type M has a thinner wall. If unfavorable water quality conditions occur before the protective coat has formed, then serious pitting attack may occur. After 3 or 4 years, the incidence of failure drops significantly even in systems having serious incidents of pitting.

In the diagram on Fig. 22-29, developed originally by Lucey (1967), the profile of a typical cold water pit in copper tubing is illustrated. Lucey

**Figure 22-29**  
Profile of a cold-water pit  
in copper tubing (Adapted  
from Lucey, 1967.)

has proposed a mechanism for copper pitting in which the formation of a membrane cell is assumed, as shown on Fig. 22-29. The cuprous oxide membrane covers the pit cavity, which contains cuprous chloride and cuprous oxide crystals. The cuprous oxide membrane acts as a bipolar electrode with oxidation taking place on the inside face and reduction taking place on the outside face. There are reactions simultaneously with the calcium bicarbonate in the waters, which result in the precipitation of calcium carbonate and basic cupric salts such as malachite [ $\text{CuCO}_3\text{Cu}(\text{OH})_2$ ] in a mound above the membrane.

Pipes made of lead (*plumbum*) were first used for plumbing by the Romans. Lead is ductile and can be bent easily into desired shapes. Use of lead in plumbing declined beginning in the nineteenth century as iron became competitive as a pipe material. Later, health concerns about lead poisoning from corrosion by-products in drinking water further reduced the use of lead in water conduits, although household lead plumbing is still in place in some older cities. Lead “pigtales” and “goosenecks” were also in use as an easily deformable connection between distribution mains and household connections. Relatively little is known about corrosion of lead except that its corrosion rate is relatively low. The primary issue with lead has not been that it corrodes but rather that lead released to the water being carried in the conduit can be toxic. The release of lead to the solution in the pipe is discussed later in the chapter.

## Lead Tubing

Throughout the developed world, solders used to bond copper fittings together had long been lead–tin alloys. In the United States a 50 percent lead, 50 percent tin alloy had been common, while in Europe a similar 60 percent lead, 40 percent tin alloy was dominant. Tin has always been

## Lead Solder

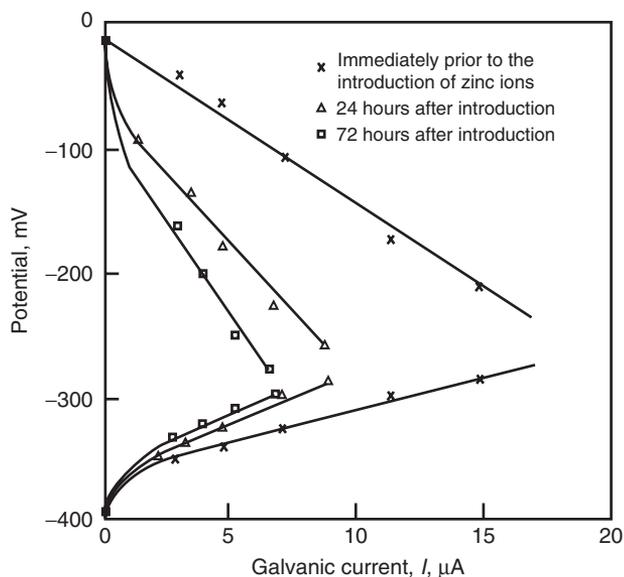

the key component in solders, maintaining their low melting point and providing effective bonding. Lead was used as a component in the interest of reducing cost, improving workability, and maintaining a low melting point. During the past two decades the use of lead-containing solders has been banned in the United States, the European Union, and Japan. In the United States, a solder that is 95 percent tin and 5 percent antimony has been the dominant replacement. In Europe, the replacements have been silver and copper alloys (95 percent tin, 5 percent silver and 95 percent tin, 5 percent copper). As a result, corrosion of lead solders is a somewhat temporary problem in the developed world. The use of lead solders is important because of the significant contribution they make toward lead at the tap, but of decreasing importance with time because the lead content in these solders will decrease over time. Only the corrosion of the lead–tin combinations is considered in this chapter, as these combinations are of principal interest, even at the present time.

As demonstrated by Oliphant and Schock (1996) and Reiber (1991), corrosion of lead-containing solders is fundamentally different from the corrosion of lead pipe, because these solders are lower on the galvanic series than is the copper pipe to which they are bound. For example, as reported in Table 22-6, the normal potential of lead–tin solder is about 200 mV lower than that of a copper surface in Seattle water. This finding would seem to be contraindicated by the standard electrode potentials of lead, tin, and copper. *The fact that the relative potential these metals exhibit in practice is the opposite of that expected by their standard electrode potentials illustrates a point made earlier.* Namely, the nature of the scale formed on a metal and the specifics of the mixed potentials acting on the metal surface in solution can result in a potential with respect to the solution that is different than might be expected from standard tables.

In the discussion of galvanic corrosion earlier in this chapter, the ratio of the area of the cathode and anode in a galvanic cell was of great importance. Unfortunately, this ratio is unfavorable for the lead–tin solder/copper couple in a soldered fitting. The ratio is unfavorable because the lead–tin solder presents only a small anodic surface; its oxidation by corrosion is driven by the cathodic reaction on a substantial copper surface.

In other work Oliphant has demonstrated that because the corrosion of the solder is driven by the galvanic cell rather than by a mixed-potential reaction on the solder surface, decreasing the solubility of the corrosion products from the solder did not result in a reduction in the rate of the corrosion reaction (Oliphant and Schock, 1996). As a result, it seems likely that the reduction in solder corrosion with increasing pH is a result of a reduction in the rate of the cathodic reaction, namely the reduction of oxygen to water.

Oliphant and Schock (1996) examined the impact of adding zinc on the galvanic corrosion of lead–tin solder. As shown on Fig. 22-30, the addition of zinc resulted in insignificant change in the behavior of the solder anode,

**Figure 22-30**  
Impact of zinc on corrosion of solder. (Adapted from  
Oliphant and Schock, 1996.)

but a significant reduction of the rate of the cathodic reaction taking place on the surface of the copper. Once again, zinc appears to be an effective cathodic inhibitor. Note that the estimated corrosion potential of the galvanic couple drops from approximately  $-260$  mV to between  $-280$  and  $-300$  mV. Strategies that reduce the cathodic reaction appear to be the principal tools suitable for reducing solder corrosion.

Valves and fittings for domestic systems are made from brasses and gun metals. Both are copper-dominated alloys and their composition and use are summarized in Table 22-8. In the United States, the 1988 Lead Contamination Control Act limited the lead content of these materials to 8 percent (U.S. EPA, 1991). Nevertheless, these fittings have been implicated as an important potential source of lead in consumer plumbing. The corrosion of these fittings depends primarily on water quality, but also on the details of the plumbing. Comparing the data in Table 22-8 and Fig. 22-31, brass fittings have copper contents high enough that their corrosion potentials should be very close to that of copper. As a result, brass fittings, when used in copper-plumbed systems, will be at much the same potential as the rest of the system, perhaps, slightly anodic. On the other hand, brass fittings employed in a galvanized system should be strongly cathodic. As a result, the brass fittings, themselves, are not likely to fail as a result of galvanic action.

The principal issue where corrosion of brass and gun metal fittings is concerned is dezincification. As the name implies, dezincification is a process whereby the zinc in the alloy is corroded selectively out of the

## Brasses and Gun Metals

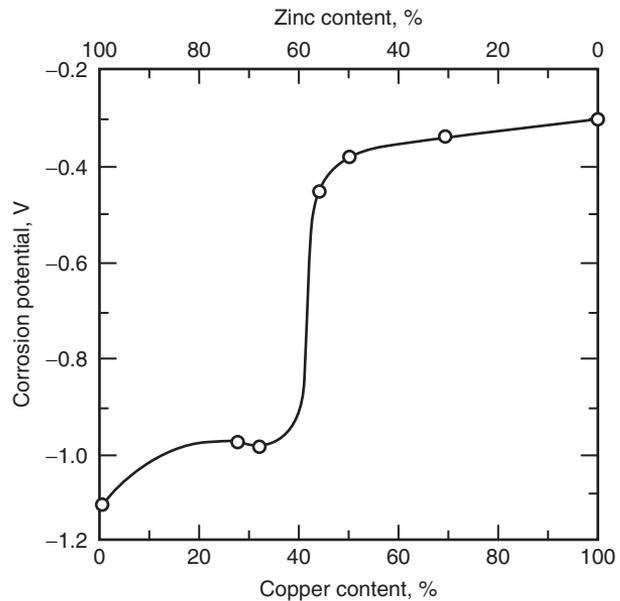

**Table 22-8**

Brasses and gun metals used in drinking water systems

Alloy	Relevant Standard	Composition, %				Common Applications
		Cu	Zn	Sn	Pb <sup>a</sup>	
Gun metal	C83600	85	5	5	5	Casting alloys used for domestic plumbing valves in United States
	C84400	81	9	3	7

Brass	LG4	88	2	5	4	Used for tube and sand cast fittings
	$\alpha$ Brass	64	30	— <sup>b</sup>	6	
	$\alpha$ - $\beta$ Brass	54	40	— <sup>b</sup>	6	

<sup>a</sup>In the United States the 1988 Lead Contamination Control Act limits lead content to no more than 8%.

<sup>b</sup>Up to 1% tin is sometimes used to improve corrosion resistance.

**Figure 22-31**

Corrosion potential versus copper content. (Adapted from Jones, 1984.)

matrix. A brass surface that has suffered from dezincification is distinctive in its reddish appearance in contrast to the more yellow appearance of a brass surface that remains intact. Alloy composition is important in dezincification. It has been found that zinc-rich alloys ( $\beta$  brasses) are more sensitive to the problem and that traces of arsenic in the alloy are known to improve resistance to dezincification. Nevertheless, water quality

is also an important consideration as well. In general, waters with higher concentrations of chloride ion and lower alkalinities are more likely to suffer from dezincification.

## 22-9 Release of Contaminants

---

So far the discussion of corrosion has been focused on water conduits, specifically processes that change the oxidation state or, in some other manner, attack the structural integrity of the material, such as a water conduit. Processes that cause the release of contaminants to the water or cause deposition of undesirable scales on the surfaces of water conduits are considered in this section and the one to follow.

Much of the following discussion is based on the work of Clement and co-workers (Clement et al., 2002). From the beginning of its use as a material for water conduits, iron pipe has been associated with the formation of discolored water. In some circumstances such water is only a minor inconvenience, in others it is a major irritation. The scale that develops on the surface of the pipe as a result of its corrosion is thought to be a key component in the development of red water. The scale that forms on iron pipe is far more complex than that found on water conduits constructed from other metals. The rather loose, porous, and bulky character of many ferric oxides and hydroxides is thought to be a root cause of these unique scales, which can become quite thick with time. It is common for the corrosion on iron pipe to form tubercles as well. Iron pipe with significant tuberculation is particularly noted for problems with discolored water, high disinfectant demand, bacterial problems, and hydraulic restrictions (reduced carrying capacity). The following discussion is focused on the mechanisms behind the formation of discolored, red water. Problems of discoloration are associated with all types of iron, steel, cast iron, and galvanized iron water conduits.

The scales formed by both ferric and ferrous iron are important. Ferric hydroxide, ferrous hydroxide, and ferrous carbonate are formed from corroding iron. Both of the iron hydroxides form rather porous oxide scales that do little to reduce corrosion. The ferrous carbonate scale is a much denser, more protective scale. As a consequence, in the last quarter of the twentieth century, quite a bit of effort was made to understand the role that ferrous carbonate (siderite) might have in the corrosion of iron pipe.

A number of researchers in the water field have tried to establish the significance of siderite in the formation of protective scales in water distribution pipes (Baylis, 1926; Larson and King, 1954). German investigators (Kolle and Rosch, 1980) reported the existence of a “shell-like layer” in scales found in cast-iron pipes. This layer seems to be important in the formation of corrosion resistance of iron in many waters. Kolle and Rosch

### **Red Water and Iron Pipe**

speculated that siderite is important as an intermediate in the formation of the shell-like layer but may not be part of the layer itself.

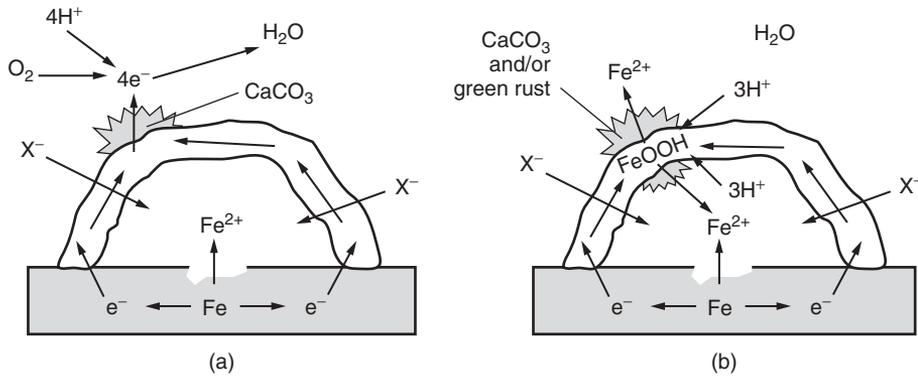

A model for scale formation proposed by German researchers is based on the concept that siderite formation is a key step in the formation of corrosion-resistant scales (Sontheimer et al., 1979). The formation of goethite ( $\text{FeOOH}$ ) in the shell-like layer may involve the conversion of siderite while retaining its dense crystalline structure (Kolle and Rosch, 1980). The formation of calcite also appears to be necessary to form a good protective scale.

To test the siderite model, experiments were designed to determine the influence of various factors related to scale formation on the corrosion rate (Sontheimer et al., 1981). It was shown that the corrosion rate decreases as the proportion of Fe(II) in the scale increases, tending to support the model. Increasing calcium concentration also showed a protective relationship.

Further research has led to a conceptual model of a tubercle pit similar to that shown on Fig. 22-18 (Clement et al., 2002; Herro and Port, 1993). Based on this work, it is suggested that tubercles take a form that includes four elements: (1) a corroded floor where the original metal has been partially removed, (2) a hard shell-like but porous cap made of a mixture of magnetite ( $\text{Fe}_2\text{O}_3$ ), a semiconducting iron oxide, and goethite ( $\alpha\text{-FeOOH}$ ), (3) a porous interior cavity composed mostly of ferrous compounds in a water matrix (often including chloride and or sulfate), and (4) a soft external crust that is mostly dominated by ferric oxides and hydroxides.

### Processes Associated with Tubercles

The processes associated with tubercles are thought to play an important role in the formation of red water (Sarin et al., 2001). Two conditions thought to be particularly important in red water and corrosion are illustrated on Fig. 22-32 using the model described above. The first condition occurs when water is flowing and oxygen is plentiful. Under these conditions, the native iron corrodes inside the tubercle, at its base. As this iron corrodes, it becomes an electron donor. The electrons generated travel through the metal, but they can also travel through the hard shell of the tubercle, as much of this hard shell is made of magnetite, a semiconductor. On the outside of the hard shell of the tubercle, oxygen, after diffusing through the soft crust, becomes the electron acceptor. In doing so, the oxygen is reduced to water, consuming hydrogen ions. As a result, the pH is elevated, and calcium carbonate may precipitate in the vicinity, *even if the bulk solution is not saturated with  $\text{CaCO}_3$* . As  $\text{Fe}^{2+}$  cations are being generated inside the tubercle, anions must diffuse inside the tubercle so that electroneutrality can be maintained (shown as  $\text{X}^-$  on Fig. 22-32). To the extent that small anions, such as chloride, are present, they can accelerate the process. The deposition of  $\text{CaCO}_3$  reduces the porosity of the hard shell and can inhibit the process, reducing the rate of the corrosion.

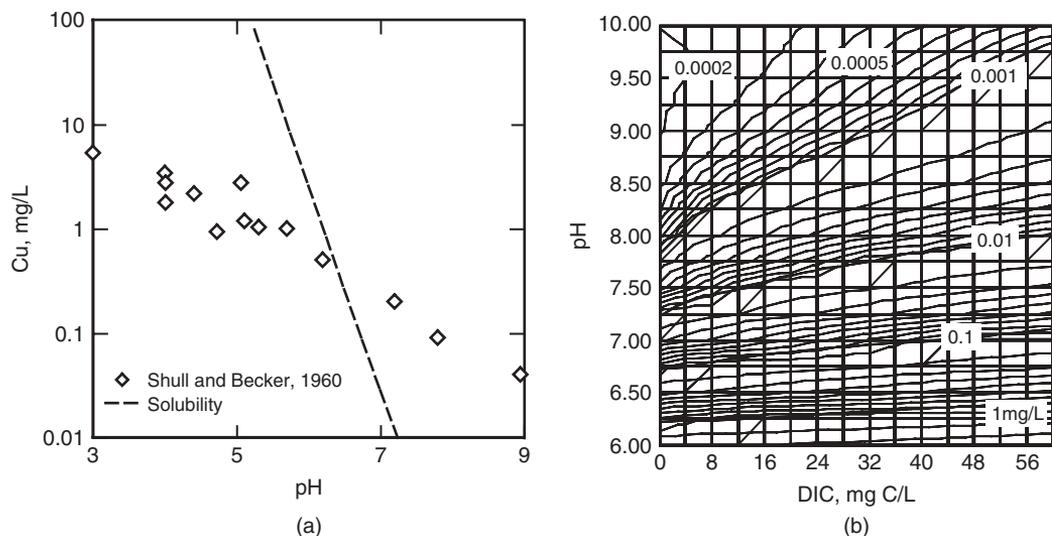

**Figure 22-32**

Processes associated with tubercles: (a) flowing water with oxygen ( $O_2$  as electron acceptor), and (b) stagnant water with no oxygen ( $FeOOH$  as electron acceptor).

Drawing from the earlier discussion on electrode kinetics, the potential of the corroding electrode will be that at which the anodic and cathodic reactions develop the same current density. The potential–current relationship for the anodic reaction in the tubercle is defined by the reversible potential of corroding iron, by the exchange current and Tafel slope of that reaction on the iron surface, and by the rate of diffusion of anions into the tubercle. The potential–current relationship for the cathodic reaction in the tubercle is defined by (1) the reversible potential of oxygen redox reaction, (2) the exchange current and Tafel slope of that reaction on the surface of the hard shell, and (3) the rate of diffusion of oxygen through the solution and the soft crust to the surface of the hard shell. If  $CaCO_3$  deposition is successful in slowing the corrosion reaction by inhibiting the influx of anions into the tubercle, then the potential of the electrode will rise and it will become more noble, resulting in anodic inhibition. This conclusion is consistent with Stumm's argument that  $CaCO_3$  behaves as an anodic inhibitor (Stumm, 1960).

The stability of the oxide layer on the surface of copper pipe is sensitive to pH. As a result, undesirably high levels of copper in solution are commonly associated with low pH water. As a broad rule of thumb, problems of blue and or green water (copper in the water) are common for water supplies with a pH below 7 and uncommon for water supplies with a pH greater than 8. The results of experiments conducted by Shull and Becker (1960) in which they examined the effect of pH on the copper released during a period of stagnation in copper tubing are shown on Fig. 22-33a. The experiments were conducted with tap water that had been adjusted to a particular pH and then placed in a section of copper tubing. After a 24-h period of stagnation the water in the copper tube was analyzed

### Blue-Green Water with Copper Pipe

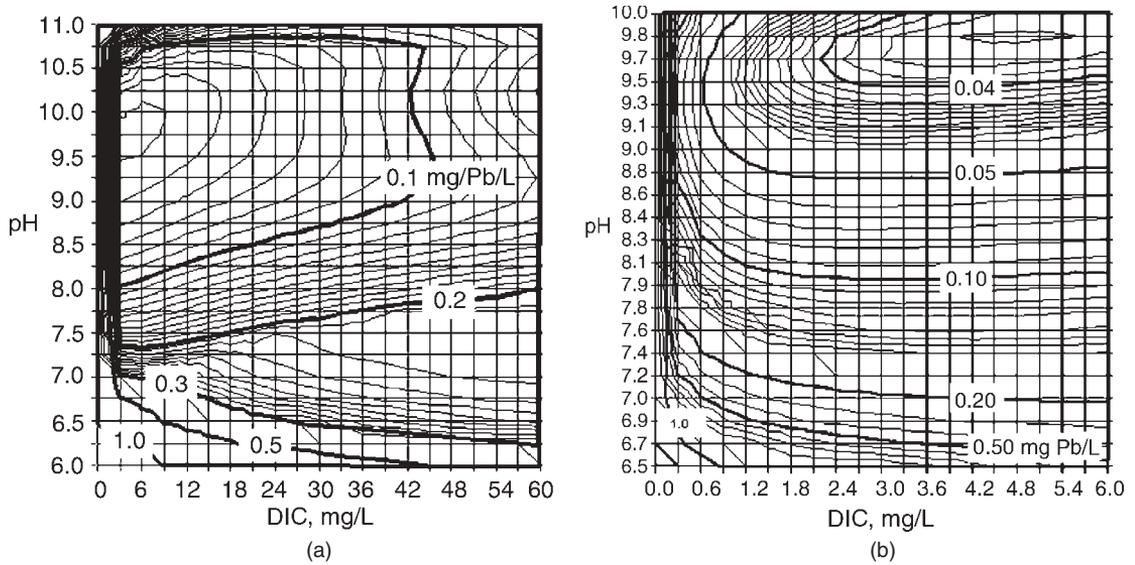

**Figure 22-33** Copper solubility as function of (a) pH and (b) dissolved inorganic carbon (DIC). (Adapted from Shull and Becker, 1960).

for copper. The experiments found a strong correlation with pH. Also shown on Fig 22-33b the dashed line is used to delineate the maximum thermodynamic solubility of copper as a function of pH for a water having 1 mmol/L of dissolved inorganic carbon. The change in solubility has an even stronger connection with pH, in fact showing theoretical solubility below the observations of Shull and Becker for pH values above approximately 6.5.

Constructed with the equilibrium constants published by Ferguson et al. (1996), an overview of copper solubility over the entire range of water conditions normally encountered in drinking water is shown on Fig. 22-34. Figure 22-34 is useful in making water conditioning decisions designed to address the solubility of copper. While it cannot be expected that the copper levels in any standing water will match the conditions in this figure exactly, actions taken to move a water's pH–DIC to a point on the diagram with lower copper solubility are likely to reduce copper at the tap. The reader should be cautioned that, while pH is often the cause of excess copper levels, this is not always so. If the water supply having high copper levels is at a pH of 8 or higher, other mechanisms should be considered, particularly mechanisms that might be related to an unusually high corrosion rate.

## Lead Release

The stable solid phase of lead also depends strongly on pH and much more strongly on the alkalinity. At lower pH, the dissolved plumbic ion ( $\text{Pb}^{2+}$ ) is the most stable form, while lead carbonate, or cerussite ( $\text{PbCO}_3$ ), is favored at neutral pH, and the hydroxycarbonate  $\text{Pb}_3(\text{OH})_2(\text{CO}_3)_2$  or

**Figure 22-34**

Contour plots of lead solubility as function of dissolved inorganic carbon (DIC): (a) for DIC concentrations from 0 to 6 mg/L and (b) DIC concentrations from 0 to 60 mg/L.

the hydroxide  $\text{Pb}(\text{OH})_2$  are favored at higher pH. Because the equilibrium between  $\text{Pb}^{2+}$  and  $\text{PbCO}_3$  tends to govern the distribution of oxidized forms of lead, the solubility of lead increases dramatically as pH decreases below pH 8 (for fixed alkalinity). The equilibrium concentration of carbonate decreases by about two orders of magnitude for each decrease of one pH unit when  $\text{H}_2\text{CO}_3$  is the predominating carbonate species. Also, as  $\text{Pb}^{2+}$  is a dissolved ion, while  $\text{PbCO}_3$  is a solid scale, the rate of dissolution of lead tends to be accelerated by low pH. Lead solubility in natural waters is controlled by pH and by the concentration of dissolved inorganic carbon.

Constructed with data from Schock and Wagner (1985), the regions of lead solubility on a pH–DIC plane are shown on Fig. 22-34. Two diagrams are provided: one to enable an overview throughout the entire range of pH and DIC normally encountered in drinking water and the second to expand the region where problems normally occur, namely low levels of dissolved inorganic carbon. The shape of the contours on these diagrams are controlled by the soluble complexes that lead forms in water, but the dominant influence on the actual concentrations shown is the solubility of the solid phases. The concentrations of lead shown on these diagrams are higher than the concentrations that are ordinarily observed in real systems, suggesting that kinetic effects dominate, that the solid phases are less soluble than available equilibria would estimate, that important solid phases have not been identified, or that electrokinetic phenomena influence solubility. Work has been done to confirm that the crystalline

minerals in place are those used in the model, but this does not eliminate the possibility of amorphous solid phases that cannot be identified by crystallography (Schock and Wagner, 1985; Schock et al., 1996).

In any case, Fig. 22-34 has been found useful in examining alternate water conditioning strategies and their impact on lead levels. Movement from one place in the diagram to another with lower lead solubility usually results in reduced concentrations of soluble lead.

## 22-10 Formation of Treatment-Related Scales on Water Conduits

---

Important natural scales form on the surface of all the metals used for water conduits. In addition to these scales, water is often conditioned in the water treatment process to manage the development of other scales, particularly calcium carbonate. The formation of these scales is discussed below.

### Calcium Carbonate Scale

During the first half of the twentieth century, one of the most prominent developments in waterworks-related chemistry was the calcium carbonate saturation index developed by Wilfred F. Langelier of the University of California at Berkeley (Langelier, 1936). Langelier's work was timely because it combined knowledge of chemical equilibria (Talbot and Blanchard, 1905) with the relatively recent availability of practical pH measurement devices (Baylis, 1929) to provide a practical means for evaluating calcium carbonate saturation. Langelier named the index the *saturation index*.

At the time, achieving calcium carbonate saturation was thought to be the principal means for controlling corrosion of iron distribution piping. If a solution were appropriately supersaturated with calcium carbonate, it would deposit protective calcium carbonate on the inside of the pipe, protecting it from the water. Earlier work had been conducted on the subject of  $\text{CaCO}_3$  and corrosion, notably by a German chemist named Tillmans (Tillmans, 1913; Tillmans and Heublein, 1913). Langelier proposed a "saturation pH" ( $\text{pH}_s$ ) at which the alkalinity and the calcium hardness would be at equilibrium with each other and with solid calcium carbonate. Without any simplifying assumptions, the saturation pH may be found with the following relationships:

- Definition of alkalinity in terms of molar quantities:

$$\text{Alk} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{OH}^-] - [\text{H}^+] \quad (22-22)$$

- Equilibrium for dissolution of calcium carbonate:

$$K'_{\text{so}} = [\text{Ca}^{2+}][\text{CO}_3^{2-}] \quad (22-23)$$

where  $K'_{\text{so}}$  = mixed solubility constant for  $\text{CaCO}_3$

- Equilibrium for dissociation of bicarbonate:

$$K'_2 = \frac{a_{\text{H}^+} [\text{CO}_3^{2-}]}{[\text{HCO}_3^-]} \quad (22-24)$$

where  $K'_2$  = acidity constant for dissociation of bicarbonate  
 $a_{\text{H}^+}$  = activity of hydrogen ( $a_{\text{H}^+} = a_{\text{H}_s^+}$  for  $\text{pH} = \text{pH}_s$ )

- Equilibrium for dissociation of water:

$$K'_w = a_{\text{H}^+} [\text{OH}^-] \quad (22-25)$$

where  $K'_w$  = mixed dissociation constant of water

In this context the term “mixed constant” refers to an equilibrium constant that has been corrected for ionic strength of all ions except for the hydrogen ion. Correction for the hydrogen ion is not necessary because the pH measurement is a measure of activity, that is,  $\text{pH} = -\log(a_{\text{H}^+})$ .

Rearranging these:

$$[\text{CO}_3^{2-}] = \frac{K'_{\text{so}}}{[\text{Ca}^{2+}]} \quad [\text{HCO}_3^-] = \frac{a_{\text{H}_s} + K'_{\text{so}}}{K'_2 [\text{Ca}^{2+}]} \quad [\text{OH}^-] = \frac{K'_w}{a_{\text{H}_s^+}} \quad [\text{H}^+] \sim a_{\text{H}_s^+}$$

Substituting,

$$\text{Alk} = \frac{a_{\text{H}_s} + K'_{\text{so}}}{K'_2 [\text{Ca}^{2+}]} + 2 \times \frac{K'_{\text{so}}}{[\text{Ca}^{2+}]} + \frac{K'_w}{a_{\text{H}_s^+}} - a_{\text{H}_s^+} \quad (22-26)$$

Rearranging,

$$(a_{\text{H}_s^+})^2 (K'_{\text{so}} - K'_2 [\text{Ca}^{2+}]) + (a_{\text{H}_s^+}) (2K'_2 K'_{\text{so}} - K'_2 [\text{Ca}^{2+}] \text{Alk}) + K'_2 [\text{Ca}^{2+}] K'_w = 0 \quad (22-27)$$

Equation 22-27 may be solved as a quadratic equation:

$$a_{\text{H}_s^+} = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \quad (22-28)$$

where  $a = K'_{\text{so}} - K'_2 [\text{Ca}^{2+}]$   
 $b = 2K'_2 K'_{\text{so}} - K'_2 [\text{Ca}^{2+}] \text{Alk}$   
 $c = K'_2 [\text{Ca}^{2+}] K'_w$

Taking the logarithm,

$$\text{pH}_s = -\log a_{\text{H}_s^+} \quad (22-29)$$

The necessary data for solving the equation are provided in Table 22-9. A simplified form of these equations has traditionally been used:

$$\text{pH}_s = \text{p}K'_2 - \text{p}K'_{\text{so}} - \log [\text{Ca}^{2+}] - \log \text{Alk} \quad (22-30)$$

Using Eq. 22-30,  $\text{pH}_s$  is a function of the same variables. In Eq. 22-30, the influence of pH on alkalinity is neglected. When the pH is between 6.5 and

**Table 22-9**

Thermodynamic data for the carbonate system

The following expressions can be used to determine equilibrium and solubility products as a function of temperature (K):

□ Plummer and Busenberg (1982):

$$\log K_1 = -356.3094 - 0.06091964 \times T + \frac{21,834.37}{T} + 126.8339 \times \log T - \frac{1,684,915}{T^2}$$

$$\log K_2 = -107.8871 - 0.03252849 \times T + \frac{5151.79}{T} + 38.92561 \times \log T - \frac{56,713.9}{T^2}$$

$$\log K_{so} (\text{calcite}) = -171.9065 - 0.077993 \times T + \frac{2839.319}{T} + 71.595 \times \log T$$

□ Harned and Owen (1958):

$$\log K_w = 6.008 - 0.017060 \times T - \frac{4471}{T}$$

For nonideal solutions (i.e., with an ionic strength above zero) the nonideality can be corrected using activity coefficients:

$$\gamma_B = \frac{\{B\}}{[B]}$$

The activity coefficient is given by the Davies equation (Eq. 5-43):

$$\log \gamma_B = -AZ_B^2 \left( \frac{\sqrt{I}}{1 + \sqrt{I}} - 0.3 \times I \right)$$

where  $Z_B$  = charge on species B

$A$  = Debye-Hückel constant, 0.5 at 25°C

$I$  = ionic strength,  $= \frac{1}{2} \sum C_i Z_i^2$

$C_i$  = concentration of species  $i$

$Z_i$  = ionic charge of species  $i$

8.5, the contribution of alkalinity may be neglected. Langelier then defined the  $\text{CaCO}_3$  or Langelier saturation index (LI) as the difference between the measured pH and the  $\text{pH}_s$ , thus

$$\text{LI} = \text{pH} - \text{pH}_s \quad (22-31)$$

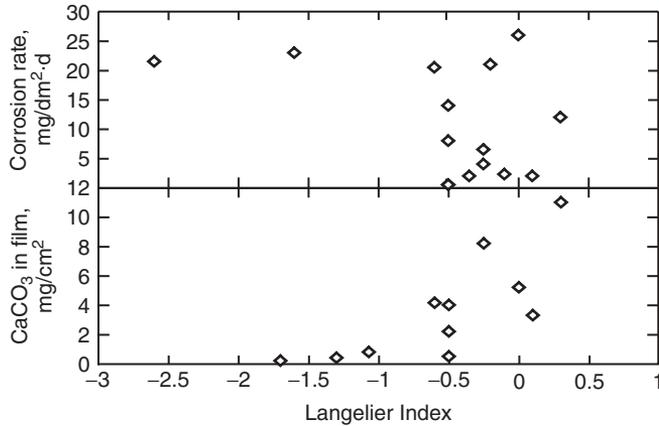

The state of saturation with respect to calcium carbonate, therefore, depends on the value of the Langelier index:

$\text{LI} < 0$  solution is undersaturated with  $\text{CaCO}_3$  (will dissolve  $\text{CaCO}_3$ )

$\text{LI} = 0$  solution at equilibrium with  $\text{CaCO}_3$

$\text{LI} > 0$  solution supersaturated with  $\text{CaCO}_3$  (will precipitate  $\text{CaCO}_3$ )

It is a common practice for utilities to add lime or caustic soda to their treated water to achieve a saturation index that is near neutral or slightly positive (0 to +0.2), and there is some evidence that this chemical addition

**Figure 22-35**

Correlation of calcium and carbonate ( $\text{CaCO}_3$ ) deposition and corrosion of gray cast iron (Adapted from Stumm, 1956): (a) corrosion rate versus Langelier saturation index, and (b)  $\text{CaCO}_3$  deposition versus Langelier saturation index.

helps to reduce red water complaints (Clement et al., 2002; DeMartini, 1938). The appropriateness of the saturation index for controlling corrosion or even the deposition of a  $\text{CaCO}_3$  scale is subject to contradictory evidence (Larson, 1975; Stumm, 1956, 1960). The problem of connecting  $\text{CaCO}_3$  deposition and corrosion is illustrated by the data on Fig. 22-35 in which there is a poor correlation between Langelier's index and the rate of corrosion. Although the saturation pH has a rational basis, the definition of the saturation index itself is empirical. Nevertheless, calcium carbonate chemistry is a subject of broad interest.

The results summarized above were developed by Stumm (1960) in a study examining the corrosion of cast-iron pipe during exposure to several different water qualities. Based on these results, no correlation was found between the Langelier index ( $\text{CaCO}_3$  saturation) and corrosion even though  $\text{CaCO}_3$  deposition did increase substantially as the Langelier index increased.

Since Langelier's original research, there have been a number of attempts to improve upon the index (Larson and Buswell, 1942), to facilitate its determination (Dye, 1944, 1952, 1958; Hoover, 1938), or to demonstrate its utility (DeMartini, 1938). Others have also proposed alternate indices associated with calcium carbonate saturation. Notable among these are the driving force index (McCauley, 1960), the momentary excess (Dye, 1952), the Ryznar stability index (Ryznar, 1944), and the aggressiveness index (AWWA, 1977). These indices represent concepts that are basically the same as Langelier's original principle.

Perhaps the calcium carbonate chemistry of a water and its relationship to stability and corrosion is best characterized by three factors: (1) the free-energy driving force of the precipitation reaction ( $\Delta G$ ), (2) the calcium carbonate precipitation potential (CCPP), and (3) the calcium carbonate saturation buffer intensity ( $\beta_{\text{Alk}}^S$ ). A brief discussion of each of these is useful.

**FREE-ENERGY DRIVING FORCE**

The free energy ( $\Delta G$ ) is a quantitative measure of the energy available to drive the precipitation reaction. It can be shown that  $\Delta G$  influences the rate of the precipitation reaction and that a certain  $\Delta G$  threshold must be reached before crystal nucleation will ensue (Nielsen, 1964; Stumm and Morgan, 1996). It can be shown that the  $\Delta G$  for  $\text{CaCO}_3$  precipitation can be defined as follows:

$$\Delta G = RT \ln \frac{[\text{Ca}^{2+}][\text{CO}_3^{2-}]}{K'_{so}} \quad (22-32)$$

Trussell et al. (1976) demonstrated that  $\Delta G$  and the Langelier index are related in the following manner:

$$\Delta G = -2.3RT (\text{LI}) \quad (22-33)$$

Thus, the LI is a *driving force index*. Calcium carbonate will spontaneously precipitate from solution at a  $\Delta G$  of less than about  $-5$  to  $-7$  kcal/mol (Trussell, 1972). When calcium saturation is used as a red water control technique, a  $\Delta G$  of about  $-0.5$  kcal/mol is probably sufficient. The calcium saturation technique should be used with caution for waters of low alkalinity and/or hardness because, even though the water is supersaturated, its capacity to precipitate protective calcium carbonate is limited. This illustrates the need for a capacity index.

**CALCIUM CARBONATE PRECIPITATION POTENTIAL**

The calcium carbonate precipitation potential, or the CCPP, is the amount of calcium carbonate that will precipitate or dissolve from the solution as it comes to equilibrium with solid  $\text{CaCO}_3$  (Merrill and Sanks, 1977a,b, 1978). The magnitude of this *capacity index* can be derived as follows:

If the amount of  $\text{CaCO}_3$  that will precipitate from a solution to achieve equilibrium is given by  $X$  mol/L, then the equilibrium condition is

$$[\text{Ca}^{2+}]_{\text{final}} [\text{CO}_3^{2-}]_{\text{final}} = K'_{so} = ([\text{Ca}^{2+}] - X) (C_T - X) \alpha_2 \quad (22-34)$$

where  $K'_{so}$  = mixed solubility product for  $\text{CaCO}_3$

$X$  = amount of  $\text{CaCO}_3$  that will precipitate, mol/L

$\alpha_2 = (K'_1 K'_2) / ([\text{H}]^2 + K'_1 [\text{H}] + K'_1 K'_2)$

Alkalinity in the equilibrated system is given by

$$\text{Alk} - 2X \simeq (C_T - X) (\alpha_1 + 2\alpha_2) + \frac{K'_w}{a_{\text{H}^+}} - a_{\text{H}^+} \quad (22-35)$$

where  $\alpha_1 = \alpha_2 [\text{H}] / K'_2$

$K'_w$  = mixed dissociation constant for water

These two equations can then be solved by the methods described by Trussell (1998) or by the computer programs identified in *Standard Methods* (APHA, 2000).

#### CALCIUM CARBONATE SATURATION BUFFER INTENSITY

The calcium carbonate buffer intensity ( $\beta_{\text{Alk}}^S$ ) is a measure of the sensitivity of the calcium carbonate saturation of the solution to changes in alkalinity (Trussell et al., 1976). This *sensitivity index* is of interest because it measures the sensitivity of the calcium carbonate saturation of the solution to changes in alkalinity near the cathodic reaction. The buffer intensity can be estimated from the following equation:

$$\beta_{\text{Alk}}^S = \left( \frac{\partial \text{Alk}}{\partial S} \right)_{C_t} = \left( \frac{\partial \text{Alk}}{\partial [\text{H}^+]} \right) \left( \frac{\partial [\text{H}^+]}{\partial [\text{CO}_3^{2-}]} \right) \left( \frac{\partial [\text{CO}_3^{2-}]}{\partial S} \right) \quad (22-36)$$

where  $S$  is the saturation with respect to calcium carbonate:

$$S = \frac{[\text{Ca}^{2+}][\text{CO}_3^{2-}]}{K'_{\text{so}}} \quad (22-37)$$

Higher values of  $\beta_{\text{Alk}}^S$  are associated with smaller changes in calcium carbonate saturation, for a given exogenous change in alkalinity, for example, by local inhomogeneities in solution associated with the reduction of oxygen at a cathodic site. Thus local supersaturation of  $\text{CaCO}_3$  would be expected at cathodic sites where hydrogen ion is being withdrawn from solution, when  $\beta_{\text{Alk}}^S$  is larger, resulting in the deposition of  $\text{CaCO}_3$  scale at the cathode, but not the anode. Therefore, it is desirable to enhance scale formation by operating in a region where  $\beta_{\text{Alk}}^S$  is small, all else being equal. When  $C_t$  is larger or  $[\text{Ca}^{2+}]$  is larger,  $\beta_{\text{Alk}}^S$  is smaller. Higher pH generally favors corrosion control by increasing  $\Delta G$  and CCP and lowering  $\beta_{\text{Alk}}^S$ ; however, not all of these fundamental indices can be optimized under the same conditions. Also, there may be practical limitations to pH control. There is probably no simple optimum for all three of these parameters. Rather it is important to consider each of them and understand their significance.

Finally, consideration must be given to the fact that calcium carbonate is a salt with inverse solubility, *that is, its solubility decreases as the temperature of the water increases*. Temperature is an important consideration because waters that appear to have satisfactory conditioning at the temperature in the water system often have problems of calcium carbonate deposition in hot water systems, resulting in undesirable deposition and sludging, reducing the useful life of water heaters.

In addition to calcium carbonate, aluminum salts can also result in undesirable deposition downstream of water treatment plants (Snoeyink, 2002). Examples of such deposits are shown on Fig. 22-36. Alum is, by far, the most

**Figure 22-36**

Alumino-silicate deposits on surface of asbestos-cement water main downstream of water treatment plant.

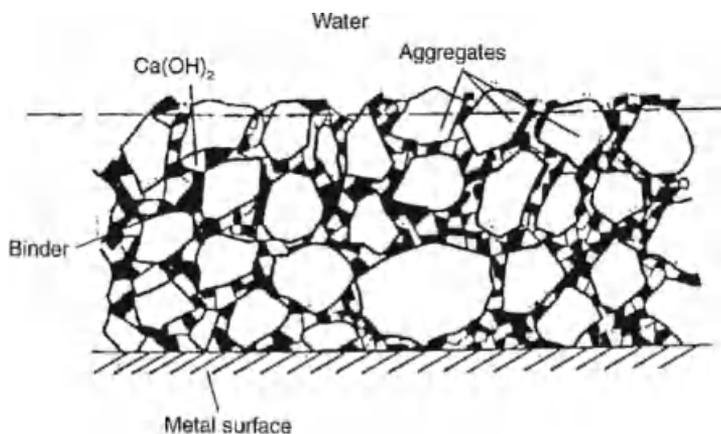

frequently used coagulant used in U.S. water treatment practice today. As it takes quite some time for aluminum hydrolysis to reach final equilibrium. As a result, virtually all water treatment plant effluents are supersaturated with aluminum. This can result in direct precipitation of aluminum hydroxide or the formation of other aluminum precipitates in downstream pipelines. When this precipitation occurs, it typically takes the form of a “washboard” surface that can significantly increase head loss. Sometimes this head loss increase can cause important problems for the distribution system.

When any metal ion is added to water, it first forms a hydroxide precipitate that is metastable in nature, meaning that in time it will hydrolyze further to form a more stable solid species. Metal hydrolysis also occurs when copper sulfate is added to water for algae control as well as when a metal ion coagulant is added to water. In the case of aluminum, which is particularly amphoteric, the amount of this unstable material can result in direct precipitation of aluminum hydroxide or the formation of other aluminum precipitates in downstream pipelines. To date, there is limited literature on this subject and all the conditions that control these problems are not well understood (Price, 1997).

## 22-11 Dissolution of Cement-Based Materials

---

Most of the largest structures and conduits used to transport, treat, and contain drinking water have surfaces of concrete or cement mortar. Use of cementaceous materials for this purpose dates back to Roman times, and evidence of the good service that concrete can provide is that some of the conduits built of these materials by the Romans are still in service today. Nevertheless, there are certain conditions when concrete will not provide good service. It is important to know what these conditions are and what can be done to mitigate them.

**Figure 22-37**  
Schematic structure of cement-based material.

Concrete is composite material consisting of a cement binder in which inert filler materials called aggregate are imbedded (see Fig. 22-37). The cement binder is made through the hydration of a cement powder. Cement powders are primarily a mixture of calcium silicates, calcium aluminates, and other components, mixed in various proportions.

Cement-based materials, such as concrete and mortar are made from three components: inert aggregates, a cement powder, and water. Once water is added and the mixture is blended, the cement powder hydrates to form a binder with significant compressive strength and resistance to erosion. When mortar is applied to the surface of a metal water conduit, it not only provides physical protection but also chemical protection as a result of its basic alkaline character.

Generally, the cement powder used to make concrete for water-carrying structures (filters, basins, reservoirs, and pipes) is Portland cement, the cement with the lowest aluminum content. Cement mortar linings on water pipe are made from a variety of cements, generally with standard composition, shown in Table 22-10 (Leroy et al., 1996). The composition of each type of cement varies somewhat from one country to the next.

Once the cement powder comes in contact with water, it begins to undergo hydration, hydrolysis, and precipitation reactions that result in hardening of the material (Leroy et al., 1996). At first, the hydration process affects only the outer layer of the particles of cement powder. After hydration has occurred the process slows down and various solid phases formed come to a metastable equilibrium with the interstitial water. In most cements, this interstitial water is rich in calcium and potassium hydroxide. Typically, this pore water has a pH value of 13 to 13.5. The metastable phases formed in these early stages continue a process of slow hydrolysis over a period of years until the cement is completely cured. These changes also result in

### Composition of Cement and Corrosion Resistance

### Reaction of Cementaceous Surfaces with Water

some changes in the crystalline structure as well. As a result, the hardened material develops a heterogeneous structure that can be porous both at the microscale and the macroscale. Generally, cements with less calcium oxide and more aluminum and iron oxides are more resistant to attack from low-pH, low-alkalinity waters.

Aggregate used in concrete ranges from fine sand used in mortars to large stones 75 to 100 mm (3 to 4 in.) in diameter. Reactive aggregates may cause durability problems in water pipe and are to be avoided. The cement mortar used as a protective liner in cast-iron or steel water pipe is made by using a fine aggregate of silica sand. When feasible, it is applied using the centrifuged spinning method, designed to assure a dense, even coating.

### Important Cementaceous Materials

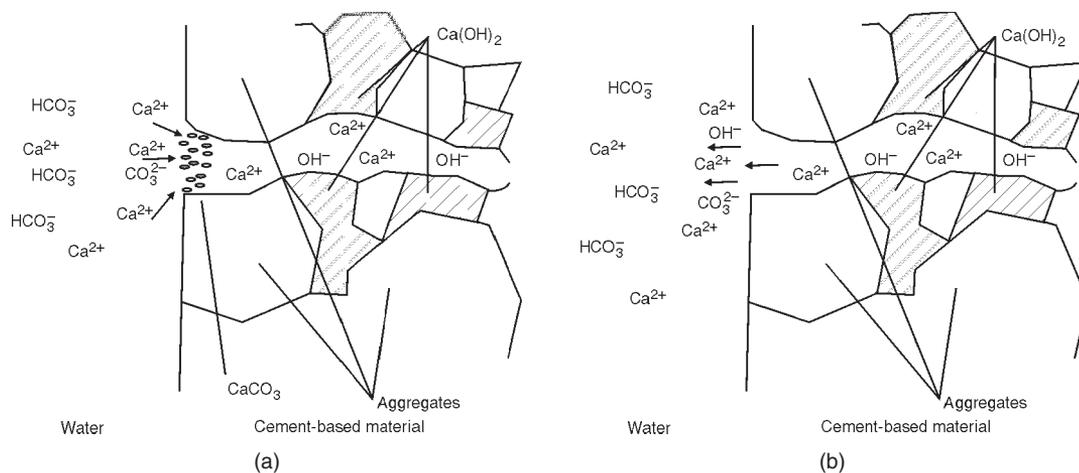

For many years asbestos–cement was used to make a light, strong, low-cost water pipe (AC pipe). An additional advantage of AC pipe is its ability to maintain a smooth surface when used for waters that are corrosive to cast iron. AC pipe, made by using asbestos fibers in place of sand or aggregate, has a relatively strong, dense pipe wall. In the 1970s concerns about the release of asbestos fibers from asbestos–cement pipe subject to corrosion by low-pH, low-alkalinity waters began to surface. Worker exposure to asbestos fibers during pipe manufacture also raised additional concerns about AC pipe. As a result of these concerns AC pipe is not available on the market today, but there are still many thousands of miles of this pipe in water systems today.

## Understanding Concrete Corrosion

The cement in reinforced concrete water pipe, cement mortar lining of steel and cast-iron water pipe, and asbestos–cement water pipe is subject to deterioration when exposed to prolonged contact with aggressive waters. There are at least two mechanisms involved in the dissolution of cements. The first is the dissolution of free lime and other compounds when in contact with low-pH, low-alkalinity waters. The second is chemical attack by aggressive ions such as sulfate and chloride.

Corrosion of cement pipe materials in domestic water systems is governed principally by solubility considerations. This statement suggests that simple chemical equilibrium could be applied to address the problem, but cement is not one simple compound, but a mixture of different solid phases. As a result, the chemistry of its interaction with water depends on the composition of the specific cement matrix as well as the composition of the water.

Leroy et al., (1996) outlined a simple conceptual model that is useful in understanding the role of  $\text{CaCO}_3$  in the deterioration of cement-based materials exposed to water. The idea is that, after they cure, most cements have a certain amount of free lime in their pore structure. Two extremes can then be envisioned. On the one hand a pore-blocking condition can occur (Fig. 22-38a). Such a condition occurs when the cement-based material is exposed to a water that is hard, alkaline, and supersaturated with  $\text{CaCO}_3$ . Under these conditions, lime attempting to leach from the pores in the cement structure immediately reacts with the hardness and the alkalinity in the water to form  $\text{CaCO}_3$ , and the  $\text{CaCO}_3$  formed seals off the pore. Because the water is supersaturated with  $\text{CaCO}_3$ , the  $\text{CaCO}_3$  plug that is formed is thermodynamically stable and the concrete is protected. The

**Figure 22-38**  
Leroy model for pore blocking: (a) blocking condition, and (b) nonblocking condition.

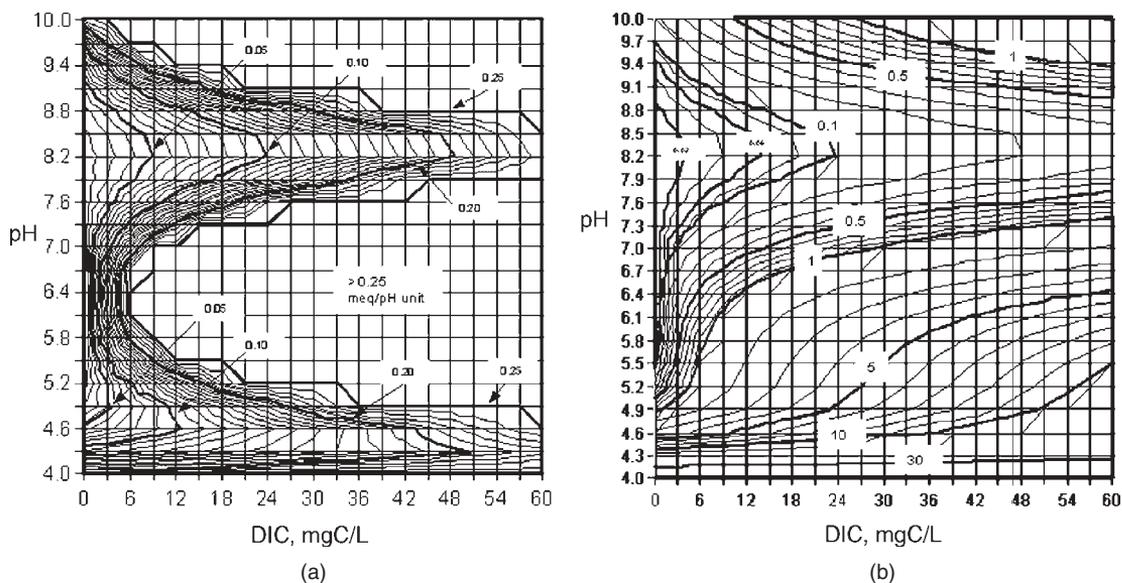

other condition (Fig. 22-38b) occurs when the cement-based material is exposed to a soft, low-pH water that is undersaturated with  $\text{CaCO}_3$ . Under these conditions, although some  $\text{CaCO}_3$  may form, lime is able to leach out of the pore and, with time, it becomes empty.

The Leroy et al. (1996) model is also consistent with certain observations about the impact of cement chemistry on the deterioration of the cement matrix in low-alkalinity waters. For example, the general observation is that waters with pH values below 7 are generally regarded as aggressive to concrete surfaces. Coagulation with alum or ferric chloride can result in significant pH reduction. Consequently, concrete surfaces in water plants downstream of coagulation often show etching and other signs of deterioration before pH adjustment. As mentioned earlier in this section, cements with less lime and more aluminum and iron are less prone to forming deposits of free lime that might be leached out in the manner shown on Fig. 22-39. Soukatchoff (1990) conducted a 14-year study where samples of cement mortar, made with three different types of cement, were exposed to a soft water with the following characteristics:

pH 5.0

Alkalinity, 0.5 mg/L as  $\text{CaCO}_3$

Hardness, 2.6 mg/L as  $\text{CaCO}_3$  ( $\text{Ca} = 0.45$  mg/L)

**Figure 22-39**

Isopleths of buffer intensity versus pH and dissolved inorganic carbon (DIC or  $C_t$ ): (a) buffer intensity with respect to changes in alkalinity  $[\partial \text{Alk} / \partial \text{pH}]_{\text{DIC}}$ , and (b) buffer intensity with respect to changes in DIC  $[\partial \text{DIC} / \partial \text{pH}]_{\text{Alk}}$ . (Adapted from Leroy et al., 1996.)

**Table 22-11**Cement character and impact of exposure to low-pH, low-alkalinity water<sup>22</sup>

Item		Composition or Value, %		
		Portland Cement	Blast Furnace Cement	High-Alumina Cement
Chemical composition	CaO	65	48	38
	SiO <sub>2</sub>	22	27	3.5
	Al <sub>2</sub> O <sub>3</sub>	5	13	36
	Fe <sub>2</sub> O <sub>3</sub>	2.5	1.50	18
	Other	6	10.50	4.5
Change after 14 years of soft water	Change in porosity	+33	+22	+10
	Change in weight	-10	-6.5	-2.5
	Change in compressive strength	-62	-32	+134

<sup>a</sup>Chemical composition from Table 22-10; porosity and strength data from Soukatchoff (1990).

From the results of Soukatchoff's experiment, summarized in Table 22-11, it appears that cements with greater aluminum and iron content are more resistant than are traditional Portland cements.

Swelling, due to the use of poor-quality aggregates or because of excessive sulfates in the water, is also a problem with cement-based materials immersed in water. Waters with high levels of sulfate are thought to react with the calcium aluminates in the concrete to form ettringite, a compound that takes up a significantly larger volume, resulting in swelling. The problem of swelling has been associated with waters with sulfate levels above 400 mg/L (Leroy et al., 1996).

## 22-12 Treatment for Corrosion Control

Because of economic losses associated with corrosion of water conduits, much research has been devoted to developing effective corrosion control measures. General categories of such approaches to corrosion control include (1) control of environmental parameters affecting the corrosion rate, (2) addition of chemical inhibitors, (3) electrochemical measures, and (4) considerations of system design (Fontana, 1985; Revie and Uhlig, 1985; Jones, 1996). Because the focus of this chapter is primarily with internal corrosion of water distribution conduits, the following discussion will be limited to those control measures applicable to drinking water distribution systems. Applicable control measures include pH adjustment and addition of chemical inhibitors such as polyphosphates, zinc orthophosphate, and silicates.

**Adjustment  
of pH–Alkalinity–  
Dissolved  
Inorganic Carbon**

Generally, pH adjustment is made in an attempt to manage the deposition of calcium carbonate. Methods for estimating the state of calcium carbonate saturation have been discussed earlier.

In addition to affecting the carbonate system, pH is a key variable in the solubility of conduit materials such as lead, copper, and zinc. The thermodynamic stability of oxidized species such as metal oxides, hydroxides, and carbonates is strongly influenced by pH also, so pH may govern whether an insoluble natural protective scale can form or whether soluble species are favored as a metal corrodes. Therefore, pH adjustment can play a major role in stabilizing a pipe material such as lead: low pH favors dissolution into plumbic ions, whereas high pH favors formation of solid scales that deter further corrosion.

Water treatment practice to adjust pH has typically involved the addition of lime [as CaO or Ca(OH)<sub>2</sub>] or sodium hydroxide to achieve a positive value of the Langelier index. The addition of these materials also increases alkalinity, which, in turn, has the side effect of decreasing the solubility of corrosion products such as lead carbonate and enhancing the formation of solid metal carbonate scales. Generally, pH adjustment may not be a satisfactory corrosion control measure for waters of very low alkalinity. In such cases, the buffer intensity is low and the amount of lime necessary to raise pH is small, but the resulting high-pH water does not have much resistance to pH changes. Therefore, it is easier for low-pH microsites to form near the surface (pits) even though the overall thermodynamic tendency is for calcium carbonate scale to form.

In waters of high alkalinity and hardness, it becomes more difficult to adjust the pH to a value above 8.0 because of the rapid precipitation of calcium carbonate in distribution lines. The interaction of pH change and alkalinity change has a complicated effect on buffer intensity, which may result in a lowered buffer intensity following treatment if not monitored carefully (Stumm, 1960).

When examining which chemicals might be used to address the solubility of copper and lead, it is often convenient to refer to solubility on contour diagrams of solubility on a pH–DIC plane. Such diagrams are provided on Figs. 22-33 and 22-39. Further insight as to which chemicals will drive the water in which direction on the pH–DIC plane is provided in Table 22-11 (Trussell, 1998).

It is also useful to consider the stability of water in three-dimensional space defined by the pH, alkalinity, and DIC. Stumm (1960) first introduced this concept by appropriating the parameter  $\partial\text{Alk}/\partial\text{pH}$  from the field of medical science. Stumm demonstrated that the concept could be used to examine the impact of the water's resistance to pH changes on corrosion. At first he appropriated the name, buffer capacity, from the medical community as well. Later on, recognizing that the alkalinity is really the capacity factor, he renamed it the buffer intensity. Of the three components that define the system—pH, alkalinity, and DIC—the pH is the only

**Table 22-12**

Effect of common chemicals on DIC, Alk, and pH

Chemical	Change in DIC, mol DIC/mol X	Change in Alk, eq Alk/mol X	pH
CaO	0	2	Increase
NaOH	0	1	Increase
Na <sub>2</sub> CO <sub>3</sub>	1	2	Increase
NaHCO <sub>3</sub>	1	1	Tends to pH 8.3
CO <sub>2</sub>	1	0	Decrease
H <sub>2</sub> SO <sub>4</sub>	0	-2	Decrease
HCl	0	-1	Decrease
CaCO <sub>3</sub>	1	2	Increase

Source: Trussell (1998).

intensive variable. There are several ways to look at buffer intensity. The buffer intensity most often referred to in connection with corrosion is a measure of the degree to which the water resists changes in pH due to reactions that change its alkalinity (the reduction of water, the hydrolysis of metal ions, etc.). The other major factor that can change the pH is exchange of CO<sub>2</sub> with the atmosphere. Thus, there are really two “buffer intensities” that characterize the system:

$$\beta_{\text{pH}}^{\text{Alk}} = \left[ \frac{\partial \text{Alk}}{\partial \text{pH}} \right]_{\text{DIC}} \quad (22-38)$$

$$\beta_{\text{pH}}^{\text{DIC}} = \left[ \frac{\partial \text{DIC}}{\partial \text{pH}} \right]_{\text{Alk}} \quad (22-39)$$

The parameter  $\beta_{\text{pH}}^{\text{Alk}}$  provides information about the water's resistance to changes in pH that result from actions that consume or produce alkalinity, and  $\beta_{\text{pH}}^{\text{DIC}}$  provides information about the resistance of the water to changes in pH that result from actions that remove or add CO<sub>2</sub> to the water. Isopleths of  $\beta_{\text{pH}}^{\text{Alk}}$  and  $\beta_{\text{pH}}^{\text{DIC}}$  on a DIC–pH plane are shown on Fig. 22-39. Using Fig. 22-39, it is possible to gain an understanding of how adjustments will affect the stability of the pH of a water. Generally, both indices are minimal in the pH range of 8 to 8.5.

Two fundamental types of phosphate compounds are commonly used in water conditioning: orthophosphates and polyphosphates. These two compounds, however, are presented in a number of different ways depending on the purpose for which they are designed.

All the forms of phosphate used in water treatment can be characterized by the formula  $P_nO_{3n+1}^{-(n+2)}$ . The most well-understood forms are those having  $n$  values of 1, 2, and 3, respectively. Phosphates with  $n = 1$  (e.g., PO<sub>4</sub><sup>3-</sup>) are called orthophosphates and phosphates with  $n > 1$  are called

### Addition of Phosphates

polyphosphates. The most well understood of the polyphosphates are pyrophosphate ( $P_2O_7^{4-}$ ) and tripolyphosphate ( $P_3O_{10}^{5-}$ ) and the least understood are probably the “glassy polyphosphates.” It should be noted that the polyphosphates, not the orthophosphates, were first used in water treatment. Polyphosphates were introduced in the late 1930s for prevention of calcium carbonate scale formation (Rice and Hatch, 1939). It was observed subsequently that polyphosphates could also act as corrosion inhibitors.

Polyphosphates, generally linear chains of phosphorous atoms held together by a  $-PO-P-$  linkage, are formed via the dehydration of orthophosphates using caustic. The chain length of the product is dependent on the ratio of  $Na_2O$  and  $P_2O_5$  used in its preparation. The “hexametaphosphate” commonly used in water treatment is actually a mixture of polyphosphates having  $n$  values ranging from 5 to 22, and is not a true hexametaphosphate (Lytle and Snoeyink, 2002). A true hexametaphosphate would have the formula  $Na_6(PO_3)_6$  and would be a cyclic compound rather than a polyphosphate.

When introduced to water, all polyphosphates hydrolyze with time, shortening their chain length until they eventually become orthophosphate. The rate at which this reversion process proceeds has been determined for certain concentrated solutions but not in conditions applicable to drinking water treatment (Green, 1950; Morgen and Swoope, 1943).

Both orthophosphates and polyphosphates are thought to behave as anodic inhibitors. It is possible that this behavior is related to the inhibition of the dissolution of the oxide layer in conformance with the theory mentioned earlier in connection with passive films on iron surfaces (Stumm, 1998). Such inhibition may be due to the formation of binuclear complexes on the oxide surface that compete with ligands attempting to promote dissolution protective scale (Stumm, 1995).

In water treatment, phosphates are employed as orthophosphates, polyphosphates, and bimetallic phosphates. Orthophosphates are most effective in slightly alkaline conditions, and they have been found to be effective with iron, galvanized, and lead pipe as well as solder, although the conditions that make orthophosphates most effective require further investigation.

Polyphosphates are most widely used for their properties in “sequestering” the color that iron and manganese impart to water. This sequestering action has been demonstrated to be due to the impact of polyphosphates on the size of particles formed in solution rather than sequestration in the chemical sense (Lytle and Snoeyink, 2002). Polyphosphates are not that effective in controlling color when  $Fe(III)$  solids are already present. Rather, they seem to be more successful at controlling color formation when they are added to water while the iron is still in the  $Fe(II)$  form. Thus polyphosphates are best added before chlorination or oxygen oxidize  $Fe(II)$  to  $Fe(III)$ . The required dose is also influenced by hardness. In the absence of hardness Kleuh and Robinson (1988) observed that

about 1 mg/L of polyphosphate as  $\text{PO}_4^{2-}$  was required to sequester 2 mg Fe/L. In the presence of a calcium hardness of 100 mg/L as  $\text{CaCO}_3$  as much as 5 mg  $\text{PO}_4^{2-}$ /L was required. Polyphosphates are also widely used to inhibit the precipitation of calcium carbonate and calcium sulfate. Mixtures of medium-molecular-weight polyphosphates, such as “hexametaphosphate,” are generally more effective than high-molecular-weight glassy polyphosphates.

Polyphosphates were once the most widely used corrosion inhibitor for recirculating cooling towers (Butler and Ison, 1966), and in that capacity they served as an effective anodic inhibitor when used at fairly high doses (20 to 30 mg/L as  $\text{PO}_4$ ) and at low pH (pH < 6). In drinking water applications polyphosphates have been used as corrosion inhibitors also, but results have been more mixed. In some cases the addition of polyphosphates has actually increased the rate of pitting. The observed increase in the pitting rate may be due to the rather weak properties of anodic inhibition they sometimes exhibit at neutral and alkaline pHs and low doses. Polyphosphates are ineffective for corrosion inhibition in stagnant water; protection for corrosion increases with velocity (Larson, 1957).

Blends of ortho- and polyphosphates have been used successfully in situations where both corrosion inhibition and iron sequestration or hardness stabilization are objectives of the same treatment program.

In 1970, Murray, at Long Beach, California, developed a zinc orthophosphate combination that has been used successfully in many drinking water applications (Murray, 1970). It appears that Murray’s formulation takes advantage of the combination of zinc as a cathodic inhibitor and orthophosphate as an anodic inhibitor (Kelly et al., 1978).

The addition of zinc orthophosphate or zinc chloride, in combination with pH adjustment, can also reduce the deterioration of asbestos-cement pipe exposed to soft waters of low alkalinity (Buelow et al., 1980; Schock and Buelow, 1981). The addition of zinc orthophosphate at dosages of 0.3 to 0.6 mg/L as Zn, with pH adjusted up to 8.2, resulted in extremely low rates of leaching of calcium from the pipe. A dense protective coating of hydrozincite [ $\text{Zn}_5(\text{OH})_6(\text{CO}_3)_2$ ] may have played a major role in reducing loss of calcium from the concrete. Orthophosphate was believed not to have played a role in this protective mechanism; therefore, Schock and Buelow (1981) recommended that zinc chloride be used instead.

Reiber (1989) found that orthophosphate forms a very thin, labile, protective surface that serves to inhibit the anodic reaction on copper surfaces. After 2 weeks of exposure, the anodic Tafel slope increased substantially and corrosion current dropped 80 percent.

Sodium silicates have been studied as an alternative corrosion inhibitor. They were first employed in the 1920s to reduce corrosion of lead piping (Butler and Ison, 1966). As with polyphosphates, the molecular composition of silicates tends to be indeterminate, with a formula of  $\text{Na}_2\text{O} : n(\text{SiO}_2)$ ,

where  $n$  is a variable ratio. The neutral silicate commonly used for treatment of alkaline waters is a silicate with  $n$  of 3.2 (Vic et al., 1996). Typical dosages required for protection range from 4 to 30 mg/L as SiO<sub>2</sub>, the higher doses being required for waters with higher hardness, higher chlorides, and/or higher dissolved solids (Lane et al., 1977).

When used at low doses, silicates, like polyphosphates, tend to operate as anodic inhibitors. As a consequence, if doses are insufficient, anodic area is reduced and pitting is exacerbated (Vic et al., 1996). Recently, the usage of silicates increased in the United States, and it appears that one of the major benefits being gained is the pH increase associated with silicate addition. Because silicates are relatively expensive, lime and sodium hydroxide should be compared as alternatives.

Based on surface analysis, it appears that silicates form a thin layer over the corroded metal that consists of ferric or other metal oxides and silicates. Therefore, some corrosion must take place for the metal surface to be protected. The scales that form are self-limiting and do not appear to build to thick layers. If silica dosage is ended, the protective films begin to break down and gradually disappear (Vic et al., 1996).

The degree of effectiveness of silicate as a corrosion inhibitor depends on the characteristics of the water. Based on extensive tests by the Illinois State Water Survey (ISWS) (Lane et al., 1977), it was found that pH controls the silicate dosage required for effective control, with higher doses needed at pH values lower than 8.5. The concentration of calcium, magnesium, chloride, and other constituents affects the optimal silicate dosage. The presence of calcium may assist inhibition by the scale that forms, while high magnesium concentrations may cause deposits of magnesium and decrease effectiveness. The ISWS concluded that silicates are the best means of inhibiting corrosion of galvanized steel and copper-based metals in domestic hot water systems, especially recirculating systems such as those used in commercial buildings. It is clear that for any particular water, detailed testing of the effect of silicate at different dosages is necessary. When added at too low a dosage, silicate may intensify the corrosion rate in some waters, while overdosage can affect the taste of the supply and cause discoloration of food.

## 22-13 Corrosion Testing

---

Test loops are often a useful way to explore treatment alternatives and to gain a better understanding of alternatives for controlling corrosion, the release of metals, and deposition of undesirable scales. The design and operation of such test loops is beyond the scope of this book but can be found in the AWWARF book on internal corrosion of water distribution systems (Snoeyink and Wagner, 1996).

Because of the potentially high costs of corrosion damage, corrosion measurement techniques have been developed to determine corrosion rates in both the field and the laboratory. Techniques have been developed to assess quantitatively the effectiveness of various corrosion control measures and the corrosion resistance of new pipe and lining materials. Until the early 1950s, corrosion measurements were almost exclusively made using weight loss methods, which are inconvenient and time consuming. Subsequently, electrochemical techniques were developed that can be used to measure instantaneous corrosion rates and can be used to continuously monitor both laboratory corrosion studies and corrosion processes in operating water systems. A good survey of corrosion monitoring methods has been published by Moreland and Hines (1979). The principal methods of corrosion measurements currently in use in the water supply field are described below.

There are two weight loss corrosion rate measurement methods in general use in the water field. The older is the coupon method and the newer is the machined nipple method developed by the ISWS. Both of these methods are described in ASTM Standard D2688 (ASTM, 1983).

## **Weight Loss Methods**

### **COUPON TEST**

The coupon method employs a flat metal coupon. The coupon is located in the center of the pipe where the velocity is higher than at the pipe wall. At the pipe wall the coupon may be subject to turbulence induced by the coupon holder, and this can affect scale and oxide film formation and the action of corrosion inhibitors. Coupon holders are normally installed in a bypass pipe loop to permit removal and checking of specimens without upsetting normal system operation. Multiple specimens are usually installed to allow determination of the corrosion rate as a function of time. Coupons are  $13 \times 102 \times 0.8$  mm ( $0.5 \times 4.0 \times 0.032$  in.) for sheet metals and  $13 \times 102 \times 3$  mm ( $0.5 \times 4.0 \times 0.125$  in.) for cast metals.

Coupons are then installed in a test loop with flow velocities adjusted to match velocities in the system under consideration. Two time series of coupons are recommended. The first set of coupons should be removed at 4- to 7-day intervals to determine initial corrosion rates. The second set is used to determine the long-term steady-state corrosion rate. The first coupon of the long-term set should be removed after 1 month with the remainder removed at 1- to 3-month intervals as the test progresses.

### **MACHINED NIPPLE TEST**

The machined nipple test employs a short length of actual pipe material machined on the outer surface. Machining permits insertion in a PVC pipe sleeve that is connected into the pipe system under test with pipe unions. The specimen holder is designed so that a smooth flow line is maintained

through the pipe specimen so as to simulate actual flow conditions. The inner surface of the pipe nipple is not altered or machined.

When monitoring corrosion in an existing system, inserts are made from the same material as used in the system being observed. A bypass pipe loop is constructed to permit removal and inspection of the pipe inserts without disturbing normal operations. A minimum upstream straight run of 1 m (3.25 ft) should be provided ahead of the ISWS tester to minimize nonuniform flow or turbulence. One insert should be exposed a minimum of 120 days before evaluation, and the second should be exposed at least 12 months if possible. The corrosion rate is then computed according to ASTM D2668.

### Electrical Resistance Method

The electrical resistance method of corrosion measurement is based on the principle that the rate of change of electrical resistance of a piece of metal is directly proportional to its rate of change of cross-sectional area, which is in turn a function of the corrosion rate (Bovankovich, 1973). Electrical resistance also changes with temperature so some means of temperature compensation must be provided. A reference element is provided by connecting in a Wheatstone bridge circuit in parallel with the measuring element. The reference element is of the same material as the measuring element but is protected from the corrosive environment. The reference element is enclosed in the body of the probe to assure that it is maintained at the same temperature as the measuring element.

### Linear Polarization Resistance Method

The linear polarization resistance (LPR) method is based on the principle that at low corrosion potentials, corrosion rate is essentially a linear function of polarization resistance. Commercially manufactured equipment based on this principle is available. It is normally calibrated to read corrosion rate directly as a function of corrosion current, usually at a fixed corrosion potential of  $\pm 10$  mV. The advantage of this method is that corrosion rates can be determined instantaneously.

The basic equation on which the linear polarization method is based is (Stern and Geary, 1957)

$$i_{\text{corr}} = \frac{1}{2.3} \left( \frac{\Delta i}{\Delta E} \right) \left( \frac{\beta_a \beta_c}{\beta_a + \beta_c} \right) \quad (22-40)$$

where  $i_{\text{corr}}$  = corrosion current,  $\mu\text{A}/\text{cm}^2$   
 $\Delta E$  = change in emf, mV  
 $\Delta i$  = change in current density,  $\mu\text{A}/\text{cm}^2$   
 $\beta_a, \beta_c$  = Tafel slopes for anodic and cathodic reactions, mV/decade

The LPR is defined as the change in polarization with changes in current at the corrosion potential:

$$\text{LPR} = \left[ \frac{\Delta E}{\Delta i} \right]_{i=i_{\text{corr}}} \quad (22-41)$$

$$i_{\text{corr}} = \frac{1}{2.3} \left[ \frac{\beta_a \beta_c / (\beta_a + \beta_c)}{\text{LPR}} \right] \quad (22-42)$$

or

$$i_{\text{corr}} = \frac{B}{\text{LPR}} \quad (22-43)$$

where

$$B = \frac{1}{2.3} \left[ \frac{\beta_a \beta_c}{\beta_a + \beta_c} \right] \quad (22-44)$$

and the units are

$$i_{\text{corr}} = \mu\text{A}/\text{cm}^2$$

$$\text{LPR} = \frac{\text{mV}}{\mu\text{A}/\text{cm}^2}$$

$$B = \text{mV}$$

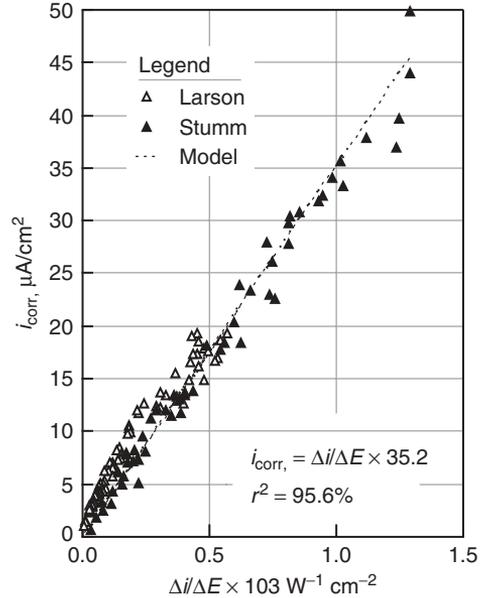

When corrosion is controlled by concentration polarization at the cathodic reaction as when oxygen depolarization is controlling,  $\beta_c$  becomes very large and Eq. 22-44 becomes

$$B \sim \frac{1}{2.3} \beta_a \quad (22-45)$$

Direct-reading corrosion meters based on the LPR principle use this relationship. The value of  $E$  is held at a constant value, usually  $\pm 10$  mV, and the instrument is calibrated to read corrosion rate directly as a function of current.

Various researchers have presented data relating corrosion rate to LPR. The principle behind the method was actually demonstrated before Stern and Geary explained the principles behind it (Skold and Larson, 1957; Stumm, 1959). A plot amalgamating the results of both these efforts is shown on Fig. 22-40. The results in the figure suggest that, for cast iron,  $B = 35.2$  mV. Values for the constant,  $B$  for a variety of metals of interest in water systems, are summarized in Table 22-13.

In 1957, Stern and Geary demonstrated theoretically that polarization resistance could be used to measure corrosion rates (Stern and Geary, 1957). Unaware of this work and working in another field, Larson and Skold published a study reporting an empirical relationship between polarization resistance and the corrosion rate of cast iron (Larson and Skold, 1958a). In 1959, Stumm published an even broader set of data demonstrating that the Stern and Geary method could be used successfully to measure the

**Figure 22-40**

Measuring corrosion of cast iron with linear polarization resistance. (Data from Larson and Skold, 1958a; Stumm, 1959.)

**Table 22-13**

Summary of polarization resistance coefficients

Solution	Iron	Steel	Cast Iron	Stainless	Copper Alloys
Seawater	22	20 ± 9	29	—	22 ± 11
Miscellaneous water (includes tap water)	50 ± 28	43 ± 19	35 ± 4	—	—
Acids	15	20 ± 9	24	22 ± 6	—
Chlorides	22 ± 15	22 ± 10	60	31 ± 11	20 ± 9
Means	31	32	38	25 ± 7	20

Source: Grauer and Stumm (1982).

corrosion rate of cast iron (Stumm, 1959). The data from both Larson and Skold (1958a) and Stumm (1959) are displayed together in Fig. 22-40, with good agreement.

## Problems and Discussion Topics

- 22-1 Describe the differences in composition of gray cast iron and ductile iron. What are the advantages of ductile iron? What is its disadvantage?

- 22-2 What are the properties of lead that led to its early use as a plumbing material?
- 22-3 Why does corrosion not necessarily result in an increase in metal concentration in the bulk solution? Under what circumstances would the concentration of a metal increase in the water being served?
- 22-4 What is the potential of the  $O_2/H_2O$  half reaction at pH 7? Calculate the potential using the Nernst equation and the data in Table 22-2.
- 22-5 What behavior would be expected from iron, copper, zinc, or lead materials at pH 7 and  $E_H -250$  mV? What about pH 6 and  $E_H +250$  mV?
- 22-6 In an American study, it is reported that iron is corroding at a rate of 10 mpy in the water system being studied. Electrochemists like to work with the corrosion rate in  $A/m^2$ , and European corrosion engineers are comfortable with units like mm/y. What is the corrosion rate of the iron in these units?
- 22-7 Using Fig. 22-10, estimate the corrosion rate of copper and zinc in 2 N  $H_2SO_4$  with and without exposure to air. Express the corrosion rate in mm/y.
- 22-8 Using Eq. 22-17, estimate the limiting current density for iron corroding in water containing oxygen at a concentration of 9 mg/L. What would the limiting corrosion rate be if the corroding metal were copper instead of iron? If it were lead?
- 22-9 Why are exchange currents hard to measure?
- 22-10 In Fig. 22-10, the  $E_{corr}$  for copper appears to be below its standard electrode potential. Explain why this might be true.
- 22-11 Zinc generally operates as a cathodic inhibitor. Will the addition of zinc raise or lower the potential of a corroding sample?
- 22-12 The standard electrode potential for copper is approximately 340 mV, yet Reiber (1989) observed an  $E_{corr}$  of approximately 0 mV in Seattle tap water, Jones (1996) observed an  $E_{corr}$  of  $-350$  mV in seawater, and Jinturkar et al. (1998) observed an  $E_{corr}$  of approximately  $-120$  mV in aerated 1 N  $H_2SO_4$ . What is a possible explanation for these observations?
- 22-13 Zinc and steel specimens are both suspended as test electrodes in a polarization apparatus like that shown on Fig. 22-7 and held at a potential of approximately  $-400$  mV. If the apparatus were adjusted to a potential of  $-600$  mV, would the behavior of the two metals differ? If so, why?
- 22-14 A hydrogeologist is having trouble with the corrosion of the casing made of 304L stainless steel in a deep well. Could the situation be

improved by replacing the existing casing with a new one made of 316 SS? The available analytical data are shown below.

#### Well water analysis

Constituent	Units	Concentration	Constituent	Units	Concentration
Ca	mg/L as Ca	20	Alkalinity	mg/L as CaCO <sub>3</sub>	80
Mg	mg/L as Mg	18	Chloride	mg/L as Cl <sup>-</sup>	35
Na	mg/L as Na	23	Sulfate	mg/L as SO <sub>4</sub> <sup>2-</sup>	48
K	mg/L as K	4	Si	mg/L as SiO <sub>2</sub>	8
Iron	mg/L as Fe	2	Ammonia	mg/L as N	1
pH	Unitless	8	TDS	mg/L	150
H <sub>2</sub> S	mg/L as H <sub>2</sub> S	2			

- 22-15 Over what range of pH is the solubility of most scales minimized? Recognizing that most water systems have a pH between 6.5 and 9.5, at which extreme of these pH values is a corrosion scale most likely to form?
- 22-16 Which anion is thought to be the most aggressive where corrosion is concerned? What properties of this ion contribute to its aggressive behavior?
- 22-17 In all models of the pitting process it is assumed that a porous layer or cap will develop over the top of the pit. Why is it necessary that this cap be porous?
- 22-18 Explain the difference between galvanic and electrolytic corrosion.
- 22-19 Why are dielectric couplings often used between dissimilar metals in home construction? Under what circumstances can these couplings contribute to internal corrosion problems?
- 22-20 Which couple is more likely to cause galvanic corrosion? Galvanized pipe and brass or 90/10 tin–antimony solder and copper? Silver solder and copper or 90/10 tin–antimony solder and copper?
- 22-21 Both Stumm (1960) and Larson (1957) demonstrated that high pH results in rougher corroded surface on gray cast iron. What might be some reasons behind these observations?
- 22-22 Describe the five layers that form on the surface of a hot-dipped galvanized pipe. Why does the protection of the galvanizing diminish as each of these layers gradually corrodes away? Zinc is much less noble than iron, so why does it provide any protection at all. Does it not just corrode faster than the iron?
- 22-23 Explain the difference in protection provided by galvanizing and by tin plating when an imperfection or a place where the coating is absent is present.

- 22-24 Brasses exhibit a certain critical composition. Beneath the critical composition they tend to behave as pure zinc. Above that, they behave more like copper. What is that critical composition?
- 22-25 A water system exhibits signs of microbiologically induced corrosion. What can be done?
- 22-26 A water system is being designed that must handle a rather soft water with a low pH. What sort of cement will give best service under these circumstances?
- 22-27 A water distribution system has red water complaints and tuberculation in portions of the system. What are some alternatives that might be considered to remedy these problems?
- 22-28 A water distribution system with lots of new copper-plumbed homes has been receiving a number of complaints about blue water. The chemical characteristics of the water are given below. What can be done?

#### Water analysis

Constituent	Units	Concentration	Constituent	Units	Concentration
Ca	mg/L as Ca	5	Alkalinity	mg/L as CaCO <sub>3</sub>	15
Mg	mg/L as Mg	0	Chloride	mg/L as Cl <sup>-</sup>	2
Na	mg/L as Na	2	Sulfate	mg/L as SO <sub>4</sub> <sup>2-</sup>	0
K	mg/L as K	0	Si	mg/L as SiO <sub>2</sub>	6
Iron	mg/L as Fe	0	Ammonia	mg/L as N	0
pH	Unitless	6.5	TDS	mg/L	25

- 22-29 The utility in Problem 22-28 is also having problems with the lead rule in the same homes. What might be done to mitigate this issue?

---

Because of varying source water quality, local site conditions, client needs, water quality requirements, and a host of other considerations identified previously in Chap. 4, every water treatment plant is different, very often unique. The purpose of this chapter is to present, discuss, and illustrate a number of functioning water treatment plants and how they evolved. So that comparisons can be made between plants, the following items are considered for each of the water treatment plants:

- The setting
- Treatment processes
- Unique design features
- Performance data

The plants considered in this chapter are all different, but for different reasons. The plants were selected to illustrate the many different types of challenges that must be overcome in developing a successful project. In presenting the process and design details for the various plants, both SI and U.S. customary units are used in this chapter, even though the design may have been done in one or the other.

The successful design, construction, and implementation of the plants described in this chapter were based on an understanding of the fundamental concepts and principles presented and discussed throughout this book. In the last section in this chapter, a number of lessons learned from these and other water treatment plant designs are presented.

## **23-1 North Cape Coral Water Treatment Plant, Florida, United States**

---

### **Setting**

Once marketed as a “waterfront wonderland,” the City of Cape Coral (City) is the third largest city, by area, in Florida. The City’s population growth has been very rapid in recent decades. Residential properties were

developed with shallow wells to the Mid Hawthorne Aquifer, stressing the raw-water resource. In addition, the South Florida Water Management District (SFWMD) reported an increase in chlorides from saltwater intrusion in the existing deep-well field serving the Southwest Reverse Osmosis Water Treatment Plant (SWRO WTP). Because of the trends in water quality, it was necessary to develop a water independence plan to serve the future development of this growing city.

Part of the solution was the construction of a new brackish water RO WTP within a residential neighborhood of North Cape Coral (Fig. 23-1). The initial treatment plant design capacity was 45 ML/d (12 mgd) but was designed to include a future expansion of 45 ML/d (12 mgd) for an ultimate capacity of 90 ML/d (24 mgd). Low-pressure RO membranes are used, consisting of a composite polyamide, thin-film composite (TFC) membranes, to reduce the concentrations of TDS, sulfate, and chloride in the raw water. A portion of the groundwater is bypassed around the main RO process and blended with the RO permeate water to produce the final blended treated water to be sent to the distribution system.

The project also included 22 raw-water supply wells, raw water transmission mains, a potable water transmission main, deep injection well for the disposal of concentrate, and a 45-ML (12-mil. gal.) above-ground storage tank. With the assistance of local regulators, nearly \$4.5 million in funding for the project was secured from the SFWMD through its alternative water supply funding program. The project was divided into multiple contracts, resulting in large savings in time and money for the City and the local community. The project was delivered to the City on time and under budget.

**Figure 23-1**  
View of the North Cape Coral  
Water Treatment Plant.

**Treatment Processes**

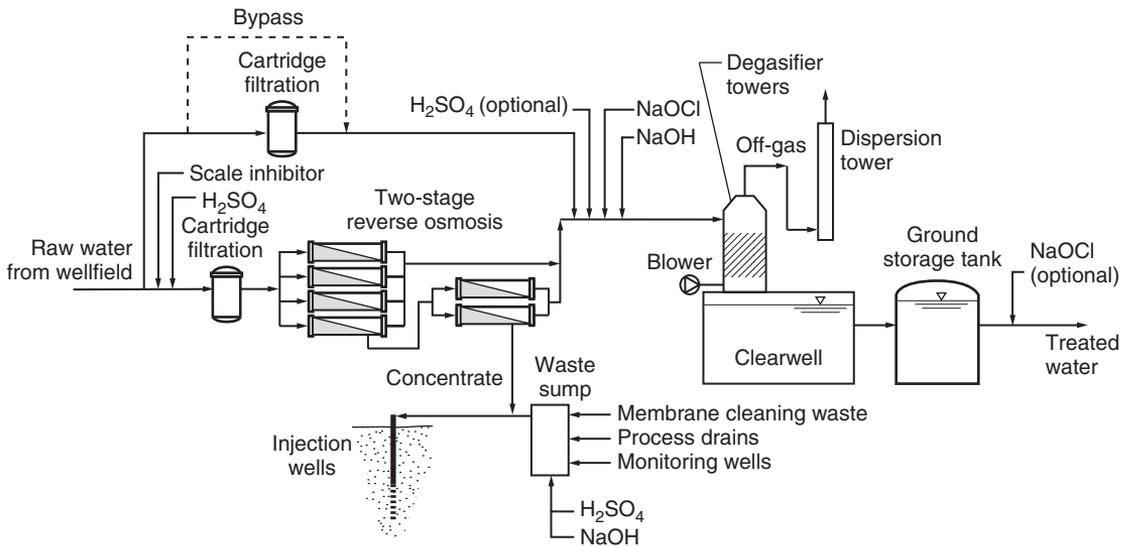

A key water quality objective was to meet current and anticipated water quality regulations. Further, to provide stable water for introduction into the distribution system, certain goals such as alkalinity, hardness, and pH had to be maintained. The treated-water goals were set below the MCL to provide flexibility in meeting the goals for the treatment process, as summarized in Table 23-1.

The full process flow diagram for the North Cape Coral WTP is presented on Fig. 23-2 and described in the following sections. Photographs of plant facilities are shown on Fig. 23-3.

**Table 23-1**  
Treated-water quality goals

Constituent	Unit	Goal	MCL
Chloride	mg/L	225	250
Sodium	mg/L	140	160
TDS	mg/L	450	500
Calcium hardness	mg/L	20	NC <sup>a</sup>
Alkalinity	mg/L	30	NC
pH	mg/L	8.5–9.0	NC
Fluoride	mg/L	0.7–1.3	2.0 (secondary)

<sup>a</sup>NC: Noncorrosive.

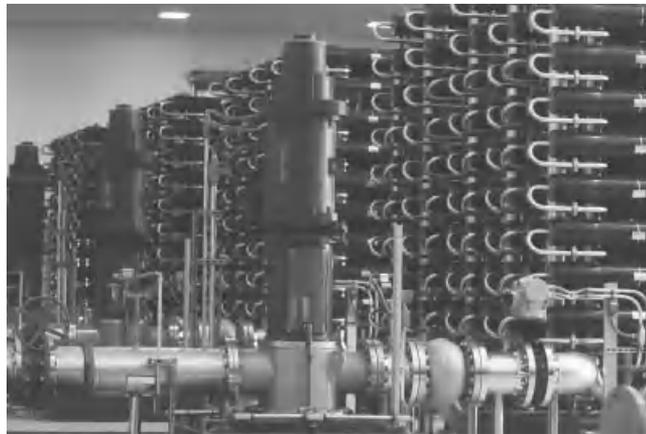

**Figure 23-2**  
North Cape Coral Water Treatment Plant process flow diagram.

(a)

(b)

(c)

**Figure 23-3**

North Cape Coral Water Treatment Plant: (a) feed water manifold in gallery below, (b) cartridge filters installed for easy access at operating floor, and (c) feed pump and RO skid.

**RAW-WATER FEED**

Raw water to the North Cape Coral WTP is pumped from the lower Hawthorne aquifer from 22 brackish wells. Each well is equipped with a variable frequency drive to meet the required system feed pressure of the plant. The plant is designed to accommodate the degradation of the water quality from these wells based on a detailed groundwater model.

**PRETREATMENT**

Pretreatment for the RO process includes chemical pretreatment with sulfuric acid and antiscalant followed by cartridge filtration. Sulfuric acid is added to adjust the pH to 5.8 or below to prevent calcium carbonate scaling. The antiscalant (scale threshold inhibitor) is added to reduce sparingly soluble salt and silica scaling. An optional sulfuric acid injection point is included prior to the degasification system for additional pH control. Four vertical cartridge filters with 5  $\mu\text{m}$  cartridges are provided to protect the RO membranes from particulate fouling as shown on Fig 23-3b.

**REVERSE OSMOSIS**

The plant was installed with four RO trains of 9.5-ML/d (2.5-mgd) permeate capacity each and provides for an additional four 9.5-ML/d (2.5 mgd) RO trains for the phase 2 expansion (Table 23-2). The RO trains are two-stage and allow for the addition of inter-stage boosting using energy recovery turbines when economically advantageous to the City. The trains are designed for a permeate production rate of 38 ML/d (10 mgd) at a design water recovery of 80 percent and a maximum water recovery of 85 percent. The plant typically operates at a maximum average flux of 27  $\text{L}/\text{m}^2 \cdot \text{h}$  (16  $\text{gal}/\text{ft}^2 \cdot \text{d}$ ) using TFC polyamide membranes with 37  $\text{m}^2$  (400  $\text{ft}^2$ ) of membrane area. However, the actual flux with all membranes installed is between 22 and 24  $\text{L}/\text{m}^2 \cdot \text{h}$  (13 and 14  $\text{gal}/\text{ft}^2 \cdot \text{d}$ ). In addition, there are spare vessel spaces on the top of the skid to allow for future expansion. The RO system includes a cleaning system to allow for cleaning each stage separately. Brine disposal is via a deep injection well.

The plant utilizes bypass blending to meet water quality and quantity goals. The phase 1 bypass operates at 7.5 ML/d (2 mgd) but is designed for

**Table 23-2**

Reverse osmosis design and operating parameters

Design Parameters	SI Units		U.S. Customary Units	
	Unit	Value	Unit	Value
Permeate capacity	ML/d	9.5	mgd	2.5
Recovery	%	80–85	%	80–85
Number of trains	Number	4	Number	4
Element filtration area	$\text{m}^2$	37.2	$\text{ft}^2$	400
Backpressure (maximum)	bar	1.7	$\text{lb}/\text{in}^2$	25
Average train flux	$\text{L}/\text{m}^2 \cdot \text{h}$	<27	$\text{gal}/\text{ft}^2 \cdot \text{d}$	<16
System configuration (stages)	Number	2	Number	2
Vessels (per stage)	Number	48:24	number	48:24
Element diameter	mm	200	in.	8
Element length	mm	1000	in.	40

Chemicals used	—	Caustic soda, citric acid	—	Caustic soda, citric acid

15 ML/d (4 mgd) under phase 2 conditions. The bypass includes cartridge filtration with 20- $\mu$ m cartridges.

#### **POSTTREATMENT AND FINISHED WATER**

Permeate is sent to two degassifiers for removal of carbon dioxide and hydrogen sulfide. Space for two additional degassifiers is provided for build-out to full plant capacity. An air dispersion tower provides odor control. A clearwell is located below the degassifiers and transfer pumps are used to convey the water to the 45-ML (12 mil. gal.) ground-level storage tank. Sodium hydroxide is added at the clearwell to raise the pH of the treated water prior to distribution. Sodium hypochlorite is added at the clearwell for disinfection. Sodium hypochlorite may also be added at the high service pump station, as needed.

The plant is designed for two 45-ML (12 mil. gal.) ground storage tanks at build-out. High service pumps provide water to the City's distribution system.

Beginning with conceptual design, the team constantly evaluated ways to boost plant efficiency, simplify the design, lower operating costs, and facilitate ease of operation and maintenance. Collaborative workshops were used to take full advantage of all team members and design disciplines. Many of the resulting innovations were incorporated into North Cape Coral WTP, providing valuable savings in current and future costs, construction schedule, and overall operability of the facility. A summary of selected design innovations are presented in Table 23-3.

Three-dimensional (3D) modeling of the facility was used during the early phases of the design process to provide the City with a visualization and tour of the proposed design. The 3D model was further used as a design tool to help visualize building layout, space configurations, and access to equipment, allowing the City and team members to see the proposed completed product and to mitigate potential conflicts. In addition, the team incorporated the future wastewater treatment facility into the 3D model. Use of this model allowed the team to find ways to consolidate facilities and systems to better utilize the existing footprint and provide cost and schedule savings.

The North Cape Coral Water Treatment Plant began delivery of treated water to the distribution system in spring, 2010. The plant has met all treated-water quality goals and provided a reliable new source of drinking water to the community. Water recovery has consistently ranged between 80 and 85 percent. The emphasis placed on collaborative design workshops and the implementation of innovative concepts achieved the goals established for cost and schedule savings and ease of operation. The North Cape Coral Water Treatment Plant was the recipient of the Design-Build Institute of American Merit Award for a Water/Wastewater Plant over \$25M.

#### **Unique Design Features**

#### **Performance Data**

**Table 23-3**

Selected design innovations

Area and Issues	Benefits
<b>Chemical Areas</b>	
Constructed drive-through bay doors	Improved safety and ease of loading and delivery
Utilized traveling bridge crane over full work area	Improved safety and maintenance for loading/unloading
Located bulk chemical storage near injection points	Reduced chemical piping and risk of leaks
Eliminated transfer and sump pumps by using gravity flow between bulk and day tanks	Reduced construction and maintenance costs
<b>Degasifier</b>	
Utilized common chemical injection point to two initial, and two future degassifiers	Eliminated three injection points and simplified chemical containment
Selected air dispersion system instead of traditional scrubbers and blowers	Reduced CO <sub>2</sub> emissions, eliminated regulated waste stream, and cut caustic use by 50%
Modified housing to remove water distributor	Improved access and maintenance
<b>Electrical System</b>	
Combined RO WTP with future wastewater plant into one shared building, with diesel generators and fuel tanks	Reduced footprint, eliminated electrical ductbanks, and lowered construction cost
<b>Instrumentation and Controls</b>	
Designed water sampling panels to consolidate instruments	Improved troubleshooting and calibration, extended probe life, and lower cost
Automated system to control water quality and quantity to maintain treated-water storage tank level	Improved efficiency in overall plant operation, cost savings in energy and chemicals
<b>Membrane Trains</b>	
Co-located first- and second-stage membranes	Reduced footprint, building size, and construction costs
Entire stage can be cleaned at once	Reduced system downtime
Installed collection piping below trains	Ease of operation and improved maintenance and cleaning

## 23-2 Lostock Water Treatment Works, Manchester, United Kingdom

### Setting

The supply of reliable drinking water to Manchester, North West England, was addressed by the Manchester Corporation Water Works between 1890 and 1925. Water from the Thirlmere Reservoir located in the Lake District, a scenic and popular area for outdoor activities, is supplied to Manchester

through the 154-km (96 miles) long Thirlmere Aqueduct. The flow is entirely by gravity and terminates at the storage reservoir at Lostock.

The aqueduct is mostly constructed in cut-and-cover and consists of a “D” section concrete-covered channel, approximately 2.2 m (7.1 ft) wide and between 2.2 m (7.1 ft) and 2.4 m (7.9 ft) high. Typically, the conduit has 1 m (3 ft) of cover and traverses the contours of hillsides to maintain a continuous slope. It is the longest gravity-fed aqueduct in the country, with no pumps along its route. The water flows at a velocity of 1.67 m/s (5.5 ft/s) and takes just over a day to reach Manchesta. The level of the aqueduct drops by approximately 0.3 m/km (20 in./mile) along its length.

The water is very soft and is low in color and turbidity. Historically, treatment at Lostock consisted of microstraining, chlorination, pH adjustment, and ortho-phosphate dosing. Because of the construction of the 100 year old aqueduct, ingress of some impurities en route cannot be prevented totally and the water was deemed at risk to infiltration of *Cryptosporidium* oocysts. At the time of the project design, inactivation of *Cryptosporidium* was not an acceptable solution to the UK Water Regulator. Physical removal with a positive barrier was required. Today the Regulator is not that adamant, if ozonation is involved.

A new Water Treatment Works (WTW) at Lostock was required to provide this physical barrier. The new Lostock WTW is situated near Bolton about 24 km (15 miles) Northwest of Manchester and supplies water to a population of half a million people in the Greater Manchester area. Sustainable development was one of the key factors in the design of the project. Lostock WTW is situated in a “Green Belt,” close to a residential area and within an area of ecological significance. Planning consent was obtained only after considerable local consultation and assessment of eight alternative sites.

Lostock WTW represents one of the largest water projects undertaken by United Utilities, the water supplier in the North West of England, as part of its Asset Management Programme (AMP3). The project included a new 180-ML/d (48-mgd) capacity works along with a new 35-ML (9.2-mil. gal.) treated-water reservoir, and was subsequently considered by United Utilities as its flagship WTW.

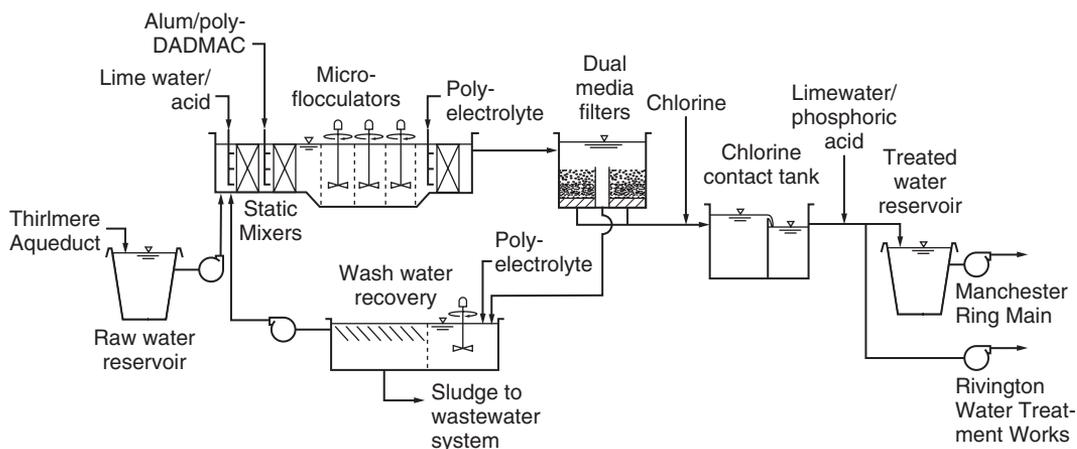

Although clarification processes had been considered and tested at other sites for the removal of *Cryptosporidium*, this process was not needed at Lostock due to the high quality feed water. As shown in Table 23-4, mean turbidity is less than 0.5 NTU, and the maximum recorded turbidity is 4.4 NTU. Direct filtration was selected to provide a very cost effective and easy to operate treatment process solution. The plant process flow diagram is shown on Fig 23-4.

A pilot study testing plan was developed to demonstrate appropriate design criteria for the filters and other facilities. Previous pilot studies and full-scale testing at similar WTW's provided a sound basis for the selection

**Table 23-4**

Summary of Thirlmere reservoir raw-water quality

Parameter	Unit	Minimum	Maximum	Mean	95 <sup>th</sup> Percentile
Turbidity	NTU	0.2	4.4	0.48	1.04
Color <sup>a</sup>	°Hazen	2	19	7.2	11.0
pH	Unitless	6.42	8.18	7.43	7.8
Alkalinity	mg/L as CaCO <sub>3</sub>	5	90	11.4	25.2

<sup>a</sup>In U.S. customary units, color is measured in platinum-cobalt color units.**Figure 23-4**

Lostock Water Treatment Works process flow diagram.

of initial parameters. Filtration rate and filter media were set at the start of testing and used to investigate coagulant type and dose, mixing, and flocculation time. The maximum filtration rate used for testing and in the subsequent design was 15 m/h (6 gpm/ft<sup>2</sup>). Similarly, the filter media was a dual-media configuration with a total bed depth of 1.2 m (48 in.), consisting of 0.4 m (16 in.) of anthracite coal with an effective size (ES) of 1.3 mm over 0.8 m (32 in.) silica sand with an ES of 0.65 mm.

Performance goals for the pilot study were established and included the following:

- Minimum 24-h filter runs
- Maximum clogging head of 3.5 m (11.5 ft)
- Filtrate turbidity <0.1 NTU 95 percent of the time

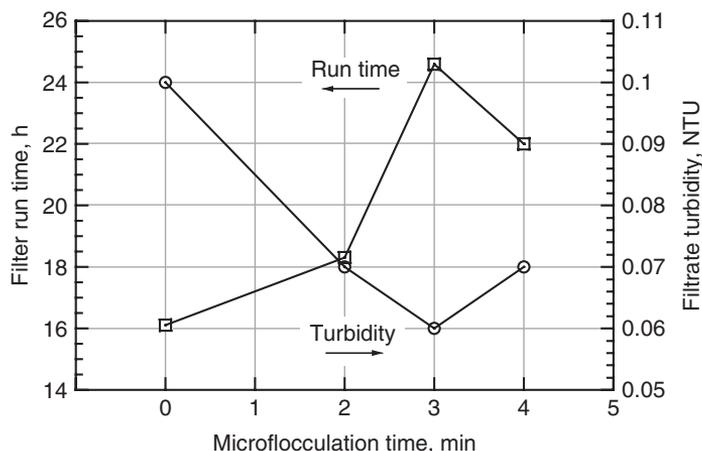

Coagulant testing included alum and two types of polyDADMAC polymer. It was immediately discovered that mixing was critically important to process performance, and this requirement was carried forward into the design.

Optimization varied with water quality for polymer type and dose, indicating the need to provide flexibility in the full-scale facilities and allow multiple polymers to be used. Filter run durations were also found to vary up to 15 percent depending on water temperature. For this reason, it was critical that the coldest water was tested. Due to scheduling concerns and the need for the trials to proceed, the feed water was chilled during some of the filter runs to investigate temperature effects and ensure minimum filter run times could be maintained.

After coagulant dose testing was optimized, flocculation time was varied to determine appropriate design criteria for the full-scale facility. It was found that extremely low flocculation times provided the best filter performance. Because of the size limitations of the pilot flocculation chambers, a length of coiled hose was used instead to provide the desired time and energy gradient. The latter was established by head loss measurements from which the  $G$  value was back calculated. As shown on Fig. 23-5, filtrate turbidity and run time were both optimized at 3 minutes in the plug flow pilot equipment. The term microflocculation was used to differentiate from flocculation upstream of clarifiers, where large and heavy floc is preferred. In the case of direct filtration, a small floc is preferred to help penetrate into the filter bed. For the full-scale design, the detention time was increased to 4 min to account for the differences in hydraulic efficiency between plug flow and mixed tanks in series.

In addition to process design considerations, site constraints played an important part in the overall design of the Lostock WTW. The site was not only in an ecologically sensitive area, it was also highly visible to the surrounding community. To achieve planning approval, the design needed to minimize the profile of the plant, and bury as many of the facilities

## Unique Design Features

**Figure 23-5**  
Pilot testing results for the microflocculation process.

**Figure 23-6**  
Aerial view of the Lostock Water Treatment Works.

**Figure 23-7**  
Lostock WTW was designed with minimum profile to blend into the surrounding landscape.

**Figure 23-8**  
Many of the structures are built below grade, including this treated-water pumping station.

as possible. Views of the plant from the air and ground level are shown in Figs. 23-6 and 23-7, and a buried pump station is shown in Fig 23-8. Unfortunately, the site was underlain by poor soil conditions consisting of variable glacial deposits, sands, and silts with artesian and subartesian conditions. Even after minimizing facility footprint, 1187 precast concrete piles were needed to support major structures.

**Figure 23-9**  
View along the microflocculation channel.

#### **MICROFLOCCULATION**

The microflocculation basins are designed as two parallel channels, each sized to convey the full design flow rate plus washwater recycle and filter to waste, as shown on Fig. 23-9. The design provides complete standby capability in the event one channel must be taken out of service, with isolation gates at each end. Upstream of each microflocculation channel are two in-channel static mixers. Acid or lime is dosed upstream of the first static mixer to provide for pH correction. Alum and polyelectrolyte (poly-DADMAC) are dosed upstream of the second mixer. The channel mixers are baffled to optimize mixing and designed to achieve a coefficient of variation (COV) of  $\leq 0.05$ , which was confirmed for all reagent applications by taking samples at various points in the channels downstream.

Each stream passes into three microflocculation chambers, each with a hydraulic retention time of 80 s under maximum flow conditions. Each chamber is fitted with a variable speed mixer and separated by perforated stainless steel dispersion screens to prevent short-circuiting. The two channels continue to the filter inlet channel, where an in-channel static mixer is used to mix polyelectrolyte (flocculant aid) fully prior to filtration.

#### **LIME SYSTEM**

An efficient and accurate lime feed system was an important part of the design, both for the coagulation process and final stabilization of the soft treated water. While milk of lime was considered initially, the lime particles can take up to 2 min or more to dissolve and would make the pH adjustment channel section very large. Another alternative was to use lime saturators to make lime water, but calcium carbonate sludge is created and active lime is lost in this process. Instead, lime water of low concentration ( $< 1700$  mg/L) was prepared directly in an accurately metered lime preparation system. No calcium carbonate formation occurs, as the water is not softened as it would be in a lime saturator, and an accurate concentration of lime

water below saturation could be produced directly and fed to both process locations.

#### FILTRATION

The design includes eight dual-media filters operating at a filtration rate of up to 15 m/h (6 gpm/ft<sup>2</sup>) with one filter out of service for backwashing. Although the ability to achieve the minimum run time of 24 h was demonstrated in the pilot studies, the washwater systems are nevertheless designed for a minimum filtration cycle of 12 h (i.e., two washes per day) to account for unforeseen conditions.

One of the requirements in the United Kingdom for filters designed specifically to remove *Cryptosporidium* from soft water is that the filter flow rate shall not change more rapidly than 1.5 percent per minute, or 5 percent for harder waters. The water at Lostock is very soft, so this lower rate of change is required to limit hydraulic shocks to the filters that could dislodge particles such as *Cryptosporidium*. It is not normal practice in the United Kingdom to provide individual filter flow measurement; rather, flow to each filter is hydraulically split by means of filter inlet weirs. Enlarging the filter gallery to provide filter flow measurement necessary to measure and control the flow changes was not an option, so an approach was developed using insertion probes installed in “drowned” filter outlet pipes in the filtered water channel. The design allowed removal of the probes without requiring access into the filtered water channel. This solution provided accurate flow measurement and filter flow change control well within the UK Water Regulator’s recommendations.

Between 2 and 4 percent of the water entering the Lostock WTW is used for filter washing. Rather than lose this water, provisions are incorporated to recycle the water back to the head of the plant. To avoid impacting the main process, facilities are provided to ensure the recycled water meets the following goals:

- >95 percent of Suspended solids must be removed.
- Turbidity must be  $\leq 2$  NTU for 95 percent of the time, never exceeding 5 NTU.

To achieve these goals, three lamella-plate settling modules (2 duty, 1 standby) are incorporated in the design, each providing 10 min of flocculation (Fig. 23-10). The maximum rise rate on the projected lamella surface is 0.65 m/h (0.26 gpm/ft<sup>2</sup>). One benefit of lamella settling is that it readily adapts to changes in flow rate, so no special restrictions are placed on water recycle. A small dose of polymer is added to assist settling of the dirty filter washwater, and residual solids are discharged to sewer.

Special care was taken to manage the overall cycle time for taking filters off-line for washing and returning them to service. Cycle time is an important design issue for direct filtration works in particular, as extreme water quality events can potentially shorten filter runs to the point where

**Figure 23-10**  
Lamella-plate settling modules provide washwater treatment prior to recycle.

production capacity must be curtailed. At Lostock, the filter backwashing controls were designed to monitor filter status and maintain minimum washing intervals between filters, even to the point of washing a filter early to prevent a backwash queue.

In addition, while filters are normally allowed to “drain to service” when taken off-line, the filter control system will override this feature to speed up cycling by discharging unfiltered water above the wash troughs. Finally, water must be drawn down below the wash troughs to just above the media to avoid media loss during air scour. This procedure is the slowest part of drawdown, as there is little driving head. Siphons are provided to speed removal of this water so the backwashing sequence can begin more quickly.

The Lostock WTW has met or exceeded all expectations for treated-water quality and production efficiency. The works routinely produces treated water with turbidity <0.05 NTU, and sampling has never detected the presence of *Cryptosporidium* in the effluent. Water supply utilization exceeds 99.8 percent, and average recycled washwater turbidity from the lamella-plate settlers averages less than 0.6 NTU. Average filter run durations are greater than 30 hours, and chemical usage closely matches results from the pilot study.

### Performance Data

## 23-3 River Mountains Water Treatment Facility, Nevada, United States

---

The water supply for the Las Vegas Valley is comprised of groundwater wells and surface water. Groundwater wells were the initial source of supply until after Hoover Dam was dedicated in 1935. Surface water from Lake

### Setting

Mead, the water impounded behind the Hoover Dam, then became a source of water supply in 1942. James M. Montgomery designed the first intake into Lake Mead, which served the City of Henderson and a private industry (Basic Magnesium Inc.), and this intake and pumping plant are still in operation today. The Alfred Merritt Smith Water Treatment Facility (AMSWTF), a new intake, and a pumping system were designed and placed into service in 1971, providing a secondary source of raw-water supply from Lake Mead.

In 1991 the Southern Nevada Water Authority (SNWA) was created to establish regional coordination of water resources and Nevada's water entitlement from the Colorado River. SNWA includes all major water and wastewater agencies in southern Nevada, which are Las Vegas Valley Water District, City of Henderson, City of North Las Vegas, Boulder City, Las Vegas, Clark County Water Reclamation District, and Big Bend Water District. In 1993, SNWA began planning for new water supplies to meet anticipated demand in 2025, which at that time was projected to be 3400 ML/d (900 mgd). The planning effort included a comprehensive integrated water resources plan, identification of recommended water treatment and transmission facilities, environmental impact analysis, and development of funding mechanisms.

Because the AMSWTF and connecting raw-and treated-water transmission systems provided approximately 80 percent of the treated water to the Las Vegas Valley in 1993, SNWA concluded that system reliability was critical for the water supply to the valley. This concern established one of the key criteria for the new facilities: the importance of reliability for the existing treatment and transmission system (Bromley et al., 2001).

Selecting the appropriate water treatment train for the new River Mountains Water Treatment Facility (RMWTF) involved the performance of bench studies and piloting. In addition, the outbreak of Cryptosporidiosis in 1994 resulted in 43 deaths in the Las Vegas Valley. The Centers for Disease Control and Prevention (CDC) were called to investigate. Although the CDC could not pinpoint the *Cryptosporidium* source, the water supply system was implicated as the only common factor among all the public health cases.

Providing a safe water supply is one of the most important goals for SNWA. *Cryptosporidium* is present in small quantities in Lake Mead, and public water quality confidence is crucial both to public health and to the local economy. SNWA took a proactive position on water quality and immediately began working toward the prevention of another *Cryptosporidium* outbreak by making the decision to include ozone in the treatment process both at the existing AMSWTF and the new RMWTF.

Chlorine was initially favored as the secondary disinfectant at the new facility. A major chlorine gas release occurred in 1992 from a nearby private industry, which affected the public's attitude toward the transportation and use of chlorine gas in or near their residential community. As a result,

SNWA chose to utilize liquid sodium hypochlorite and to produce it onsite at the RMWTF using a sodium chloride electrolysis process. This approach proved to be highly economical compared to the transport of bulk liquid sodium hypochlorite to the facility.

The first phase of the RMWTF went online in 2002, and construction on the second phase of the RMWTF began in 2003 and concluded in 2005. The aerial photograph on Fig. 23-11 shows most of the facilities provided in these two phases of design and construction. The facility is currently capable of 1140 ML/d (300 mgd) of finished-water production as a minimum.

Since 2000 the water level in Lake Mead has been falling, reaching approximately 331 m (1086 ft) above mean sea level by the end of 2010. This declining lake level has resulted in a variety of treatment implications, including higher raw-water temperatures, higher total organic carbon (TOC) values with greater potential for disinfection by-product formation, and higher algae content for both plants. The AMSWTF intake has been lowered to an elevation of 305 m (1000 ft) to draw higher quality water from deeper zones within Lake Mead. Treatment processes have also been affected due to the change in water quality, resulting in reduced filter run times and greater coagulant usage. SNWA has recently considered use of chloramination in lieu of chlorine as a secondary disinfectant, nanofiltration treatment and blending, enhanced coagulation, and GAC, either as a filter media operated as a biologically active filter or as a separate process following filtration.

**Figure 23-11**  
Aerial view of portion of the new SNWA treatment and transmission facilities.

## Treatment Processes

Treatment objectives for the design of the RMWTF included meeting or exceeding known regulations, planning for uncertainties in future regulations, and meeting customer expectations for safety, aesthetics, reliability, and quality. Existing regulations included the Disinfection Byproducts Regulations (DBP rule) and the Enhanced Surface Water Treatment Rule (ESWTR), among others, which were in effect at the time that the RMWTF was being designed or that were scheduled for imminent adoption.

SNWA also sought to provide a design to meet anticipated regulatory concerns. One specific area of consideration was improvement in DBP precursor removal. The pilot study conducted for the RMWTF included two processes that could assist in removing DBP precursors: enhanced coagulation and GAC adsorption. Pilot testing and cost analyses were used in the decision process that identified which processes were appropriate to include in the site planning and hydraulic profile for possible future construction.

Softening was another objective considered in the RMWTF design due to very high carbonate and noncarbonate hardness in the source water. The softening evaluation included piloting nanofiltration, evaluating capital and operating costs, and investigating the feasibility and implications of residuals disposal from the softening process. This evaluation was performed in conjunction with the Citizens' Advisory Committee, which provided input on the public's point of view to SNWA.

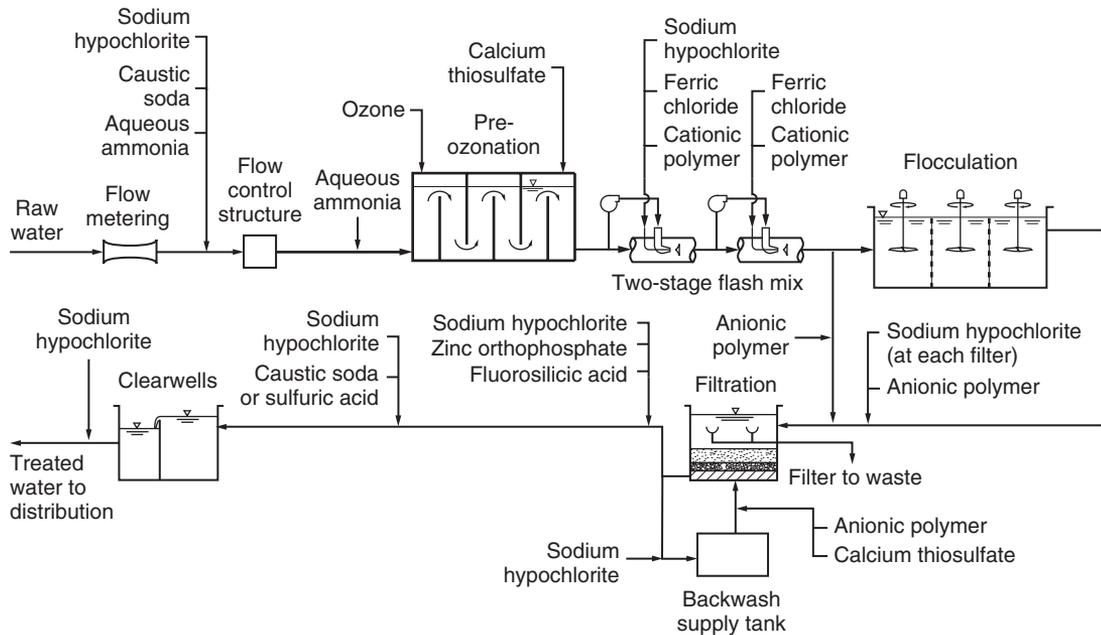

Initially, at least 13 treatment trains were considered as listed in Table 23-5. These were evaluated against the goals and objectives for treated-water quality, together with the decision to include ozone for *Cryptosporidium* inactivation (Tate, 2002). After an initial screening process, the remaining applicable treatment trains, featuring the greatest benefits to SNWA and customers, were further investigated.

Final process selection was based on pilot data, operational advantages, and factors important to the local community. The raw water quality from Lake Mead is normally good with low turbidity, low TOC, and low microbiological counts. There was extensive and relevant water treatment experience from treating Lake Mead water at the AMSWTF and an additional WTP

**Table 23-5**

River Mountains Water Treatment Facility process flow diagram.

located nearby in Henderson, Nevada. Also, the local purveyors were familiar with using free chlorination as a primary and secondary disinfectant and wanted to avoid a new disinfectant such as combined chlorine and ammonia (chloramination).

The selected treatment process consists of preozonation, direct filtration with tapered flocculation, and chlorination as illustrated on Fig. 23-12. Space was reserved onsite for post filtration GAC contactors if required to meet more stringent DBP regulations in the future, and for membrane filtration if selected by future Citizens' Advisory Committees or public preference (Snow and Bromley, 2004). SNWA is also able to substitute GAC for anthracite in the rapid gravity filters if appropriate. In fact, two of the second-phase filters were provided with GAC as a full-scale demonstration test condition.

The RMWTF was engineered for construction in four, 570-ML/d (150-mgd) phases. One of the most difficult aspects for design was ensuring equal flow splitting to each sequential phase. The solution took the form of a circular upflow basin with peripheral weirs and an extensive diffusion grid above the bottom entry point. The design was tested and adjusted based on scale model results at a hydraulics laboratory. The flow-splitting basin is presented on Fig. 23-13.

## Unique Design Features

**Figure 23-13**  
Flow-splitting basin, viewed from above.

Based on the pilot results, filters were designed to operate at a maximum hydraulic capacity of 19.6 m/h (8 gpm/ft<sup>2</sup>). The filters consist of 1.8 m (6 ft) of anthracite with a 0.2-m (8-in.) layer of sand below the anthracite, directly on top of the gravel-less underdrains. The filters were initially operated at a filtration rate of 14.7 m/h (6 gpm/ft<sup>2</sup>), providing 570 ML/d (150 mgd) reliable capacity per phase with one filter out of service. During 2004, a full-scale field test of the RMWTF was performed to demonstrate effective treatment at 760 ML/d and 19.6 m/h (200 mgd, 8 gpm/ft<sup>2</sup>).

This facility has one of the largest operating onsite sodium hypochlorite generation facilities in the world, using an average of 5900 kg (6.5 tons) of food-grade salt per day to treat 570 ML/d (150 mgd) of raw water, based on 3.5 lb of salt per pound chlorine equivalent and 3 mg/L total chlorine usage. This system enabled SNWA to respond to neighborhood concerns with transporting and storing gaseous chlorine, while maintaining the use of free chlorine as desired by water purveyors in the valley.

The flash mix for the RMWTF is an MWH-patented two-stage pump diffusion flash mixer. One two-stage flash mixer is located in each of the two 2.1 m (84-in.)-diameter pipes that connect the ozone contactor to the filters. The primary coagulant (ferric chloride) is added in the first-stage mixer followed by coagulant aid (cationic polymer) addition in the second-stage mixer. The chemical to be mixed is injected into the process

water from the chemical feed pipe that protrudes from the center of the water nozzle. This water jet hits the deflector plate resulting in rapid flow dispersion and nearly instantaneous chemical mixing. Standby and redundant injectors are provided.

Ozone is the primary disinfectant used at the RMWTF. Ozone is generated from high-purity oxygen gas using a 45,000 kg/d (50-ton/d) vapor-swing adsorption (VSA) system with liquid oxygen (LOX) backup. For the RMWTF first and second phases, five ozone generators are provided, each with 900 kg/d (2000 lb/d) of generation capacity (Bromley, 2002). The LOX system and one ozone generator are shown on Fig. 23-14. From pilot studies it was found that using ozone in place of chlorine as a preoxidant will reduce total coagulant chemical use by approximately one-third.

Treated-water quality has been excellent at the RMWTF. Selected raw-and treated-water characteristics are shown in Table 23-6.

### Performance Data

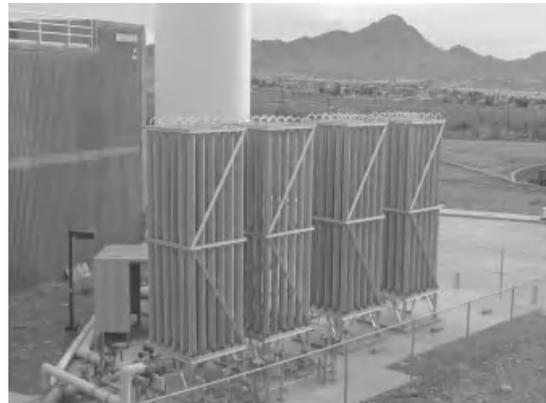

## 23-4 Gibson Island Advanced Water Treatment Plant, Queensland, Australia

The Gibson Island Advanced Water Treatment Plant (AWTP) is part of the regional water recycling project in South East Queensland, Australia. An aerial view of the plant is shown on Fig 23-15. The Western Corridor Recycled Water Project (WCRWP), a key part of the Queensland Government's South East Queensland Water Grid, enhances water supply security in drought-stricken South East Queensland. The WCRWP provides

high-quality recycled water for use in surface water augmentation of Queensland reservoirs, irrigation, and cooling water for power plants.

The WCRWP includes more than 200 km (125 mi) of pipeline to link existing wastewater treatment plants with three new advanced water treatment plants. The Bundamba AWTP and the Luggage Point AWTP each have a production capacity of up to 66 ML/d (17.4 mgd). The third plant,

**Figure 23-15**  
Aerial View of Gibson Island Advanced Water Treatment Plant.

Gibson Island AWTP has a capacity of 100 ML/d (26.4 mgd). The Gibson Island AWTP is one of the largest recycled water plants in the Southern Hemisphere.

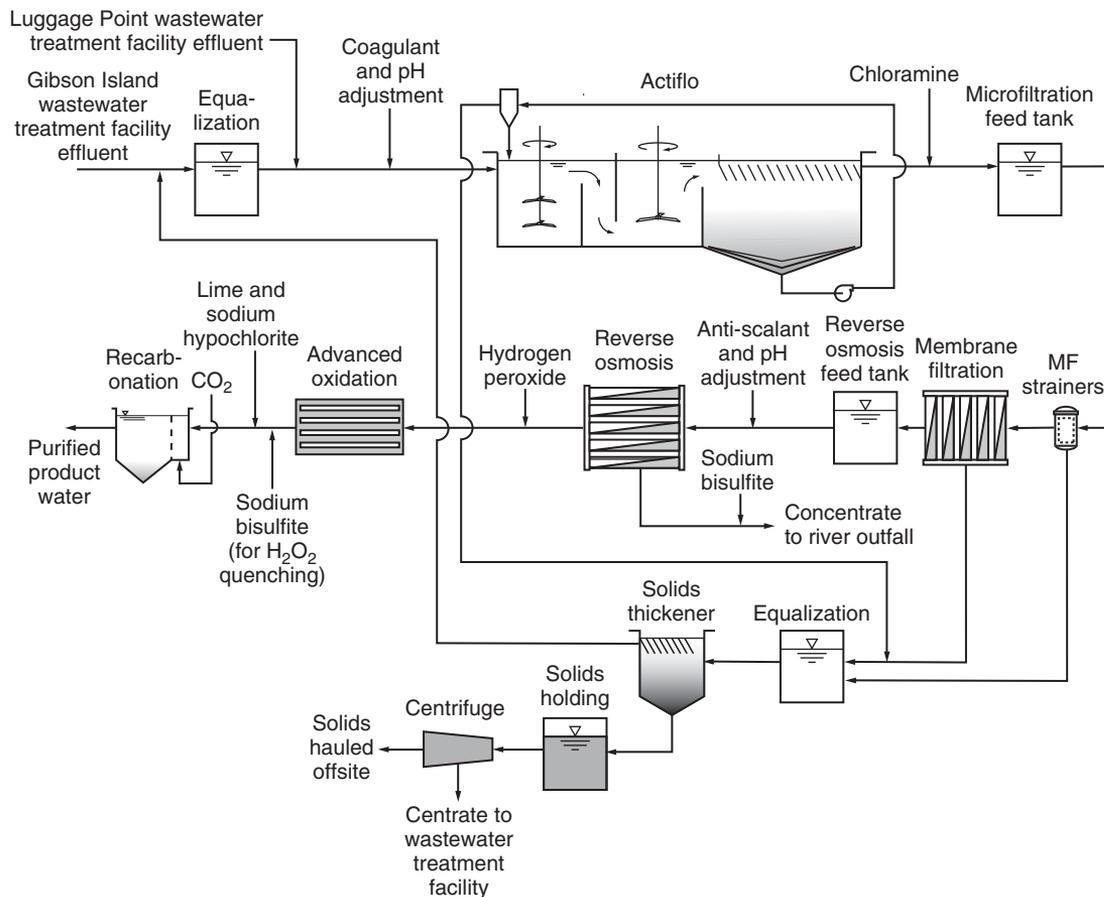

Secondary wastewater effluent from the Gibson Island and the Luggage Point wastewater treatment plants (WWTPs) are pumped to Gibson Island AWTP for treatment. Treatment processes include chloramination, high rate ballasted clarification, microfiltration (MF), reverse osmosis (RO), advanced oxidation ultraviolet disinfection, and posttreatment (stabilization and disinfection) and residuals (solids) treatment. The process was designed to meet the standards set forth for Potable Water Quality in the Australian Drinking Water Guidelines (ADWG) and additional parameters designed to protect the surface water reservoirs (Findley, 2009). Ongoing operation of the plant will be monitored for compliance with the Australian Guidelines for Recycled Water, which was finalized after the plant design was completed.

The Gibson Island AWTP process flow diagram is presented on Fig. 23-16 and described in the following sections (Samson et al., 2010).

#### **RAW-WATER INTAKE**

Raw water to the Gibson Island AWTP is a combination of secondary wastewater effluent from the Gibson Island WWTP and secondary wastewater effluent from the Luggage Point WWTP. Flows from the two raw-water sources are adequately blended prior to reaching the pretreatment system.

#### **Treatment Processes**

**Figure 23-16**  
Gibson Island Advanced Water Treatment Plant process flow diagram.

#### PRETREATMENT

One of the primary goals of the pretreatment system is to reduce total phosphorus in the feed water to the membrane filtration system from approximately 5 mg/L to less than 0.5 mg/L of total dissolved phosphorus. There are two reasons for this goal. First, the RO concentrate is discharged to the Brisbane River and must meet strict limits of less than 4 mg/L phosphorus. Second, removal of phosphorus prior to the RO system reduces the likelihood of calcium phosphate scaling in the RO system. Actiflo was selected as the pretreatment process, and treatment is accomplished via a series of consecutive process steps consisting of coagulation, microsand and polymer injection, flocculation, settling, and sand recirculation processes. Residuals from the pretreatment system are sent to the solids handling system for treatment.

### MEMBRANE FILTRATION

A pressurized microfiltration (MF) membrane filtration system is provided as pretreatment to the RO system as shown on Fig 23-17a. MF provides a consistently high-quality feed to the RO and reduces particulate fouling. The membrane filtration system includes a feed pump station, feed strainers, the MF system (including ancillaries such as backwash, blower, and compressed air systems), and a clean-in-place (CIP) system. The MF system is configured into two trains, each having the capability to produce 61 ML/d (16 mgd) of filtrate. The MF system is designed to produce filtrate water with a turbidity less than 0.15 NTU at any time, a daily average turbidity less than 0.10 NTU, and a 15-min silt density index (SDI) of less than 3 (see Sec. 17-6 in Chap. 17). This very high feed water quality provides security and more efficient operation of downstream cartridge filters and RO membranes.

In addition to providing high-quality feed water to the RO system, the MF acts as a barrier to microbial contaminants. The MF system is designed to achieve 4 log removal of *Cryptosporidium* and *Giardia*. Backwash waste from the MF system is treated in the solids handling system, with the majority of the water used in the backwash being recycled to the head of the AWTP. Design and operating parameters for the MF system are shown in Table 23-7.

### REVERSE OSMOSIS

The RO system was installed to remove the majority of dissolved salts, minerals, and organic compounds from the MF system filtrate. The RO system is shown on Fig. 23-17b and c. To provide an additional barrier to solids or debris that may enter the system, cartridge filters were provided between the MF system and the RO system. The RO system also includes feed pumps, interstage booster pumps, the RO skids, and cleaning and flush systems. Design and operating parameters for the RO system are shown in Table 23-8. The recovery, or percentage of feed water that can be made into RO permeate, is controlled by the formation of scales of sparingly soluble salts on the concentrate side of the membrane. For each stage the recovery is limited to between 50 and 60 percent. To achieve a recovery of 85 percent for the RO system with the given raw water quality, three RO stages were required. The RO system recovery of 85 percent was required to achieve the overall plant recovery of 82 percent.

### ULTRAVIOLET ADVANCED OXIDATION PROCESS (UV-AOP)

The design includes an ultraviolet advanced oxidation (UV-AOP) system. In this system UV light is used to both directly oxidize organic molecules such as NDMA or to split hydrogen peroxide into hydroxyl radicals that can oxidize organic species such as 1,4-dioxane. The system was sized to provide 1-log NDMA removal and 0.5-log removal of 1,4-dioxane at the minimum design UV transmittance of 95 percent at a wavelength of 254 nm and at a maximum flow rate of 102 ML/d (26.9 mgd). The equipment to achieve

this consists of three duty trains and one standby train, with each train comprised of three chambers in series. Each chamber has two reactors and each reactor contains 72 low-pressure, high-output lamps. The competitively bid tenders provide guarantees on power consumption, operating lifetimes and guaranteed replacement costs from the UV equipment supplier to ensure minimum operating costs for the plant.

**POSTTREATMENT AND SOLIDS HANDLING**

Posttreatment at the Gibson Island AWTP consists of hydrogen peroxide quenching, stabilization, final chlorine disinfection, and treated-water storage. Hydrogen peroxide is dosed prior to the UV-AOP, but not all of the hydrogen peroxide is consumed in the UV-AOP process. Sodium bisulfite is added downstream of the UV trains to quench residual hydrogen peroxide.

Treated water must not cause corrosion of the distribution piping and requires specific pH and alkalinity adjustments to meet calcium carbonate precipitation potential requirements. RO treatment results in low pH and alkalinity along with low concentrations of calcium. To stabilize the water prior to distribution, chemical addition including lime and carbon dioxide is included after the UV-AOP treatment process.

Sodium hypochlorite is added after the UV-AOP to provide a chlorine residual prior to discharge of the treated water to the distribution system, as well as to remove ammonia remaining in the RO permeate by breakpoint chlorination.

The Gibson Island AWTP produces residuals as a result of phosphorus and suspended solids removal in the high rate clarification, backwashing of the membrane filtration feed strainers, and backwashing of the membrane filtration system. The solids handling system consists of flow balancing, combined lamella clarification and thickening, centrifugal dewatering, and sludge cake storage. Supernatant from the lamella is returned to the head of the AWTP.

**Unique Design Features**

Chloramination is required upstream of the membrane system to inhibit organic and biological fouling. Unfortunately, chloramination comes with the potential for NDMA formation. NDMA is a difficult contaminant to remove once it enters or is formed in water because it is highly soluble. Therefore, bench-scale evaluation of NDMA formation while using chloramines was a key component to establishing appropriate design criteria. This evaluation focused on comparing sequential ammonia and chlorine addition to form chloramines or using preformed chloramines. Preformed chloramines were selected for the plant based on bench-scale testing and have proven at full scale to form little to no NDMA. The formation of NDMA in the full-scale AWTP has been minimized by limiting the addition of chloramines to monochloramine only, and allowing time for the monochloramine reaction to be completed before mixing with nitrogenous precursors. Design was implemented in the full-scale AWTP for the operational flexibility needed for monochloramine formation and thus reduction of NDMA formation.

In addition to meeting the requirements of the Australian Drinking Water Guidelines, the AWTP is required to meet stringent total nitrogen limits. Of most importance is the need to reduce total nitrogen to 0.8 mg/L as N. A model was developed to determine the maximum level of nitrogen

**Table 23-9**  
Treated-water quality

Parameter	Unit	Typical Treated-Water Quality	ADWG/Contractual Treated-Water Requirement
Total nitrogen (as N)	mg/L	0.3	0.8
Total phosphorus (as P)	mg/L	0.01	0.13
Total dissolved solids	mg/L	150	500
Total alkalinity (as CaCO <sub>3</sub> )	mg/L	78	>40
Hardness (as CaCO <sub>3</sub> )	mg/L	70	>50
Chloride	mg/L	23	250
Sodium	mg/L	20	180
Sulfate	mg/L	10	250
NDMA	ng/L	<5	10

that could be accepted into the AWTP feed water while meeting the treated-water requirements at full capacity.

Pilot testing of nitrogen rejection was a key component in establishing appropriate design criteria. While RO manufacturer projection software may be an effective way in which to predict rejection of nitrate and ammonia, it does not predict the removal of organic nitrogen, one of the constituents that comprise total nitrogen. Because nitrate is the only compound that can be modeled for rejection by reverse osmosis, a pilot study was conducted to predict more accurately the amount of organic nitrogen that would be rejected by the full-scale AWTP. The piloting resulted in the prequalification of only a few RO membranes that could meet the guidelines as well as a determination that ammonia associated with monochloramine addition to the water elevated the total nitrogen level of the RO permeate, indicating that monochloramine was not well rejected by the RO membranes. Breakpoint chlorination was included in the post treatment system to remove ammonia associated with monochloramine, ensuring the stringent total nitrogen goal was consistently achieved.

The Gibson Island AWTP has been in operation since December 2008. Since completion, the Gibson Island AWTP has met all Australian Drinking Water Guidelines and has complied with the contracted treated-water quality requirements, as summarized in Table 23-9.

## Performance Data

## 23-5 Sunol Valley Water Treatment Plant, California, United States

The Sunol Valley Water Treatment Plant (SVWTP) is one of two water treatment plants operated by the San Francisco Public Utilities Commission

## Setting

(SFPUC). The plant is shown on Fig 23-18. The SVWTP normally treats water from two local reservoirs: the Calaveras Reservoir and the San Antonio Reservoir. At times, the SVWTP also treats water from the Hetch Hetchy Aqueduct.

The SVWTP was constructed in the mid-1960s with a hydraulic capacity of 300 ML/d (80 mgd) and expanded to 600-ML/d (160-mgd) capacity in the 1970s. Since then, it has undergone three major upgrade and modification projects in 1993, 2003, and a current project to meet changing water quality regulations and service requirements. The plant was originally designed to operate in either a conventional treatment or a direct filtration mode. Conventional treatment was practiced when the raw-water turbidity was relatively high (e.g., >5 NTU), and direct filtration was practiced when the raw-water turbidity was relatively low (e.g., <5 NTU).

Since 1995, the SVWTP has been operated exclusively in a conventional, enhanced coagulation mode with the goal of achieving 25 percent or more TOC reduction through the coagulation–flocculation–sedimentation processes using high doses of coagulant chemicals (alum in the 30- to 40-mg/L range). However, particle removal in the sedimentation process was not adequate to meet operational goals under all water quality conditions. Settled-water turbidity was highly variable and tended to increase proportionally with increases in raw water turbidity. Whenever the raw water turbidity was above approximately 10 NTU, the plant was unable to meet the goal of the Partnership for Safe Water (2 to 3 NTU) or the goal of the California *Cryptosporidium* Action Plan (<2 NTU 90 percent of the time) (Montgomery Watson et.al, 2000).

The inability to meet the action plan goal prompted an upgrade project, completed in 2003, that addressed deficiencies in the coagulation, flocculation, and sedimentation processes. The primary objective of that upgrade project was to identify and implement improvements needed to produce settled-water turbidities less than 2 NTU at a plant flow of 600 ML/d (160 mgd), regardless of raw-water quality.

In 2005, the SFPUC reassessed the reliability of its water supply system and adopted a level of service program in response to concerns about the vulnerability of supply to earthquakes and other disruptive events. The “sustainable” capacity of each facility was assigned based on the largest piece of equipment or treatment train being out of service. Thus, the total sustainable treatment capacity of the SVWTP was redefined as 450 ML/d (120 mgd), and a fifth treatment train was required to increase capacity back to 600 ML/d (160 mgd). Construction of this current upgrade is underway and scheduled to be completed in 2013.

## Treatment Processes

The evaluation and modification of the SVWTP treatment processes span across multiple projects and illustrate many of the issues associated with retrofitting existing facilities. In response to changing regulations, the

(a)

(b)

**Figure 23-18**  
Sunol Valley Water Treatment Plant: (a) aerial view of plant and (b) view of existing basins with retrofitted plate settlers.

coagulation (rapid mix), flocculation, and sedimentation processes were modified to correct operational and design deficiencies that were adversely impacting settled-water quality. Filtration upgrades were implemented to achieve more efficient operation and reliable production under extreme water quality events. Disinfection and storage upgrades will allow greater control of disinfection by-products and operational flexibility during swings in plant production.

#### COAGULATION

Prior to the upgrades of 2003, the existing flash mix system consisted of a pump that drew suction from the vertical flash mix chamber and returned water with alum added back into the chamber. Cationic polymer was then fed inside the chamber. The system was able to hydraulically treat 160 mgd, but there was no redundant pump, the pump was undersized, and the flow patterns inside the chamber resulted in an uneven distribution of coagulant. A  $G$  value of 750 to 1000  $s^{-1}$  is typically recommended for dispersing primary coagulants into the water. With low pump mixing flow, the coagulation process relied on influent turbulence in the mixing chamber for energy. However, at plant flows less than 230 ML/d (60 mgd), the turbulence was minimal and mixing energy was inadequate.

To resolve the issues of inadequate mixing energy and different chemical requirements for different source water, the concept to separate the flash mix into two separate source water flow trains was developed. One flash mix was dedicated to the pipeline that carries Calaveras Reservoir water, and the other was dedicated to the pipeline that carries either San Antonio Reservoir or Hetch Hetchy water. This mixing concept also included a pumped flash mixer on each pipeline with much higher mixing water flow rates and variable-speed drives on the pumps to enable the operators to adjust the mixing energy as needed. Downstream of the flash mix process, a flow distribution structure was constructed to allow the different source waters to remain separate through flocculation, sedimentation, and filtration.

#### FLOCCULATION

The original 1960s plant included two flocculation/sedimentation basins. The flocculation basins were equipped with six rows of horizontal shaft paddle wheel flocculators. For the subsequent two basins in the 1970s expansion, 12 (four rows of three) vertical-shaft, pitched-blade turbine flocculators with 0.9-m (36-in.) blade diameters were constructed. The overall dimensions for all four basins are identical; however, analysis of settled-water turbidity data indicated that the vertical-shaft flocculators performed slightly better than the horizontal-shaft units. The difference in performance was likely due to better residence time distribution provided by the baffling between stages, although uneven flow distribution to the different basins may also have played a role (Price, 1997).

Flocculation improvements were made to all four flocculation basins. These included installation of new vertical shaft, hydrofoil flocculators with 2.4-m (96-in.) blade diameter to replace the existing flocculators and an over/under baffle arrangement to replace all except the last of the existing flow-through perforated baffles. Based on jar tests and full-scale trials, the ability to feed flocculant aid chemicals to the flocculation basins was maintained.

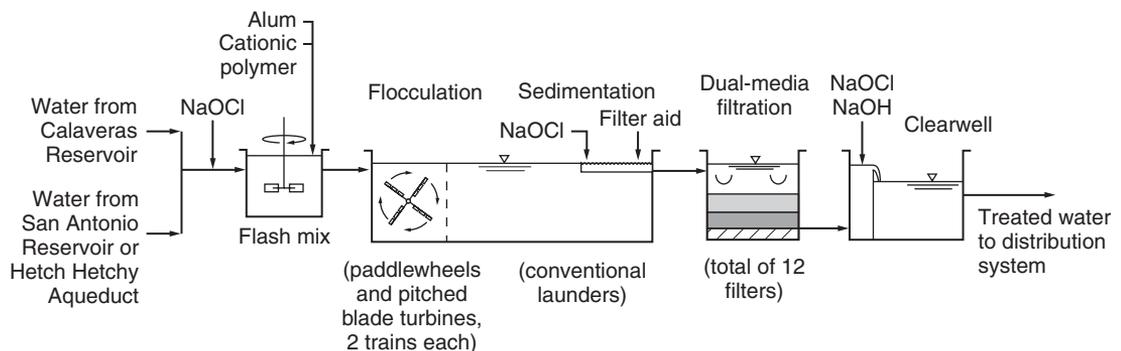

#### SEDIMENTATION

Retrofit of the sedimentation basins with a high-rate process was selected as the most economical and feasible solution to improve settled-water turbidity and meet operational goals. Due to site and basin constraints, the only two processes considered feasible were lamella plate settlers and tube settlers. Plate settlers were chosen based on the experience of other utilities and the ability to add more projected surface area in the existing basins. The plate settlers are shown on Fig. 23-18.

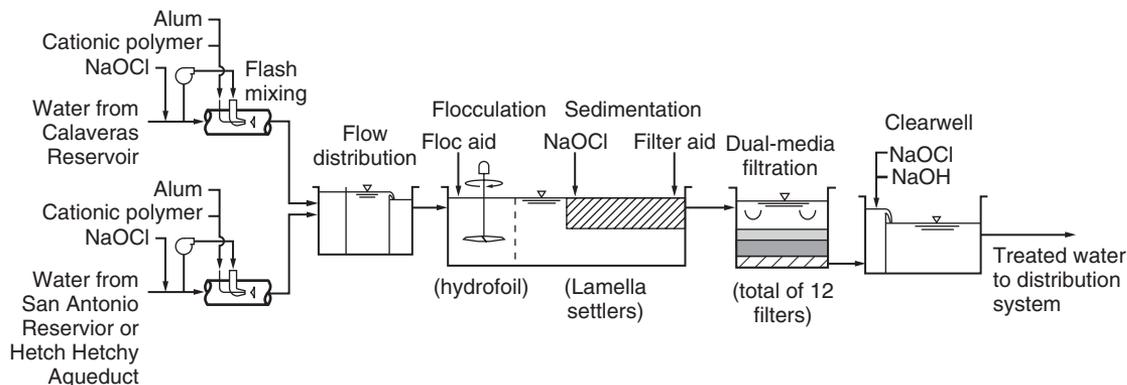

The plates installed on the four existing basins have an effective surface loading rate of 1.2 m/h (0.5 gpm/ft<sup>2</sup>) based on projected plate area, sufficient to meet the settled-water turbidity goal of 2 NTU under all flow and raw-water quality conditions. Removal and replacement of the plant's existing traveling bridge sludge collectors was necessary to accommodate the plate settlers. The shallow basin depth and the extensive cross bracing required for seismic stability of the plate settler supports made chain and flight and traveling vacuum systems infeasible. Therefore, SuperScrapper units were installed.

Schematic process flow diagrams of the SVWTP before and after the upgrade of the coagulation, flow-splitting, flocculation, and sedimentation processes are shown on Figs. 23-19 and 23-20.

A new fifth basin is currently being installed and is designed specifically as a plate settler basin. It did not need to match the footprint of the basins

**Figure 23-19**  
Process flow diagram for original SVWTP.

**Figure 23-20**  
Process flow diagram of SWWTP after 2003 modifications.

constructed in the 1960s and 1970s. This resulted in a significant reduction in the footprint of the basin, as described more fully under unique design features.

#### FILTRATION

The original filters at the SWWTP remained in service for nearly 50 years, with only minor maintenance and periodic topping off of filter media lost to backwashing. The current upgrade project will modify the filters to improve efficiency and take advantage of newer filter technology.

A comparison of the existing and modified filter design is presented in Table 23-10. The filter structure, number of filters, and design filtration rate did not need to be changed, as they already complied with regulatory limits and sustainable capacity goals. However, filter media was replaced with a new, deeper dual media design. This allowed about a 10 percent increase in the  $L/d$  ratio (depth of filter bed divided by the effective size), while significantly increasing the effective size of the top layer of anthracite media. These changes have been proven at the SFPUC's other treatment plant to provide lower effluent turbidity with less head loss accumulation and longer filter runs (Sabastiani et al. 1997). Following construction, the modified filters will be able to produce up to 76 ML/d per filter at 18.3 m/h (20 mgd/filter, 7.5 gpm/ft<sup>2</sup>) assuming successful demonstration testing.

To achieve space for the greater media depth, the filter underdrains will be replaced with a gravel-less design and the washwater troughs raised by 0.6 m (2 ft). The fixed grid surface wash system also will be replaced with air scour.

#### DISINFECTION AND STORAGE

A chlorine contact tank and treated water reservoir are also being added as part of the current upgrade project. These facilities are required in

**Table 23-10**

Comparison of existing and modified filter design criteria

Parameter	Units	Existing Filters	Modified Filters
No. of filters	Number	12	12
Filter area, each	m <sup>2</sup>	172	172
	ft <sup>2</sup>	1850	1850
Approved filtration rate	m/h	14.7	14.7
	gpm/ft <sup>2</sup>	6.0	6.0
Sand:			
Media depth	m	0.25	0.30
	in.	10	12
Effective size	mm	0.41–0.45	0.65–0.75
Uniformity coef.		—	<1.5

Total bed depth	m	1.2	1.5
	in.	47	60
L/d Ratio		1,170	1,370
Underdrain type	—	“Teepee” concrete underdrains	Plastic block underdrains with porous plate media retaining cap

response to the water quality level of the service goal and compliance with regulations. The chlorine contact tank will have total volume of 13.2 ML (3.5 mg) and is designed to achieve 0.5 log *Giardia* inactivation with free chlorine. Computational fluid dynamics modeling was used to evaluate various basin configurations and ensure that a baffling factor (i.e.,  $t_{10}/\tau$ , see Sec. 13-8) greater than 0.70 is achieved (Price, 2009a). Space is incorporated for a future UV disinfection facility, should this become necessary to meet the requirements of the Long Term 2 Enhanced Surface Water Treatment Rule.

The chlorine contact tank is divided into two cells. The SVWTP flow data shows that the SVWTP average flow is less than 300 ML/d (80 mgd) 90 percent of the time. Because this value is close to half the design sustained flow rate, the two cells will be identical in size and will provide for better control of disinfection by-product (DBP) formation, prior to quenching of the free chlorine residual to form chloramines for subsequent storage and distribution. The treated-water reservoir will provide capacity for operational, emergency, and startup storage with a maximum storage volume of 66 ML (17.5 mil. gal.).

### Unique Design Features

The SVWTP is one of the largest plants in the world to use plate settlers. It is also unique in its use of both retrofitted and new plate settler basins. A comparison of new and retrofit design criteria are presented in Table 23-11. All of the basins have a rated capacity of 150 ML/d (40 mgd), but the new basin is less than one third the length of the retrofitted basins and less than half the volume. This is because the new basin was designed with greater sidewater depth, which allowed 3-m (10-ft) plates to be used instead of the 1.8-m (6-ft) plates required by the shallow depth of the existing basins.

Sedimentation performance has long been recognized to be related to surface area. The original horizontal sedimentation basins from the 1960s and 1970s were designed with an overflow rate of 3.3 m/h (1.36 gpm/ft<sup>2</sup>). This difference was considered “high-rate” sedimentation and appropriate for plants operating in both conventional and direct filtration mode. The addition of plate settlers to these basins increased surface area in each basin from just over 1850 to over 5100 m<sup>2</sup> (20,000 to over 55,000 ft<sup>2</sup>). In the new basin, surface area will again be increased to over 7150 m<sup>2</sup> (77,000 ft<sup>2</sup>) of projected plate area. The larger plate area of the new basin, and consequent

**Table 23-11**

Comparison of new and retrofit basin design criteria

Parameter	Units	Existing Basins	New Basin
No. of basins	Number	Four	One
Basin dimensions	m	103.6(L) × 18.3(W)	30.5(L) × 18.3(W)
	ft	340(L) × 60(W)	100(L) × 60(W)
Side water depth	m	3.3	4.9
	ft	11	16
Basin volume	m <sup>3</sup>	6,297	2,717
	gal	1,663,600	718,000
Plate loading rate	m/h	1.22	0.88

<sup>b</sup>UltraScraper is a trademark of Meurer Research, Inc.

lower plate loading rate, are in response to sustainable level of service goals.

The SVWTP represents an interesting study in the evolution of a major treatment facility. In service for nearly 50 years, the plant has been expanded and modified to address new regulations, new technologies, and new operating goals in ways the original designers could not have imagined.

The SVWTP's new flash mix, flow distribution structure, and flocculation/sedimentation upgrades installed in 2003 have met and exceeded expectations. Settled-water turbidity has been less than 2 NTU 95 percent of the time, and less than 3 NTU 99 percent of the time, regardless of plant flow or raw-water turbidity (Price, 2009b). The flocculation/sedimentation basins have operated for extended periods at 150 ML/d (40 mgd) per basin, and raw-water turbidity has been as high as 50 NTU without process upset. Plant operators have been able to turn down the flash mix pumps and flocculator speeds well below their maximum rates for optimized performance. In the past, all of these systems operated at full speed and yet still did not meet performance goals.

The new plate settler basin, modified filters, chlorine contact basin, and treated-water reservoir are under construction and anticipated to be online in 2013. It is reasonably certain that this will not be the last upgrade project for the SVWTP.

## Performance Data

## 23-6 North Clackamas County Water Commission Water Treatment Plant, Oregon, United States

---

The North Clackamas County Water Commission (NCCWC) is comprised of the Sunrise Water Authority, Oak Lodge Water District, and the City of Gladstone. The NCCWC Water Treatment Plant draws its water from the Clackamas River and delivers quality drinking water to over 80,000 customers in the southeast suburbs of Portland, Oregon. The river is a pristine water supply typical of the snow melt waters originating in the Cascade Mountain Range (Fig. 23-21). Turbidity levels are typically low for most of the year but can increase significantly during storms when rain runoff washes sediment and organics into the river. In addition, in late summer, algal activity in upstream reservoirs can result in taste- and odor-causing compounds that require treatment at the plant.

In response to the participating agencies' urgent need to meet new demand from rapid population growth in the region, the original 38-ML/d (10 mgd) slow sand filter plant constructed in 1998 was expanded to 76 ML/d (20 mgd) in 2005 using low pressure, submerged membrane filtration technology. This modification created an interesting contrast between the earliest and latest in water filtration technologies, with membranes

## Setting

**Figure 23-21**  
Upper Clackamas River Watershed.

providing an ideal compliment to slow sand filtration. The slow sand plant had to be shut down whenever the river's turbidity exceeds 10 NTU. Membranes, on the other hand, readily accommodate an increase in water turbidity, as well as allow rapid changes in flow rates to meet service area needs.

One of the significant challenges was to complete the project within 17 months, including bench and pilot studies, membrane vendor selection, design, construction, and commissioning. The membrane manufacturer was selected using a qualifications-based process that required submittal of comprehensive proposals including complete system layouts, equipment cut sheets, process and instrumentation, and electrical single lines drawings. The request for proposals (RFP) for membrane filtration equipment selection was largely performance-based allowing the manufacturer to optimize its system design while meeting submittal deadlines.

Design of the plant proceeded on the basis of the selected vendor's proposal content, while the vendor conducted a required 6-week pilot-scale

validation study to verify the proposed design and operating parameters. The pilot study results exceeded performance expectations allowing the design to progress rapidly without modification to the original membrane equipment proposal. Conducting membrane pilot testing after selection helped save 2 to 3 months in the schedule and proved a valuable time saver. In addition to the validation pilot testing, time and equipment was donated to continue pilot testing for an additional 3 months as part of an American Water Works Association Research Foundation (AWWARF) study examining optimization of pretreatment for membrane filtration. The report provided invaluable data for determining the appropriate level of pretreatment needed to optimize the performance of the membrane system.

Similar to the RFP process for membrane equipment selection, an RFP process was used for general contractor selection, as well as for selection of key subcontractors including mechanical, electrical, and instrumentation specialties (Grounds, 2007). General contractors submitted statements of qualifications that included qualifications of their preferred subcontractors. Qualified generals and subcontractors were then asked to submit proposals that included an approach to completing the work, a detailed critical path schedule, value engineering ideas, and price. This alternative approach to procuring construction services achieved the goal of producing water in less than 11 months from start of construction.

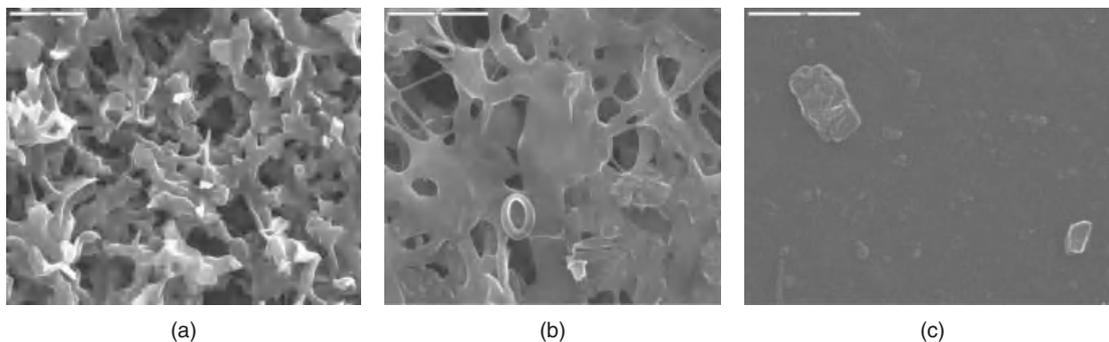

Bench and pilot studies resolved many important process issues and were extremely important to overall project success. Key process issues included the following:

- Membrane material
- Coagulant type and dose
- Taste and odor control

#### **MEMBRANE MATERIAL**

Bench-scale tests were performed on Clackamas River water with polysulfone (PS) ultrafiltration and polyvinylidene fluoride (PVdF) microfiltration membranes. Results varied significantly when comparing the two materials. Raw Clackamas River water caused minimal fouling of the PVdF membrane and extensive fouling of the PS membrane. The opposite result occurred with the addition of coagulation (alum or ferric) and clarification, where the PS membranes showed significant improvement but the PVdF membrane performance actually decreased. The constituents in Clackamas River water that contribute to fouling appear to behave differently for each membrane, which, in turn, respond differently to coagulation and clarification.

To help understand these results, scanning electron microscopy (SEM) was employed to examine fouling of the membrane material. The scans for the PVdF membrane are presented on Fig. 23-22 showing the new

**Figure 23-22**

NCCWC Water Treatment Plant: (a) SEM image of new PVdF membrane, (b) SEM image of PVdF membrane fouled with raw Clackamas River water, and (c) SEM image PVdF membrane fouled with alum coagulated Clackamas River water.

membrane material, the membrane fouled with raw water, and the membrane fouled with alum coagulated and clarified water (Adham et al., 2005). The original membrane structure is still clearly visible after fouling with raw water, reflecting the low fouling results of the bench and pilot testing. Despite coagulation and clarification, the surface of the PVdF membrane is completely coated with a cake layer consistent with its observed performance.

Subsequent pilot testing of the PVdF membranes confirmed the bench-scale results. It was concluded that PVdF membrane material should be used for the full-scale plant. The full scale membrane facility is shown on Fig 23-23. While the membrane could operate effectively without pretreatment under normal water quality conditions, it was decided to include provisions for coagulation and flocculation as discussed below.

#### COAGULANT TYPE AND DOSE

Bench and pilot testing of coagulant type and dose showed that neither the use of alum nor ferric coagulants resulted in improved membrane performance. However, results were more promising with aluminum chlorohydrate (ACH), which produced lower fouling rates. This result reinforces the time-tested lesson that the selection of the best coagulant is always site specific. Dosing with ACH was extremely sensitive, and even small changes in ACH dose resulted in significant changes in membrane performance. Results of the pilot tests on Clackamas River water showed that increasing ACH dose from 0.2 to 0.5 mg/L (as Al) was enough to increase the rate of fouling under normal water quality conditions. During high-turbidity events, ACH dose was not as sensitive and higher doses were beneficial.

The coagulant system was also needed to assist in the removal of DOC. The slow sand filters achieve DOC removal in a seasonal range from 8 percent in winter to 45 percent in summer, due mostly to temperature effects on the biological process. Pilot testing showed that the membranes

**Figure 23-23**

NCCWC Water Treatment Plant: (a) membrane filters from top deck and (b) membrane filters pipe gallery.

removed less than 10 percent of the DOC without pretreatment. However, removal increased to over 20 percent with the use of small doses of ACH. Full-scale operation of the membranes has subsequently confirmed this level of removal, which is consistently achieved year-round.

#### **POWDERED ACTIVATED CARBON**

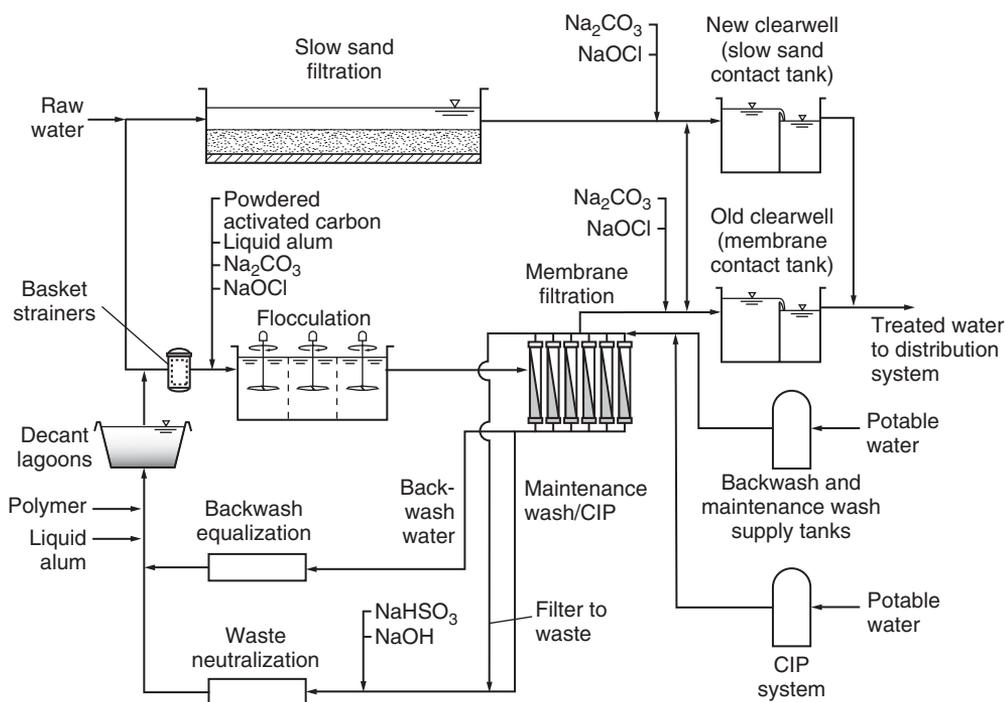

The seasonal presence of taste and odor compounds in the Clackamas River was a particular concern in the planning of the plant expansion. Public appreciation of drinking water quality is frequently driven by aesthetic perceptions, and none of these is as potentially detrimental as water that smells or has off-tastes. The slow sand filters had performed extremely well in controlling taste and odor due to microbiological activity in the schmutzedecke, and the expansion facilities needed to do so, as well. The characterization of the taste and odor in the Clackamas River is “earthy-musty” and likely caused by MIB and/or geosmin, which typically require the use of activated carbon or ozone for effective treatment with conventional and membrane plants. The use of ozone or GAC contactors would significantly impact the cost and schedule of the project, so the use of powdered activated carbon (PAC) with the membrane filtration system was evaluated at bench and pilot scale.

Testing was conducted using stepped increases in the dose of PAC, while monitoring performance of the PVdF membranes. The results showed that doses up to 50 mg/L could be used without major short-term impact to the rate of fouling or duration of cleaning cycles. High doses of PAC are generally not recommended by manufacturers, who suggest limits of 10 mg/L with nonabrasive wood-based PAC. The performance of PAC for taste and odor control is a function of both dose and time, so being able to provide contact time helped reduce PAC dosing. From modeling studies it was found that 10 min of contact time would be sufficient and could be provided by the flocculation basin ahead of the membranes (Grounds et al., 2006). This approach provided contact time for the PAC, kept the PAC fully suspended in the water, and provided an additional level of flexibility to the coagulation process.

Resolution of these key process issues laid the foundation for the overall treatment process, as summarized on Fig. 23-24.

### Unique Design Features

The NCCWC Water Treatment Plant is a combination of new and old technologies. What makes this particularly interesting is how well the processes of slow sand and membrane filtration complement each other.

**Figure 23-24**  
NCCWC Water Treatment Plant process flow diagram.

**Table 23-12**

Process strengths and weaknesses complement each other

Process	Turbidity Spikes	DOC Removal	Taste and odor Control	Operational Complexity	Operating Cost
Slow sand filtration	Fair (<10 NTU)	Good	Excellent	Excellent	Excellent
Membrane filtration	Excellent	Good (w/ACH)	Excellent (w/PAC)	Good	Fair

The strengths of membrane treatment address the weaknesses of slow sand filtration, and vice versa. This comparison is presented in Table 23-12 (Schacht et al., 2006).

The strength of membrane filtration is its ability to remove turbidity and particles, while the strength of slow sand filtration is in its simplicity and lower operating cost. Both can be equally effective in controlling DOC and T&O, provided the membranes are supplemented with effective coagulant and PAC dosing.

Another advantage of membrane filtration is its relatively small footprint, as illustrated on Fig. 23-25, which shows aerial views of the plant as initially planned and during construction. While only 38 ML/d (10 mgd) of membrane modules were installed as part of this expansion, space was provided for up to 57 ML/d (15 mgd) of membrane capacity. Even with this enlarged footprint, the membrane facilities are smaller than even one of the four slow sand filters. This space efficiency provided a more compact layout of facilities, minimized sitework, and improved operability.

In addition to new membranes, the plant expansion also included addition of three new solids lagoons, two PAC slurry basins, a flocculation tank, chemical feed systems, new baffled clearwell, additional raw- and finished-water pumps, and 2000 kW emergency generator.

(a)

(b)

**Figure 23-25**

NCCWC Water Treatment Plant: (a) aerial view after 6 months of construction and (b) identification of process facilities.

**Performance  
Data**

The membrane plant consistently produces high-quality water and operates smoothly during challenging turbidity events when the slow sand plant must be taken out of service. Regardless of the incoming raw-water quality, the new membrane plant has consistently produced treated water with less than 0.03 NTU turbidity, less than 5 total particles per mL and over 5-log particle removal.

Further, like the slow sand plant, the fully automated membrane plant requires little operator attention and can be operated remotely, if desired.

The winter of 2005/06 proved to be one of the wettest in history with frequent turbidity events at levels as high as 300 NTU. This caused the slow sand plant to be shut down for extended periods. The membrane system handled the elevated turbidity events without exception, while still maintaining design fluxes and cleaning frequencies at maximum production rates. During several turbidity events, plant operators found higher ACH coagulant doses beneficial in allowing longer filter runs between chemical cleans. Thus, the coagulation system proved a valuable additional tool in the treatment toolbox of the plant.

Seasonal taste and odor events have continued to occur in late August and early September and are treated with the addition of powdered activated carbon (PAC) to the raw water. Control of taste and odor has been excellent, with very few complaints from consumers. Full-scale operation has confirmed the plant's ability to control taste and odor while maintaining treated-water production.

## 23-7 Lessons Learned

---

In reviewing the implementation of the various water treatment plants presented and discussed in this chapter, a number of useful lessons can be derived.

1. The water quality of every raw-water supply source is different.
2. Because the water quality of raw-water sources is so variable, there is no standard water treatment plant design that is applicable to all waters.
3. For every raw-water source, a number of treatment processes are available.
4. Pilot plant testing is always beneficial and sometimes required to select among alternative processes and develop design and operational criteria.
5. Pilot plant testing must be interpreted properly to account for untested water quality conditions.
6. Many process requirements such as mixing and flow splitting, which are quite easy to accomplish in bench- or pilot-scale processes, are more difficult to achieve in full-scale plants.

7. Site restraints often limit the types of treatment processes that can be used.
8. The impacts of future regulations, capacity expansion, and the possibility of unknown process additions must be considered during plant design. Space considerations, hydraulic capacity, access for construction, and ease of connection to an operating facility should also be considered.
9. Analyze each proposed treatment train to be sure the treatment process will provide a multibarrier treatment approach.
10. Creative approaches to retrofitting or upgrading existing plants are necessary to address issues that are usually not solvable with standard textbook solutions.
11. Recognize the uncertainties of cutting-edge technologies or unproven process applications, and include additional flexibility.
12. Always design for ease of operation, as these facilities will perform better, last longer, and be more highly valued.
13. Operator experience is invaluable and frequently provides key insights not present in records or reports.
14. Design for flexible and reliable operation to the extent it is economically feasible. Equipment failures, power outages, process upsets, and similar events should be anticipated and addressed with contingency plans.
15. Remain sensitive and open to nontechnical issues, such as neighbor concerns and issues, when embarking on a treatment plant design or upgrade.
16. Use a team approach to design wherever possible and have a variety of perspectives represented on the team.

# APPENDIX B

## Physical Properties of Selected Gases and Composition of Air

**Table B-1**

Molecular weight, specific weight, and density of gases found in water at standard conditions (0°C, 1 atm)

Gas	Formula	Molecular Weight, g/mol	Density, g/L
Air	—	28.97 <sup>a</sup>	1.2928
Ammonia	NH <sub>3</sub>	17.03	0.7708
Carbon dioxide	CO <sub>2</sub>	44.00	1.9768
Carbon monoxide	CO	28.00	1.2501
Hydrogen	H <sub>2</sub>	2.016	0.0898
Hydrogen sulfide	H <sub>2</sub> S	34.08	1.5392
Methane	CH <sub>4</sub>	16.03	0.7167
Nitrogen	N <sub>2</sub>	28.02	1.2507
Oxygen	O <sub>2</sub>	32.00	1.4289

Source: Adapted from R. H. Perry, D. W. Green, and J. O. Maloney (1984) *Chemical Engineers' Handbook*, 6th ed., McGraw-Hill, New York.

<sup>a</sup>Value reported in the literature vary depending on the standard conditions. Note:  $(0.7803 \times 28.02) + (0.2099 \times 32.00) + (0.0094 \times 39.95) + (0.0003 \times 44.00) = 28.97$ .

**Table B-2**

Composition of dry air at 0°C and 1.0 atm

Gas	Formula	Percent by Volume <sup>a</sup>	Percent by Weight
Nitrogen	N <sub>2</sub>	78.03	75.47
Oxygen	O <sub>2</sub>	20.99	23.18
Argon	Ar	0.94	1.30
Carbon dioxide	CO <sub>2</sub>	0.039	0.05
Other <sup>d</sup>	—	0.01	—

<sup>a</sup>Adapted from *North American Combustion Handbook*, 2nd ed., North American Mfg., Cleveland, OH.

<sup>b</sup>Hydrogen, neon, helium, krypton, xenon.

**Table B-3**

Density and viscosity of air (SI units)

Temperature <i>T</i> (°C)	Density $\rho$ (kg/m <sup>3</sup> )	Dynamic Viscosity <sup>a,b</sup> $\mu$ ( $\times 10^{-5}$ kg/m · s)	Kinematic Viscosity $\nu$ ( $\times 10^{-5}$ m <sup>2</sup> /s)
0	1.293	1.736	1.343
5	1.269	1.762	1.388
10	1.247	1.787	1.433
15	1.225	1.812	1.479
20	1.204	1.837	1.525
25	1.184	1.862	1.572
30	1.165	1.886	1.619
35	1.146	1.910	1.667
40	1.127	1.934	1.716
45	1.110	1.958	1.765
50	1.093	1.982	1.814
60	1.060	2.029	1.915
70	1.029	2.075	2.017
80	1.000	2.121	2.121
90	0.972	2.166	2.228
100	0.946	2.210	2.336

<sup>a</sup>Dynamic viscosity can also be expressed in units of N · s/m<sup>2</sup>.

<sup>b</sup>Dynamic viscosity calculated at <<http://www.lmnoeng.com/Flow/GasViscosity.htm>>

## B-1 Density of Air at Other Temperatures

---

The following relationship can be used to compute the density of air,  $\rho_a$ , at other temperatures at atmospheric pressure:

$$\rho_a = \frac{PM}{RT}$$

where  $\rho_a$  = density of air, g/m<sup>3</sup>

$P$  = atmospheric pressure,  $1.01325 \times 10^5$  N/m<sup>2</sup>

$M$  = molecular weight of air (see Table B-1), 28.97 g/mol

$R$  = universal gas constant, 8.314 N · m/(mol · K)

$T$  = temperature, K ( $273.15 + ^\circ\text{C}$ )

For example, at 20°C, the density of air is

$$\begin{aligned}\rho_{a,20^\circ\text{C}} &= \frac{(1.01325 \times 10^5 \text{ N/m}^2)(28.97 \text{ g/mol})}{[8.314 \text{ N} \cdot \text{m}/(\text{mol} \cdot \text{K})][(273.15 + 20)\text{K}]} \\ &= 1204 \text{ g/m}^3 = 1.204 \text{ kg/m}^3\end{aligned}$$

## B-2 Change in Atmospheric Pressure with Elevation

---

The following relationship can be used to compute the change in atmospheric pressure with elevation:

$$\frac{P_b}{P_a} = \exp\left[-\frac{gM(z_b - z_a)}{RT}\right]$$

where  $P_b$  = pressure at elevation  $z_b$ , N/m<sup>2</sup>

$P_a$  = atmospheric pressure at sea level,  $1.01325 \times 10^5$  N/m<sup>2</sup>

$g$  = acceleration due to gravity, 9.81 m/s<sup>2</sup>

$M$  = molecular weight of air (see Table B-1), 28.97 g/mol

$z$  = elevation, m

$R$  = universal gas constant, 8.314 N · m/(mol · K)

$T$  = temperature, K ( $273.15 + ^\circ\text{C}$ )

# APPENDIX C

## Physical Properties of Water

Source: Adapted from J. K. Venard and R. L. Street (1975). *Elementary Fluid Mechanics*, 5th ed., Wiley, New York.<sup>a</sup>At atmospheric pressure.<sup>b</sup>In contact with the air.

The following equations (R. C. Weast, 1983, *CRC Handbook of Chemistry and Physics*, 64th edition, CRC Press, Boca Raton, FL) can be used to compute the density  $\rho_w$  (kg/m<sup>3</sup>) and dynamic viscosity  $\mu_w$  (kg/m·s) at other temperatures:

$$\rho_w = \frac{\left[ \frac{999.83952 + 16.945176(T) - 7.9870401 \times 10^{-3}(T)^2}{-46.170461 \times 10^{-6}(T)^3 + 105.56302 \times 10^{-9}(T)^4 - 280.54253 \times 10^{-12}(T)^5} \right]}{1 + 16.879850 \times 10^{-3}(T)}$$

$$\text{For } 0 < T < 20^\circ\text{C}, \quad \mu_w = 10^{-3}(10^A)$$

$$\text{where } A = \frac{1301}{998.333 + 8.1855(T - 20) + 0.00585(T - 20)^2} - 1.30223$$

$$\text{For } 20 < T < 100^\circ\text{C}, \quad \mu_w = (1.002 \times 10^{-3})(10^B)$$

$$\text{where } B = \frac{1.3272(20 - T) - 0.001053(T - 20)^2}{T + 105}$$

# APPENDIX D

## Standard Atomic Weights 2001<sup>a</sup>

The atomic weights of many elements are not invariant but depend on the origin and treatment of the material. The standard values of  $A_r(E)$  and the uncertainties (in parentheses, following the last significant figure to which they are attributed) apply to elements of natural terrestrial origin. The footnotes to this table elaborate the types of variation that may occur for individual elements and that may be larger than the listed uncertainties of values of  $A_r(E)$ . Names of elements with atomic numbers 110 to 116 are provisional.

Alphabetical order in English				
Name	Symbol	Number	Atomic weight	Footnotes
Actinium*	Ac	89		
Aluminum	Al	13	26.981 538(2)

\*Element has no stable nuclides.

†Commercially available Li materials have atomic weights that range between 6.939 and 6.996; if a more accurate value is required, it must be determined for the specific material.

‡Geological specimens are known in which the element has an isotopic composition outside the limits for normal material. The difference between the atomic weight of the element in such specimens and that given in the table may exceed the stated uncertainty.

§Modified isotopic compositions may be found in commercially available material because it has been subjected to an undisclosed or inadvertent isotopic fractionation. Substantial deviations in atomic weight of the element from that given in the table can occur.

¶Range in isotopic composition of normal terrestrial material prevents a more precise  $A_r(E)$  being given; the tabulated  $A_r(E)$  value should be applicable to any normal material.

## Electronic Resources Available on the John Wiley & Sons Website for This Textbook

---

Website URL: <http://www.wiley.com/go/mwh>

Table or Resource	Filename	Description
E1	Standard_Reduction_Potentials.pdf	Selected standard reduction potentials for inorganic compounds at 25°C.
E2	Ozone_Reactions.pdf	Reactions of ozone with inorganic and organic compounds.
E3	Extinction_Coefficients.pdf	Extinction coefficients for common inorganic chemicals.
E4	Hydroxyl_Rate_Constants.pdf	Second-order rate constants between hydroxyl radical and various species in water.
E5	Freundlich_Isotherm_Parameters.xlsx	Freundlich isotherm parameters K and 1/n for various organic compounds in aqueous and gaseous phases.

(Continued)

Table or Resource	Filename	Description
E6	HSDM_Solutions_for_PAC.pdf	Parameters for the empirical equation that describes solutions to the HSDM for PAC in a batch or plug flow reactor.
E7	HSDM_Solutions_for_GAC.pdf	Parameter values used in Equations 15-173 and 15-178 for constant pattern solutions to the plug-flow homogeneous surface diffusion model.
E8	HSDM_Solutions_for_GAC.pdf	Minimum Stanton number for which constant pattern calculations can be used with a 10% error in calculated breakthrough times.
E9	HSDM_Solutions_for_GAC.pdf	Values of $\gamma$ and $St_{\min}$ , at various $1/n$ values that are required for constant pattern and external mass transfer control.
E10	AirStripCalc.xlsx	Spreadsheet designed to facilitate the calculations for countercurrent packed tower design.
